WORLD LIST OF THE MYSIDACEA, CRUSTACEA*

John Mauchline** and Masaaki Murano***

(3 Text-figures)

A complete list of genera and species of the Order Mysidacea, Crustacea known at present is given. The latitudinal occurrence, range in body length, geographic region and habitat of each species are described on current information. The source of a good description, modern if possible, is quoted for every species. There are at present some 765 species distributed between about 120 genera. There is no indication that the world list of species is nearing completion because many new species are being described each year. Mysids are predominantly coastal organisms and detailed sampling of the coasts of Africa, South America, Australasia and Oceania may result in many further new species and records.

Introduction

The crustacean Order Mysidacea currently includes some 765 species distributed between about 120 genera. The most recent list of species was produced by Gordon (1957) who compiled an almost complete bibliography of the Order. This bibliography was closed in 1955 and listed approximately 520 species divided between 106 genera. More than 240 species have been described since 1955 and some taxonomic revision has taken place. The relevant papers are widely scattered in the literature and no current publication provides a concensus of modern information on this large Order.

Gordon (1957) classified her bibliography to list papers describing families, genera and species. She also provides lists of general references as well as those specialising in taxonomy, morphology, embryology, life history, growth, physiology, behaviour and symbiosis. Further lists describe the distributions of mysids in the fresh and brackish waters of Europe, America, Asia, Australia, New Zealand, Japan, Africa and the Arctic. She also details papers describing the oceanic distribution of species in the Atlantic, Indian, Pacific, Arctic and Antarctic Oceans and in the Mediterranean. Finally, she details lists of references to the distributions of species in various regions of the coasts of the continents and oceanic islands.

No attempt is made here to present a modern edition of Gordon (1957). The purpose of this paper is to provide a list of known species, information on their body size and geographical region of occurrence and a valid, and accessible, source of a good description of each species. Mysids are dominant coastal organisms in many coastal regions of the world and there is an increasing interest in them, not only from a scientific point of view, but also as a possible economic fishery.

Taxonomy

The first few chapters of Tattersall and Tattersall (1951) are still the best introduction to this Order, because they present historical and contemporary accounts at that time

which are still valuable and are not restricted to British species. The most generally useful works in any taxonomic study of mysids are W.M. Tattersall (1951), Tattersall and Tattersall (1951), O.S. Tattersall (1955), Ii (1964) and the series of papers by the following authors: Bacescu, Brattegard, Holmquist, Murano, Nouvel and Pillai.

The number of known species is increasing each year (Fig. 1). Euphausiids are an example of a more normal situation in the modern taxonomy of a marine Order (Fig. 1). Most of the species were described between 1880 and 1920, the period when the ocean expeditions of discovery took place. A few were described before 1880 but mostly from the seas off northwestern Europe. Relatively few species were described after 1920, and some of these have resulted from taxonomic revisions. The situation present in modern mysid taxonomy is rather different. Many mysids live in coastal habitats and are easily accessible to land-based investigators. About 80 species were described before 1880 but the impetus of the ocean expeditions is seen with many species being discovered between 1880 and 1920. No exponential type decay in the numbers of species described per decade subsequent to 1920 takes place, as is present in the Euphausiacea (Fig. 1). Instead, the numbers of new species described has continued to increase to the present time. Thus, there is no indication that the present world list of the Mysidacea is approaching completion.

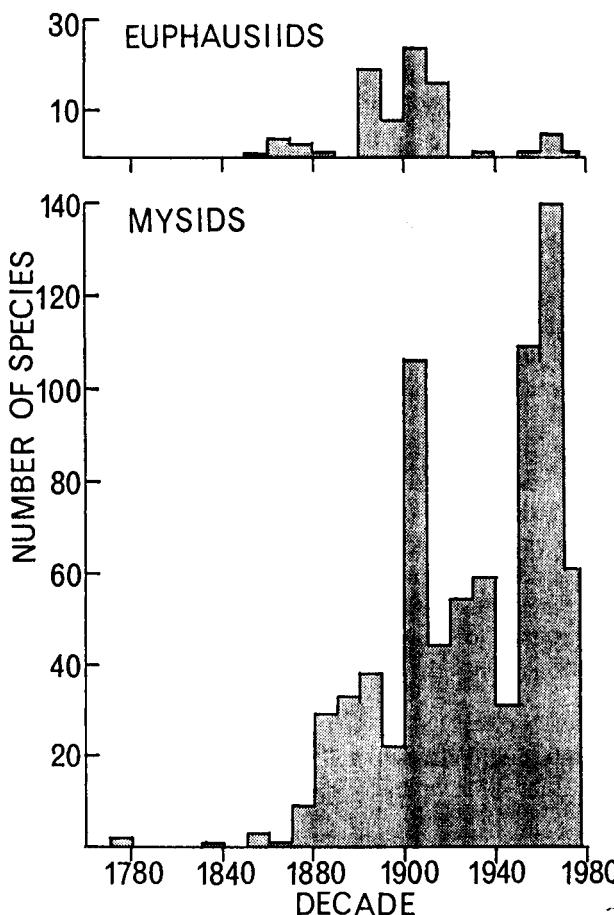

Fig. 1. Number of species described as new each decade.

Distribution

The distribution of the present known species have been grouped into 10° regions of latitude (Fig. 2). Relatively more species would appear to occur in northern than in southern latitudes. This probably arises, however, because the distributions of the northern species are better known and many extend through two or three 10° regions of latitude. Many records of southern species are single and their regions of occurrence are incompletely known. The majority of species live in close association with the sea bed and are not sampled at all efficiently by either conventional plankton nets or benthic samplers. The most efficient samplers are nets mounted on sledges that are towed over the surface of the sediment.

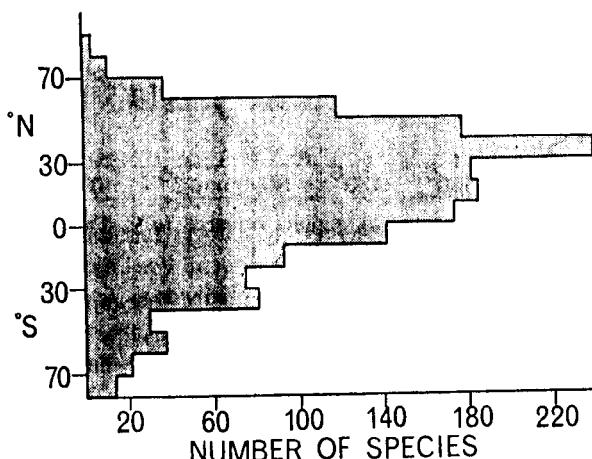

Fig. 2. Number of species of mysids recorded in each band of 10° latitude.

A few species of mysids occur in freshwater habitats, the most notable of these being *Mysis relicta*. Some 450 species live in coastal environments and probably half of these are littoral in habit for the greater part of their lives. *Praunus inermis* is usually found among *Laminaria* and other sea weeds in shallow coastal areas but Mauchline (unpublished) has caught it in an oblique haul through a vertical water column of 2800 m at 55°N 13°W ; this position is about 300 km from the nearest landmass. Consequently, with the limited amount of information available on many species, it is difficult to describe their habitat with much confidence.

There are coastal and oceanic species that are strictly pelagic in habit but they are relatively few in number. Nets on sledges towed over the surface of the sediment have been used more frequently in water of depth less than 200 m than in deeper regions. Consequently, many records of "mesopelagic" and "bathypelagic" species have been obtained from pelagic nets and epibenthic samplers may not have been used. Further sampling may show that many supposed pelagic species are more normally closely associated with the sea bed.

The oceans and seas of the world have been divided into several large regions (Fig. 3). These regions have been numbered in order to refer to them in Table 1. The regions conform very approximately to biogeographical limits applicable to the Mysidacea. A more detailed analysis of distributions is of little value until further information becomes

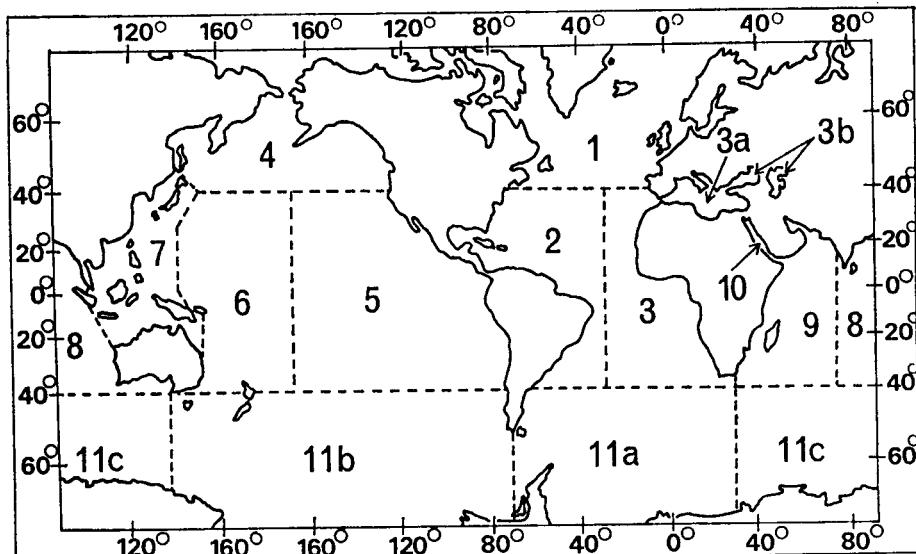

Fig. 3. Geographical regions referred to in Table 1.

available. Two regions, the sea areas of Japan and the Caribbean, have received considerable attention in recent years (Ii, 1964; Murano, 1966-1977; Brattegard, 1969-1977); many species have been described as new and many distributional records have been produced. These areas are both in the northern hemisphere and responsible in part for the large number of distributional records between 40°N and the equator (Fig. 2). Similar detailed studies of the mysids of the coasts of South America, Africa, Australasia and Oceania would probably produce species lists of equal length.

Sampling methods

Several sampling methods must be used to sample the majority of mysid species living in a sea area. The greater number of species will tend to occur in shallow water, often extending well into the mouths of rivers or streams. Wading with a hand-net or 0.5 m townet along the shoreline among areas of sea weed is usually productive. A small boat with outboard engine can be used to tow a D-net (Mauchline, 1965, 1967) which consists of a light metal sledge frame to which is attached a medium townet, 0.5 m² mouth opening, and mesh aperture about 0.3 mm. Brattegard uses an Ockelmann detritus sledge (Brattegard, 1973), while Murano uses a net described by Omori (1969). A self-closing net has been designed by Clutter (1965). The nets should be towed through the weed because many species live among the weeds. Sea weed and coral can be washed in a basin and this will often result in a sample of mysids. Some species of littoral mysids, for example some species in the genus *Gastrosaccus*, bury themselves in sand and sledge nets often do not sample them effectively. Sampling of littoral environments during periods of darkness is often more successful for such species.

The above sampling methods are usually satisfactory for species living in a depth range of 0-40 m. Heavier equipment capable of being used from larger boats is usually required for sampling species living close to the sea bed in depths of 40-200 m. A beam trawl design in which the trawl always lands the same way up on the sea bed is useful because small

pelagic nets can be attached to vertical supports bolted to the beam. This equipment is then capable of sampling species living in direct contact with the sea bed as well as those swimming immediately above it.

Standard pelagic nets should also be employed. These should be towed as close to the sea bed as possible but should also effectively sample the whole water column. The combination Rectangular Midwater Trawl 1+8 m² (Baker et al., 1973) is excellent in deep offshore regions where the large bathypelagic species like *Gnathophausia* spp. occur. These nets also catch the smaller species such as *Katerythrops oceanae* and *Parerythrops obesa*.

Biology of species

Studies of the biology of several species have been made although the biology of the great majority of species is almost completely unknown. References to publications prior to 1955 are given by Gordon (1957). Many are quoted in the more recent papers of Mauchline (1965-1973) and Amaralunga and Corey (1975).

Comments on Table 1

Table 1 lists the genera and species of the Mysidacea in alphabetical order and states the range of latitude in which they have been recorded. The body length of mature adults is given and followed by the ocean region or regions (Fig. 3) in which they occur. The habitat—fresh or brackish water, littoral or coastal—is defined where possible; in some cases, a range of depth in which the animals occur is stated. The offshore habitats are described with less confidence as oceanic, epipelagic, mesopelagic, or bathypelagic. In the case of many species, the depth or range of depth at which the animals were caught is stated. The vertical distribution of most species is incompletely known.

Many species, on present information, have very restricted geographical distributions. Thus, in the next column 6 of Table 1, "Notes on occurrence", the geographical location at which the species has been recorded is given. Region 3b (Fig. 3) denotes both the Caspian and Black Sea. A species recorded from the Caspian Sea is noted in Column 6.

Finally, the paper with the type description is often old and no longer obtainable by most workers. An attempt has been made, where possible, to quote a source of a good modern description of the species. References to type descriptions published before 1955 are given by Gordon (1957) and not quoted in the reference list of the present paper unless they still remain the only valid detailed description of the species.
