nule-like, round, smooth scales, not imbricate;" while C. marmoreus is again placed in the genus Tonicia of Gray, which is described as having the "mantle simple, horny, naked, smooth, or glabrous." C. mediterraneus, Gray (probably meant for C. siculus, Gray, = C. olivaceus, Spengler), is placed in both the genera Lepidopleurus of Risso and Leptochiton. C. Hanleyi, Bean, = C. mendicarius, Mighels, has the same kind of sculpture as C. scabridus, and belongs to the genus Chaetopleura of Shuttleworth.

I may mention that C. cancellatus was sent me by the late Professor Sars as his C. alveolus; but the latter, as since described and figured by his no less eminent son, is a different species.

[Continued from vol. v. p. 457.]

[Plates IV.—VI.]

SPONGIDA.

The descriptions of the Spongida found in and about the Melobesian nodules from the Gulf of Manaar will, so far as they go, be arranged after the classification proposed in my "Notes," &c. ('Annals,' 1875, vol. xvi. p. 128 et seq.); so that I must refer the reader for the characters of the orders &c. respectively.

In the measurement of the spicules it should be remembered that their form is of much more consequence than their dimensions, as the latter may vary:—1st, in different specimens; 2nd, in the same specimens (as they present themselves under all degrees of development); and 3rd, in the same species, where the average largest vary in proportion to their stoutness, the stoutest being the shortest, and vice versa. My measurements are taken from the average largest of the specimens, as these may be assumed to represent the ultimate size, and will be given in parts of an inch, for the purpose of conveying an idea of the relative rather than the real size of the spicules; while, to avoid repetition, it may be stated here, once for all, that, unless otherwise mentioned, they will refer to the greatest diameters of the object. It should not be forgotten that all the specimens are dry.
Ceratina.

Aplysina purpurea, n. sp.

Form irregular, membranous, hollow, cactiform on the surface. Colour black-purple. Fibre weakly developed, so that, when elementarily examined, nothing can be distinguished beyond a laminated condensation of the membranous structure densely charged with purple pigment-cells like that of Ianthella flabelliformis, Gray (Proc. Zool. Soc. Jan. 1869, p. 50), extending among the Melobesian nodules and detritus of the sea-bottom, so as to form an agglomeration in which the contrast of the dark pigment-cells and the purple stain that accompanies them with the whiteness of the fragments over which the sponge may be spreading is very striking, even to the naked eye. In this respect it is very like A. navus (Annals,’ 1876, vol. xviii. p. 229, pl. xii. fig. 2).

I also possess a large specimen of a similar sponge from Trincomalee, on the N.E. coast of the island of Ceylon, in which the purple colour is not so dark, but the fibrous structure is almost entirely absent, although the surface is cactiform and drawn up into puckered monticules; so the latter is not always dependent on the presence of fibre. It is pyramidal in shape, compressed, and 5 inches high, with a base also 5 inches long and 2 inches thick.

Aplysina fusca, n. sp.

Massive, digitate, hollow, cactiform on the surface. Colour dark brown. Growing like the last. Fibre well developed, of a light brownish colour, opaque, hollow in its dry state, with the axial cavity largely developed in proportion to its horny investment.

Psammonemata.

Hircinia arundinacea, n. sp. (provisional).

This imperfect specimen, which is in long stalks about 1-6th inch in diameter and of a light yellow colour, has had its sarcodic parts replaced by the parasite which usually attacks the Hircinace in all parts of the world, viz. Spongiphaga communis.

Hircinia fusca, n. sp. (provisional).

Massive, digitate, branched lobate, cactiform on the surface. Colour dark brown. Growing like the species of Aplysina above described, but solid and charged with fibre covered with foreign material.
Rhaphidonemata.

The Chalinida are only represented by a mere amorphous fragment not more than an inch in diameter, in which the fibre is resilient as usual, and charged with small acerate spicules only.

Desmacidon Jeffreysii, Bk.

This species, described by Dr. Bowerbank, under the name above given, in his Mon. Brit. Spong. (vol. ii. p. 347, and figured in vol. iii. pl. lxii.), also by the Rev. A. M. Norman under the generic name of Oceanapia (Brit. Assoc. Report, 1868, p. 334), is, with a slightly varied form, found in the Gulf of Manaar, where the body portions (for there are two specimens) are not more than an inch in diameter respectively, although the tubular extensions are much branched and upwards of 6 inches in length, covered with an overgrowth of other organisms, together with sea-bottom detritus which nearly obscures the surface both of body and tubes. Internally, however, it is essentially the same as Desmacidon Jeffreysii, but, with the exception that it contains no flesh-spicules—that is, minute bihamates (fibulae)—thus resembling that from the south coast of Australia, where it also occurs, but more under the British form, viz. turnip-like; while the British form does contain the bihamates, as mentioned by Mr. Norman (l. c.), and found by myself in the identical specimen figured by Dr. Bowerbank (l. c.), although the latter has neither figured nor mentioned them in his description or illustrations (B. S. vol. iii.).

In classification, I feel inclined to place this sponge among the Cavochalinida, on account of its fibrous structure charged with simple acerate spicules, and its hollow tubular extensions; but it should, I think, be considered the type of a distinct group.

Echinonemata.

Dictyoecylindrus manaarensis, n. sp.
(Pl. IV. fig. 1, a-g.)

Stalk-like, erect, cylindrical, branched dichotomously; branches round, obtusely pointed (Pl. IV. fig. 1). Consistence firm. Colour now dark brown. Surface slightly hispid. Structurally consisting of spicules in juxtaposition, arranged in tufts perpendicularly round a condensed axis of a like nature. Spicules of six forms, viz.:—1, long, smooth, curved, acuate, 45 by 1½-1800th (fig. 1, a); 2, shorter, smooth, curved, acuate, proportionately stouter, with inflated
micospined round head, 27 by $1\frac{1}{2}$-1800th (fig. 1, b); 3, hair-like, smooth, acuate, about 17-1800ths long (fig. 1, d); 4, thick, fusiform, slightly curved, shaft with inflated round and micospined extremities, 17-1800ths long (fig. 1, c); 5, flesh-spicule, smooth, tricurvature, 12-6000ths long (fig. 1, e, g); 6, flesh-spicule, equianchorate, naviculiform, 4-6000ths long (fig. 1, f, j). Nos. 1–4 form, in plurality, the tuft, of which 3 is the most numerous, and all have their long axis respectively outwards; 5 and 6 are plentifully distributed about the base of the tuft. Size of specimen (which is imperfect) about 1$\frac{1}{2}$ inch long, stem 1-10th inch in diameter.

Loc. Gulf of Manaar.

Obs. This well accords with the genus *Dictyocylindrus* as established by Dr. Bowerbank. The thick short spicule with inflated and micospined extremities (no. 4) may be considered the echinating form.

*Dictyocylindrus sessilis*, n. sp. (Pl. IV. fig. 2, a–d.)

Massive, convex, sessile, spreading, becoming subhemispherical (Pl. IV. fig. 2). Consistence hard, rigid. Colour light brown. Surface uniformly uneven. Structurally composed of tongue-shaped columns radiating and branching from the base to the circumference, where they are more or less divided, and thus altogether, when dry, present the appearance of a cauliflower, consisting of tufts of spicules densely packed together, and rendered almost inseparable without fracture by their tough sarcodic union. Spicules of three forms, viz.:—1, large, stout, smooth, acuate, curved chiefly towards the blunt end, which is slightly larger than the shaft, 45 by 2-1800ths (fig. 2, a); 2, thin, hair-like, smooth, acuate, about 20-1800ths long (fig. 2, b); 3, flesh- or echinating spicule, shaped like no. 1, but spined throughout, sparsely towards the large end, 35 by 2-6000ths (fig. 2, c, d). The large acuates are surrounded by bundles of the hair-like ones, having the echinating spicule at their base, to form, all together, the "tuft." Size of specimen about 6-12ths inch high in the centre by 1$\frac{1}{2}$ inch in horizontal diameter.

Loc. Gulf of Manaar.

Obs. In this, as in many other species of the Echinonemata, the tufts, when dissected out, will be found to be almost identical in form with those of *Microciona atrosanguinea*, Bk., showing not only an alliance between the two genera, but that *Dictyocylindrus* is only a more complicated structure of *Microciona*. 
Microcionina.

I intended this family to include Dr. Bowerbank's genera Microciona and Hymerhaphia (Brit. Spong. vol. i. pp. 188, 189), chiefly because they are all thin, flat, incrusting and laminiform species, containing respectively a setaceous form of spicule, and another more or less allied to the echinating one of the Echinonemata.

The distinguishing character between these two genera, according to Dr. Bowerbank, is that the spicules of Microciona are arranged in tufts or "columns" (ex. gr. M. atrosanguinea = Scopalina, Sdt.), and those of Hymerhaphia are not. But the spiculation is more persistent than the "columns" in many instances, whereby the diagnosis would break down, as the Microciona thus becomes a Hymerhaphia. Taking an opposite view of the case, Hymerhaphia vermiculata, Bk., of course contains no "columns;" but H. vermiculata, var. erecta ('Annals,' 1876, vol. xviii. p. 307, pl. xii. fig. 4 &c.), does (that is, "fasciculi"), with identical spiculation; so here the diagnosis of Hymerhaphia breaks down. Again, Dr. Bowerbank's Microciona carnosa of 1866 is made identical with Halichondria plumosa, Johnston, 1870 (B. S. vol. iii. p. 61), and renamed Microciona plumosa. Now, considering that Halichondria plumosa grows up into an erect massive form, it must, according to Dr. Bowerbank's diagnosis, be a Microciona at one time, viz. when flat and incrusting, and at another not—that is, when it is erect and massive; hence I have proposed a group "Plumohalichondrina" for this and similar species, the most remarkable of which that I have seen comes from Port Elizabeth, South Africa, where it appears to be very abundant; it is large, branched, and compressed, like an elk's horn; and they all possess the angulated (Bk.) equianchorate, not the naviculiform spicule of Microciona.

Nor is it uncommon to find an Echinonematus sponge beginning in the flat form of a Microciona and then becoming erect, as appears to be the case with Halichondria plumosa just mentioned. But while this shows that the "columns" in Microciona are not of much generic value, it also points out that genera formed upon the characters of indigenous species are very likely to break down when applied to world-wide collections; yet the same may be said of the latter until all the species of a class are known.

There is still another of Dr. Bowerbank's genera which, both in spiculation and growth, is very nearly allied to these thin, flat, incrusting laminiform sponges, viz. Hymedesmia; but here, again, his chief distinguishing character, viz. the
"recumbent" or horizontal position of the linear spicules, seems to me to be by no means constant and often dependent on circumstances. Even in his description of *Hymedesmia stellata* (B. S. vol. ii. p. 150) he uses the term "hispid," and in the species *Hymedesmia spinatostellifera,* to be hereafter described, I was obliged to seek for an illustration of the entire skeleton-spicule among erect or projecting ones in the more protected parts.

Dr. Bowerbank admits that all these three genera, which are given one after another in his 'British Spongidae,' are very nearly allied; and I now feel much inclined to place them all in my group Microcionina, although the Hymedesmina in my classification stand as the ninth group of my Holorhaphidota; but then the species which illustrate it (p. 197), viz. *Hymedesmia Johnsoni,* Bk., and *Desmacidon titubans,* have not the long, setaceous, acuate, or spinulate spicule which characterizes Dr. Bowerbank's original species (viz. *H. radiata* and *H. stellata,* described in 1866, B. S. vol. ii. pp. 149 and 150, and illustrated in 1870, vol. iii. pl. xxviii.), and which, together with its accompaniments, is characteristic of the kind of *Hymedesmia* that I should place in my group Microcionina. *Hymedesmia Johnsoni* and *Desmacidon titubans* would be much better placed alongside with Esperina, where they now are in my classification.

There are, however, species which have not this kind of spiculation, viz. the setaceous acuate, &c., ex. gr. *Rhaphidhistia spectabilis* ('Annals,' 1879, vol. iii. p. 300, pl. xxvi. figs. 13, 14 a); and there are specimens which may be so circumstanced as never to get beyond a thin lamina, although under other conditions they might grow up into erect forms: such is perhaps *Hymedesmia zetlandica,* Bk., judging from its spiculation in the type specimen now in the British Museum, which I should be inclined to regard as allied to *Halichondria plumosa,* in which case it would come under my Plumohali-chondrina.

Having premised these remarks it will be understood that although hereafter I shall describe the species of *Hymedesmia* found on the Melobesian nodules among the Holorhaphidota, yet I am of opinion that they ought to be under the Echinonemata, in the group Microcionina, together with the following ones of *Microciona* and *Hymerhaphia.*

*Microciona atrosanguinea,* Bk., and *M. armata,* Bk.

Both these species occur on the Melobesian nodules, now of a red-cinnamon colour, but were probably "blood-red," like the British specimens of the same sponges when alive. Both
are characterized by the large, setaceous acuate, accompanied by a thin one, together with a small clavate-spined spicule (the echinating form), a smooth tricurvate and a naviculiform, small, equianchorate (flesh-spicules), all arranged in tufts with the flesh-spicules about their base; but the tufts or "columns" are much more developed in the former than in any other species of the kind, whence it was called "Scopalina" by Schmidt in 1862. In *M. armata* the tufts are not so strongly developed, but the tricurvate spicule is unusually so, and in some instances so spread out as to resemble a long, thin, straight acerate with a short abrupt curvature in the centre.

*Microciona affinis*, n. sp. (Pl. IV. fig. 15.)

This species is very like the type species, *Microciona atrosanguinea*, in spiculation, but is extremely thin, has no tufts ("columns"), and the colour now is whitish yellow. Its chief specific difference, however, lies in the form of the equianchorate, which being extremely abundant and thicker (but not longer), from a greater projection of the central tongue-shaped arm, presents the appearance of being barbed on the inner side of the point, so that when viewed laterally this has much the appearance of a fish-hook (Pl. IV. fig. 15).

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaar.

_Obs._ This is one of the species to which I have above alluded, in which the spiculation is essentially like that of the type specimen of Dr. Bowerbank's genus *Microciona*, viz. *M. atrosanguinea*, although it possesses no "columns." The "fish-hook"-like appearance at the end of the central arm of the equianchorate, when viewed laterally, may be owing to a deficiency or hole in the upper part of the falcate septum which ordinarily unites this arm to the shaft, and a corresponding thickening of the septum at this part, which in some instances appears to extend to the shaft itself; but the object is too small for me to state, with any certainty, more than that it presents the "fish-hook appearance" mentioned.

*Microciona bulbo-retorta*, n. sp. (Pl. IV. fig. 3, a–e.)

Laminiform, extremely thin, hirsute, spreading. Colour, when dry, whitish yellow. Spicules of four forms, viz.:—1, long, setaceous, smooth, acuate, with inflated blunt end turned to one side, 175 by 2-1800ths (Pl. IV. fig. 3, a); 2, the same, but short, and spined halfway up from the blunt end, 30 by 1½-1800th (fig. 3, b); 3, the same, about half the length of the last (fig. 3, d, e); 4, thin, smooth, acuate, 40-1800ths long (fig. 3, c). All the spiculation is erect, and no. 4 in tufts
around no. 1. Size variable; that of specimen about ¼ inch in horizontal diameter.

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaar.

_Obs._ The large inflation of the fixed end, which is turned to one side, occurs in all the spicules except no. 4. There are no anchorates and no tricurvates; so that the spiculation is something like that of _Hymeraphia clavata_, Bk.; but, as above stated, all the spicules are erect like those of a _Microciona_, whereas in Dr. Bowerbank’s illustration of that species (B. S. vol. iii. pl. xxvi. fig. 4) part, at least, are reclined confusedly; but then, as I have also said before, this may have been occasioned by circumstances, viz. protection or exposure respectively during growth.

_Microciona quadriradiata_, n. sp.

(Pl. IV. fig. 4, a–d.)

Laminiform, extremely thin, hirsute, spreading. Colour, when dry, dark brown. Spicules of three forms, viz.:—1, large, setaceous, smooth, acuate, curved chiefly towards the blunt end, which is globular and rather less in diameter than the shaft, from which it is separated by a slight constriction, 75 by 3-1800ths (Pl. IV. fig. 4, a); 2, thin, smooth, acuate, frequently more or less crooked, 25-1800ths long (fig. 4, b); 3, quadriradiate, consisting of three arms radiating at equal angles from a common central point, which, raised and tripod-like, supports the fourth arm in an erect position; all densely and uniformly micropined, 5½ by 6-1800ths (fig. 4, c, d). No. 1, together with tufts of no. 2, projects vertically out of the lamina, which is densely charged with no. 3, whose erect arm thus becomes the _echinating_ spicule. Size variable; that of specimen about ¼ inch in diameter.

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaar.

_Obs._ The quadriradiate spicule of this species is almost identical in form with that of _Dictyocylindrus Vickersii_ (‘Annals,’ 1879, vol. iii. p. 292, pl. xxvii. figs. 5–8), where the vertical arm in like manner becomes the _echinating_ element or spicule; and the crooked form of the thin acerate is also similar; but the skeleton- or setaceous spicule is different. In the species, however, to which Mr. Thomas Higgin has called attention, and which also grew on a _Melobesia_ (“Nullipore”), both the quadriradiate and setaceous spicule are essentially identical; therefore this is a specimen of _Microciona quadriradiata_ from the West Indies (‘Annals,’ 1877, vol. xix. p. 296, pl. xiv. fig. 9).
Microciona quinqueradiata, n. sp.
(Pl. IV. fig. 5, a–e.)

Laminiform, extremely thin, hirsute, spreading. Cream-colour. Spicules of four forms, viz.:—1, long, setaceous, curved, simple, acuate, 125 by 1-1800th (Pl. IV. fig. 5, a); 2, short, thick, acuate, curved generally, with blunt end round and a little less in diameter than the shaft, from which it is differentiated by a slight constriction, 33 by 2-1800ths (fig. 5, b); 3, thin, slender, simple, acuate, 30-1800ths long (fig. 5, c); 4, quadriradrate, consisting of four smooth pointed arms radiating opposite each other from a common centre that is raised so as to form a four-legged base to the fifth arm, which is erect, longer than the rest, gradually pointed, thickly spined throughout and the spines recurved, 6 by 5-1800ths (fig. 5, d, e). Nos. 1–3 are erect, and the latter in greater plurality than the others, while the long, spined arm of the quadriradrate, which is very numerous, forms the echinating part. Size variable; that of the specimen about $\frac{1}{4}$ inch in horizontal diameter.

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaar.

_Obs._ This species is in growth, colour, and spiculation very like the foregoing one; but while the quadriradrate or echinating spicule in _M. quadriradriata_ is most like that of _Dictyo-cylindrus Vickersii_ (l. c.), it is the setaceous and thick, short, acuate spicules respectively here which most resemble the spiculation of that sponge.

Microciona curvispiculifera, n. sp.
(Pl. IV. fig. 6, a–d.)

Laminiform, extremely thin, hirsute, spreading. Cream-colour. Spicules of three forms, viz.:—1, long, setaceous, smooth, acuate, curved chiefly towards the blunt end, which is smooth and not differentiated from the shaft, 100 by 1-1800th (fig. 6, a); 2, the same, but much shorter, although proportionately stouter, 15 by 1-1800th (fig. 6, b); 3, cylindrical, bent in the centre, round at the extremities, smooth at first, becoming when fully formed spiniferous throughout, 15 by $\frac{2}{3}$-1800th (fig. 6, c, d). Nos. 1 and 2 are erect and fixed in a layer of the bent spiniferous spicules, which project outwards so that half of their length, lying parallel with the other spicules, becomes the echinating part. Size variable; that of the specimen about $\frac{1}{4}$ inch in horizontal diameter.

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaar.
Obs. This species is well-characterized by the bent spicules, many of which present different degrees of smoothness in proportion to the amount of development, which ends in their becoming thickly spinous throughout.

**Microciona fascispiculifera**, n. sp.

(Pl. IV. fig. 7, a–g.)

Laminiform, extremely thin, hirsute, spreading, covered with little bundles of spicules of different lengths respectively (Pl. IV. fig. 7, g). Cream-colour. Spicules of four forms, viz. :—1, long, setaceous, smooth, acuate, curved chiefly towards the blunt end, which is not differentiated from the shaft, 70 by 1½-1800th (fig. 7, a); 2, acerate, hair-like, in bundles, of different lengths below 20-1800ths (fig. 7, c, d); 3, spined acuate, 5-1800ths long (fig. 7, b and e); 4, minute, simple, bihamate, 2-6000ths (fig. 7, f). Nos. 1 and 3 project from a layer formed of nos. 2 and 4, the former in sheaf-shaped bundles of various dimensions lying on the surface. Size variable; that of the specimen about ¼ inch in horizontal diameter.

**Hab.** Marine. On hard objects.

**Loc.** Gulf of Manaar.

Obs. This species is also well characterized, viz. by the fasciculi of hair-like spicules, which respectively vary from 1-3000th to 1-90th inch in length, and by reflected light under the microscope look very much like minute white sawdust, for which, at first, I mistook them, partly on account of the specimens having been packed in this material that had more or less adhered to them. It is not the first time that I have found a hair-like spiculation of this kind in *Microciona*, as may be seen by a reference to the illustration of *M. minutula* (Annals, 1876, vol. xviii. p. 239, mendose script, “pusilla,” pl. xvi. fig. 51, &c.).—N.B. Never pack sponges in cotton wool or sawdust, but place them at once in spirit and water in a jar or keg, with a vellum label on them written in black-lead pencil.

The presence of sheaf-shaped fasciculi of hair-like spicules looking, as just stated, like minute sawdust by reflected light (Pl. IV. fig. 7, g) is a very common feature in different species of *Esperia*, where they often appear to replace the tricurvates. I delineated them first in 1871 ('Annals,' vol. vii. pl. iv. fig. 22), in *Stelletta lactea*, and again in *Esperia socialis* (ib. ib. pl. xvii. fig. 7, d, p. 277). Finally in 1874 ('Annals,' vol. xiv. p. 104) I conjectured not only that they were produced in cells like tricurvates similarly developed (ib. ib. pl. x. figs. 3–8), but
that, in some instances, they were identical with the latter; and now they have presented themselves in Microciona fuscispiculifera, which seems to be a very common species in the Gulf of Manaar, as there are many specimens of it on the Melobesian nodules. This, however, is not the only instance in which the flesh-spicules may be developed together in groups, as we see by the rosettes of inequianchors, also another common feature of Esperia; and I have little doubt that bichamates may be produced in the same way, particularly after considering the illustration of Hymedesmia zetlandica, Bk. (Brit. Sponges, vol. iii. pl. xxix.), in which the bichamates are not single, as is usually the case, but in groups like the tricurvates &c. It should, however, be remembered that these spicules are often developed singly as well as in groups in their cells (‘Annals,’ l. c. pl. x. figs. 11 and 12). We must view the sheaf-shaped bundles, then, I think, as “flesh-spicules” closely allied to, if not identical with, tricurvates; and therefore they may occur in any kind of spiculiferous sponge; hence it is not strange that we should find them in a Microciona, where the tricurate is such a common flesh-spicule.

Mr. Sollas has proposed for them the name of “trichites” (‘Annals,’ 1880, vol. v. p. 133), which it would be as well henceforth to adopt, as they are evidently not peculiar to one kind of sponge, and may occur in a great number; so that they should, for convenience of description, have a fixed designation, although, as I have above stated, they seem to me to be but another form of the tricurate.

**Hymerhaphia unispiculum, n. sp.**

(Pl. IV. fig. 8.)

Laminiform, extremely thin, hirsute, spreading. Cream-colour. Spicules of one form only viz. large, setaceous, smooth, acuate, curved chiefly towards the blunck end, which is hemispherical and a little more in diameter than the shaft, from which it is differentiated by a slight constriction, 70 by 1¾-1800th (Pl. IV. fig. 8). Size variable; that of the specimen about ¼ inch in horizontal diameter.

*Hab.* Marine. On hard objects.

*Loc.* Gulf of Manaar.

*Obs.* **Hymerhaphia unispiculum** is not so remarkable for the form of its spicule, which is common to many species, as for there being no other, in which respect it resembles Hymedesmia simplicissima, Bk. (Brit. Sponges, vol. iii. pl. lxxx. fig. 1). It seems to me questionable, however, if this is not
accidental, and that the other spicules, which often accompany a similar form, are, from some cause or another, absent here; the record, therefore, is only made provisionally.

_Hymerhaphia vermiculata, var. erecta._

This, which is but an erect form of _Hymerhaphia vermiculata, Bk._ I found plentifully among the dredgings of the 'Porcupine' from the bed of the Atlantic Ocean between the north of Scotland and the Faroe Islands ('Annals,' 1876, vol. xviii. p. 307, pl. xii. fig. 4, &c.); and it seems to be equally plentiful in the Gulf of Manaaar, with this difference only, that the acuate spicules are not so large or so setaceous as those in the specimens from the Atlantic sea-bed.

_Hymerhaphia clavata, Bk._

Laminiform, extremely thin, hirsute, spreading. Cream-colour. Spicules of four forms, viz.:—1, large, smooth, acuate like that of _H. unispiculum_, 100 by 3-1800ths; 2, clavate, nearly straight, with the blunt end differentiated from the shaft by being one third more in diameter, spined throughout, 14 by 2\(\frac{1}{2}\)-1800ths; 3, the same, but not more than half the size; 4, thin, smooth, acuate, 30-1800ths long. All these spicules are erect; and no. 1, which is rather sparse and very large and long, is surrounded by a great number of the fine acuates no. 4. Size variable; that of the specimen about \(\frac{1}{4}\) inch in horizontal diameter.

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaaar.

_Obs._ This is so nearly allied in spiculation to _Hymerhaphia clavata, Bk._, that I think it must be a specimen of the same species; but lest it should not be, I have given the description, merely adding that if it differs from _Microciona_ in the absence of the "columns," it certainly comes so near it in the elements and arrangement of its spiculation that it is almost questionable whether it should not be called a _Microciona._

_Hymerhaphia eruca, n. sp._ (Pl. IV. fig. 9, a–c.)

Laminiform, extremely thin, hirsute, spreading. Colour light brown. Spicules of three forms, viz.:—1, large, smooth, setaceous, acuate, chiefly curved towards the blunt end, which is slightly inflated hemispherically, and slightly differentiated from the shaft by constriction, 70 by 1\(\frac{1}{2}\)-1800th (Pl. IV. fig. 9, a); 2, vermiculate, acerate, annulated at more or less equal distances by projecting ridges, which here and there are broken or imperfect, 25 by 1\(\frac{1}{2}\)-1800th (fig. 9, b); 3,
the same, but smaller and smooth, in an earlier stage of
development (fig. 9, c). No. 1 projects from a bed of no. 2.
Size variable; that of the specimens about \( \frac{1}{4} \) inch in hori-
zontal diameter.

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaar.

_Obs._ This sponge, in spiculation and arrangement of the
spicules, is very like _Hymerhaphidia vermiculata_, Bk.; indeed
the early form of the caterpillar-like spicule (that is, before the
annulations are developed) is precisely like the contort spicule
_of_ _H. vermiculata_ (fig. 9, c).

**Baculifera.**

This group was established for receiving a great number
of different forms of a sponge both suberitic in its consistence
and in the form of its spicules, but Echinonematous in their
arrangement, wherefore it was placed in the order Echinone-
mata. So far as I have had an opportunity of examining
these forms they have all had only one and the same form of
spicule, which is pin-like, with the head elongated at right
angles to the shaft, like that of a crutch, but so peculiar that
there is no mistaking it anywhere when once known. The
specimens which I have seen chiefly come from the south-
west coast of Australia; and the first described were named
_Caulospongia verticillaris_ and _C. plicata_, by Mr. Saville
Kent (Proc. Zool. Soc. 1871), of which the former is in
the Liverpool Free Museum, and the latter in the British
Museum. I found a small fragment of this group of a light
brown, which is the usual colour, in two places on the
Melobesian nodules.

**Holorhaphidota.**

**Renierida.**

Much information is yet needed to make the species in the
groups of this family clear; for the acrate form of spicule is
so common among them that, unless accompanied by a flesh-
spicule, which is seldom the case, the descriptions only of a
great number of fully developed specimens can establish the
species. Thus in the British Museum there are two species
on a large, branched, stony coral from Madeira, both massive
and amorphous, one yellow, the other white or colourless;
both belong to my group "Crasso," from the large size of
their spicules. The yellow one has a cylindrical spicule with
obtuse ends (sausage-shaped); the white one, a still larger
spicule, which is long, thick, fusiform, acerate, more like
that of *Halichondria panicea*—that is, gradually pointed. Now just the same kind of sponges appear on the Melobesian nodules; but although the spicule of the colourless or white species is almost identical with that on the Madeira coral, that of the yellow one, instead of being cylindrical and sausage-shaped, is acerate and sharp-pointed; while there is a third species about the Melobesian nodules, which is dark brown, that has a cylindrical obtusely-ended spicule. Under these circumstances all that I can do is briefly to describe them respectively by the terms yellow, white, and dark brown, provisionally—that is, until the species to which they respectively belong shall have been satisfactorily defined.

*Reniera*, yellow.  (Pl. V. fig. 17.)

Massive, lobate. Consistence firm. Colour ochre-yellow. Surface even. Spicule of one form only, viz. smooth, acerate, fusiform, curved, abruptly sharp-pointed, 17 by 1½-1800th (Pl. V. fig. 17). Colour variable—some specimens being greyish yellow, and others almost white. Size of largest specimen about 2½ inches in its longest diameter.

*Reniera*, white.  (Pl. V. fig. 16.)

Massive, lobate, rising into short tubular processes. Consistence firm. Colour white. Surface even. Spicule of one form only, viz. smooth, acerate, fusiform, curved, gradually pointed, 60 by 2½-1800ths (Pl. V. fig. 16). Size of largest specimen about 3 inches in diameter.

*Reniera*, dark brown.  (Pl. V. fig. 18.)

Amorphous, growing in small portions here and there in the depressions of the Melobesian nodules. Consistence firm. Colour dark brown. Spicule of one form only, viz. smooth, cylindrical, curved, rounded at the extremities, 23 by 1-1800th (Pl. V. fig. 18). Size of largest specimen about an inch in horizontal diameter.

*Reniera fibulifera*, Sdt.

This sponge, which seems to be world-wide in its distribution, was represented by a small growth, about 1-16th inch in horizontal diameter, which was identified at the time, but overlooked afterwards, so that there is no slide or mounted specimen of it.

*Halichondria albescens*, Johnston.

Here and there on the nodules.
Halichondrina.

_Halichondria aceratospiculum_, n. sp.  
(Pl. V. fig. 19, a–d.)

There was only a minute trace of this, but sufficient for mounting and for the following description of its spicules, which consist of four forms, viz.:-1, acerate, fusiform, curved, sharp-pointed, thickly spined throughout, 25 by 1½-6000th (Pl. V. fig. 19, a); 2, smooth, acerate, fusiform, curved, slightly inflated in the centre, and gradually pointed, 35 by 1-6000th (fig. 19, b); 3, bihamate, simple, 8-6000ths long (fig. 19, c); 4, equianchorate, shaft slightly curved, arms linear in appearance, and distinct when viewed laterally, 3½-6000ths long (fig. 19, d).

Obs. This is evidently the spiculation of a variety of _Halichondria incrustans_, in which the flesh-spicules, viz. nos. 3 and 4, are in form identical, while the acerate forms of the larger spicules respectively lead to the designation.

Esperina.

_Esperia tunicata_, Sdt.

This consists of a thin fragment, about ½ an inch in horizontal diameter, abounding with the usual Esperian rosettes, composed of the inequianchorate of the species, accompanied by a great number of nondescript forms, which appear to be half-developed inequianchorates that have respectively been generated in separate cells.

_Esperia serratohamata_, n. sp.  (Pl. V. fig. 20, a–d.)

Of this sponge, which I have long wished to find, viz. since I published a representation of the peculiar form of the bihamate found among the spicules in one of the chambers of a specimen of _Carpenteria balaniformis_ (‘Annals,’ 1876, vol. xvii. pl. xiii. fig. 10), a minute portion has grown on one of the Melobesian nodules, which has yielded sufficient for mounting and retaining in the dried state respectively. It possesses four forms of spicules, viz.:-1, the usual Esperian skeleton-spicule, smooth, fusiform, sub-pinlike, with oval inflation at the blunt end, 43 by 1½-6000th (Pl. V. fig. 20, a); 2, large, bihamate, serrated on the outside towards each extremity, with the teeth directed backwards, 24 by 1½-6000th (fig. 20, b); 3, tricurvate, simple, hair-like, dispersed and in groups, 12-6000ths long (fig. 20, c); 4, inequianchorate, small, with the head nearly two thirds of the entire length, 4 by 2½-6000ths (fig. 20, d), dispersed.
singly and combined in the form of rosettes respectively. Size of specimen about 1-6th inch in horizontal diameter.

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaar.

_Obs._ The remarkable form of the biamate, together with the short thick inequianchorate, is distinctly characteristic of this _Esperia_, which is not the case with many other species, in which the spiculation is so much alike that much confusion still exists respecting them.

**Hymedesmina.**

**Hymedesmia stellivarians**, n. sp.  
(Pl. IV. fig. 10, a–e.)

Laminiform, extremely thin, spreading, smooth or hirsute. Colour yellow. Spicules of two forms, viz. — 1, pin-like, smooth, fusiform, with oval head, 32 by 1-1800th (Pl. IV. fig. 10, a); 2, globostellate, rays short and conical, or short and capitulate, or long and pointed, respectively; hence the designation (fig. 10, b and e, d, e). Pin-like spicule incorporated with the bed of stellates where the parts are exposed, more or less erect where protected. Size variable; that of specimen about an inch in horizontal diameter.

_Hab._ Marine. On _Hircinia fusca._

_Loc._ Gulf of Manaar.

_Obs._ I am inclined to think that the real colour of this species is white, and that its yellow tint has been derived from the brown colouring-matter of the _Hircinia_ on which it has grown. It is chiefly distinguished from the following sponge, whose stellate is very similar, by the form and smallness of the linear pin-like spicule.

**Hymedesmia Moorei**, n. sp.  (Pl. IV. fig. 11, a–e.)

Laminiform, extremely thin, spreading, smooth or hirsute. Colour glistening white. Spicules of two forms, viz. — 1, pin-like, smooth, fusiform, chiefly curved towards the blunt end, which is spherical, varying to simple uninflated acuate, 62 by 2-1800ths (Pl. IV. fig. 11, a); 2, globostellate, rays at first long and pointed, with body proportionally small, then short, thick, and conical, with proportionally enlarged body, finally mitre-shaped and microspined, 5-6000ths (fig. 11, b and c). Where exposed the linear spicule is incorporated with the layer of stellates horizontally, but where protected it is erect. Size variable; that of specimen about an inch in horizontal diameter.
Loc. Gulf of Manaar.

Obs. Like the last species but for the form of the skeleton-spicule no. 1. Named after Mr. T. J. Moore, the assiduous Conservator of the Liverpool Free Museum.

**Hymedesmia spinatostellifera, n. sp.**
(Pl. IV. fig. 13, a–d.)

Laminiform, extremely thin, spreading, smooth or hirsute. Salmon-colour. Spicules of two forms, viz.:—1, pin-like, very long and slender, smooth, curved, head at first round and smooth, then elongated transversely by a convex addition to both sides, and, finally, by similar growths all over so as to become tuberose, shaft 130 by 1-1800th, head much larger than the shaft (Pl. IV. fig. 13, a and b); 2, stellate, multiradiate, rays cono-cylindrical, spined in annular rows towards the extremity, fixed on a body which is about one third of the diameter of the whole stellate, 10-6000ths in diameter (fig. 13, c and d). Linear spicules, where exposed, imbeded among the stellates, but erect and projecting where protected. Size variable; that of specimen extending over the whole of a Melobesian nodule upwards of an inch in diameter.

Loc. Gulf of Manaar.

Obs. This species is characterized by its pink or salmon-colour, the peculiar tuberose form of the head of the linear spicule when fully developed, the large size of the stellate, and the peculiar form and microspination of its rays.

**Hymedesmia capitatostellifera, n. sp.**
(Pl. IV. fig. 12, a–c.)

Laminiform, extremely thin, spreading, sparsely hirsute. Colour snow-white. Spicules of two forms, viz.:—1, pin-like, curved, smooth, long, setaceous, head oval and wider in diameter than the shaft, which is 80 by 1-1800th (Pl. IV. fig. 12, a); 2, stellate, with large globular body, multiradiate, rays terminating in a globular, inflated, and spined head with constricted neck, 12-6000ths in diameter (fig. 12, b and c). Pin-like spicule fixed by its head in the sarcoic layer of the sponge, which is densely charged with the stellates. Size variable, that of specimen about ¼ inch in horizontal diameter.

Loc. Gulf of Manaar.
Obs. This species is characterized by its brilliant snow-white colour, the large size of its stellates, and the peculiar capitation of their rays.

*Hymedesemia trigonostellata*, n. sp.  
(Pl. IV. fig. 14, a–d).

Laminiform, extremely thin, spreading, smooth or hirsute. Colour snow-white, glistening. Spicules of three forms, viz.:—1, acute, long, thin, smooth, 50 by ½-1800th (Pl. IV. fig. 14, a); 2, pin-like, ensiform, smooth, with inflated fusiform shaft, long neck, and small round head not more than one third of the diameter of the shaft, 25 by 1-1800th (fig. 14, b); 3, stellate, quadriradiate, in which three of the rays form a kind of tripod to the fourth, that is erect, thus presenting a triangular appearance; each ray expanded at the extremity by a multifid spinous division, 3-6000ths in diameter (fig. 14, c, d). No. 1, sparsely scattered, projects beyond no. 2, which is parquetted in among no. 3 in great abundance, so as to present a smooth glistening surface. Size variable; that of specimen about ¼ inch in horizontal diameter.

*Hab.* Marine. On hard objects.

*Loc.* Gulf of Manaar.

Obs. The peculiar sword-like form of the pin-like spicule no. 2, together with that of the stellate, characterizes this species unmistakably; while the latter, which always resembles that of *Axos Clifoni* in the multifid spine-like division of the extremities of its rays, is often rendered still more like it by being sexradiate.

**Suberitida.**

*Suberites vestigium*, n. sp.  (Pl. V. fig. 21.)

Laminiform, extremely thin, spreading. Colour glistening white, asbestos-like. Spicule of one form only, viz. pin-like, shaft slightly curved and slightly fusiform, head spherical, a little less than the shaft in diameter, 27 by 1-1800th (Pl. V. fig. 21). Spicules confusedly arranged, among which many project irregularly. Size variable, that of the specimen about ¼ inch in horizontal diameter.

*Hab.* Marine, on hard objects.

*Loc.* Gulf of Manaar.

Obs. This species, although very like a *Hymedesemia* in growth and appearance, is also very different in spiculation. As may have been observed, there is no long setaceous spicule here markedly projecting from a layer of smaller ones of a
dredged up from the Gulf of Manaar.

different form, but the whole composed of one only, viz. pin-like, and that, too, not characterized by any one in particular being longer than the rest. It often presents a bluish-green tint (now dry) like that of a similar species on the rocks here (Budleigh-Salterton); but the head of the latter is different in form, viz. globoconical followed by an inflated ring like that of Suberites (Halichondria, Johnston) carnosa. It may be remembered that the colour of the British species (which, when fresh, is cobalt-blue) is owing to the presence of a minute parasitic Oscillatoria, for which I have proposed the name of "Hyphoeothrix caerulea" ('Annals,' 1878, vol. ii. p. 164). How far this, as well as the British species, may be that which, under other circumstances, grows into a larger and distinct form of Suberite, I am not able to state; all that I can say is that both are frequently found under the conditions above mentioned.

Suberites fistulatus, n. sp. (Pl. V. fig. 22, a, b.)

Irregularly globular, elongate, sessile, appendiculate, the appendages consisting of long tubular extensions of different sizes, irregularly scattered over the surface, which is otherwise even. Colour now pinkish brown. Internally cavernous, densely charged with two forms of spicules, viz.:—1, linear, fusiform, slightly curved, and inflated at both ends, which are micropinned, 23 by 1½-1800th (Pl. V. fig. 22, a); 2, equianchorate (fleshy-spicule), naviculiform, 8-6000ths long, comparatively large and numerous (fig. 22, b). The tubular appendages are prolonged from large vents, which are in connexion with the cavernous structure of the body. Size of specimen 3 inches long, 3 broad, and 2½ high.

Loc. Gulf of Manaar, and Fremantle, S.W. Australia.
Obs. Having found a minute portion of this sponge on one of the Melobesian nodules of the Gulf of Manaar, I at once recognized in it the spiculation of the sponge above described, which is in the general collection of Dr. Bowerbank’s sponges purchased by the British Museum. The cavernous and cork-like consistence claims for it a place among the Suberitida.

General character largely and irregularly placophorous, hard, petrous, Geodia-like, dichotomously branched; branches angulated irregularly and therefore variable in diameter.
Colour white or brown. Surface even, divided into irregular, polygonal, placoid spaces varying in size, under half an inch in diameter, slightly concave towards the centre, raised at the margin, where they meet each other, but do not join. No pores and no vents visible over the placoid spaces themselves, but a line of separation between them where in apposition, through which communication with the interior is obtained. Plates or placoid portions crust-like, composed of siliceous globules, like those of Geodia, united together by exceedingly tough fibrous sarcode; subjacent to which is another layer composed of areolar sarcode charged with pin-like spicules, whose points project slightly beyond and between the marginal appositions of the plates respectively; within which, again, is a solid thick axis, entirely composed of the same kind of siliceous globules as the plates. Spicules of four forms, viz.:—1, large, pin-like, straight, smooth, shaft subconical and abruptly pointed, head globular, as wide as the thickest part of the shaft, 65 by 1-1800th; 2, siliceous globule, more or less elliptical, compressed slightly in the direction of a hilous depression, which is on one side; surface uniformly consisting of minute stelliform points, more or less multifid and in juxtaposition, being the ends of the radiated crystalline structure of which the interior is composed, 17 by 13-6000ths; 3, a much smaller siliceous globule, which is spherical and covered with minute conical points in juxtaposition, that give it a multiangular appearance, 3-6000ths; 4, smooth, microscopic, siliceous globules, which appear to be originally developed in cells, about 3-6000ths in diameter. No. 2 (siliceous globule), with which no. 3 is sparsely mixed, forms the staple spicule of the hard axis and mail-like plates respectively; while no. 1, the pin-like spicule, is confined to the areolar sarcodic layer between the two, where it is arranged in glistening tufts, whose points, as before stated, project through the line of separation between the plates. The microscopic globules appear to be chiefly situated in the dermal layer. Size of largest specimen (for there are two) about 1½ inch long, 8-12ths inch broad, and 4-12ths thick.

Hab. Marine. Attached to hard objects.

Loc. Gulf of Manaar.

Obs. I have partly described this species from the specimens in the British Museum, one of which was well figured by Dr. Gray (l. c.); but the description not being detailed with that minuteness which this remarkable sponge deserves, has led to my making the above additional statements. It will have been observed that the siliceous globule is identical with
that of a Geodia, but the rest of the structure so totally different that, wherever located among the Holorhaphidota, it must form a distinct group. The sponge not only grows independently, as above stated, but also parasitically (that is, laminiform over hard objects), yet always presenting the placophorous or mail-plated surface, which is already evident in the smallest of the Manaar specimens, although it is extremely thin and only 1/12th inch in horizontal diameter, with a correspondingly diminutive form of the spiculation, indicating not only that it is a very young specimen, but that the separation of the plates from the commencement favours its subsequent enlargement, and thus explains the mode of growth.

Besides this there is a species, or, rather, variety, in which a spinispirular flesh-spicule is added to the foregoing spiculation, consisting of a slightly sigmoid microspined shaft like the flesh-spicule of Cliona corallinoides, whose spines afterwards may become elongated, and sometimes multifid at the extremity, so as to present the appearance shown by Dr. Bowerbank (Proc. Zool. Soc. 1874, pl. xlvi. fig. 4). The British-Museum specimen, of which I made a mounting in Canada balsam some years ago, came from “Puntas Arenas” in “Central America,” and has been in the collection (as learnt from the registration) since 1850. In my “Notes” I see that it came “off a Gorgonia,” while that described and called by Dr. Bowerbank “Geodia carinata” (l. c. fig. 1), now also in the British Museum, is on the same kind of black horny Gorgonia-stem from the “South Sea;” hence it is not impossible that both may have come from the tropics; but, be that as it may, these are the only two specimens that I have seen in which the spinispirula is present. It seems, however, to afford corroborative evidence of this sponge being allied to the Suberitida rather than to the Geodina; for when the pin-like spicules and the spinispiro Ula are seen together, in addition to the structure generally, there is only one link left which causes Placosponia to resemble the Geodina; and that is the siliceous ball; so that the characters are far more in favour of the Suberitida than the Geodina. Hence, as before stated, the group of which Placosponia may be considered typical should be placed among the Suberitida. I might here mention that in the hilous depression of the siliceous globules of my mounted preparations there is a plug of sarcode, showing the way in which the former are connected with the latter.
Eccoelonida.

(Excavating Sponges.)

In the 'Journal of the Royal Microscopical Society' (1879, vol. ii. p. 496) I proposed the name of "Eccoelonida" for this family, enumerating thereunder three genera, viz. Cliona, Thoosa, and Alectona, and stating that the skeleton-spicle of Thoosa had not been determined. Previously ('Annals,' 1879, vol. iii. p. 352) I had indicated that, judging from the figures which he has given, Hancock had probably based this genus on spicles of some kind of Samus. I further added, in the 'Microscopical Journal' (l. c. p. 497), that it was not impossible that Samus anonymus would ultimately have to come in as a fourth genus of the Eccelonida. All this is now ascertained by the undoubted excavating habit of Samus anonymus in some of the Manaar nodules, and the existence of Thoosa in others, where no spicle of Samus, or any thing like Hancock's figures, is present. New species of Samus have also been determined, as well as more Eccelonida, including a new genus—which will now be successively described.

Thoosa socialis, n. sp. (Pl. V. fig. 23, a-c.)

General form (when dry and contracted) a minute sarcodid mass densely charged with the spicles of the species, in which no particular figure or structure can be distinguished. Colour yellowish. Spicles of two forms, viz. — 1, short, thick, nodose, consisting of a central shaft upon which are developed ten globular microspined projections that finally obscure it from their enlargement and approximation, so arranged that one occupies each extremity and the eight others two circular rows respectively in the centre of the shaft, all touching each other when the spicle is fully developed, 8 by 5-6000ths (Pl. V. fig. 23, a); 2, circular, compressed, rough or irregularly microspined and wrinkled, 5 by 4-6000ths (fig. 23, b, c); the latter sparsely mixed among the former. Size of largest specimen about 1-16th inch in diameter.

Hab. Marine. In excavated cavities of the Melobesian nodules, alone or in company with other sponges which have made or have occupied them after they have been made.

Loc. Gulf of Manaar.

Obs. Whether this is the sponge to which Hancock alludes (l. c.) or not, he has omitted to mention its accompanying spicle, viz. the cake-like one no. 2; while the presence of the species not only by itself, but together with different other sponges now occupying some of the previously ex-
cavated cavities of the Melobesian nodules, has led me to designate it "socialis." The specimen of Samus anonymus, to which I have alluded I first found, together with a Cliona, in an excavated cavity; and knowing of no other sponge but a Cliona that made such cavities, I viewed the Samus as an intruder; but now that, in the Melobesian nodules, I have found Samus anonymus filling the excavations alone, I am constrained to admit it as a new genus of the Eecelonida. If such shall be found to be the case with Thoosa, then also there will be no doubt of its excavating power; but the specimens of it that I have seen have been so minute and so mixed up with other sponges, that at present I consider this only a provisional determination. Had I obtained it as I did the following species, which is equally minute, viz. by solution of the piece of Melobesia containing it in nitric acid, I might have seen the sarcode holding the spicules; but in the dried state in which I found it I could only infer its existence from the contracted appearance of the little mass. On account of its presence in specimens of many other sponges from the excavations of the Melobesian nodules that I have mounted in Canada balsam, it seems to me to be very plentiful, but in very minute portions. The larger spicule, no. 1, also exists in the neighbourhood of the Seychelle Islands, as represented in the 'Annals' of last year (vol. iii. pl. xxix. fig. 21).

_Dotona pulchella_, n. gen. et sp.  
(Pl. V. fig. 24, a–d.)

General form (when dry and contracted) a minute sarcodic mass densely charged with the spicules of the species. Colour white. Spicules of three forms, viz. — 1, a cylindrical curved shaft, round at the ends, which are micropinned, interrupted throughout by apparently annular lines at equal distances from each other, but which, by alteration of the focus, are found to be parts of a spiral ridge formed of microscopic points, united longitudinally and respectively by striae, which thus extend throughout the spicle, 12 by 1½-6000th (Pl. V. fig. 24, a, d); 2, acuate, simple, smooth, hair-like, very fine, 20-6000ths long (fig. 24, b); 3, flesh-spicule, minute, consisting of a straight shaft spined over both ends divergingly, and in a ring round the centre, 2 by ½-6000th (fig. 24, c). Spicules mixed together generally; very variable in size and in various stages of development; the flesh-spicules very minute and sparse. Size of specimen about 1-8th inch in diameter.

_Hab._ Marine. In excavated cavities of the Melobesian
nodules, sometimes in company with other sponges, and sometimes alone.

Loc. Gulf of Manaar.

Obs. The extreme beauty of the large spicule of this species so attracted my attention while it made its appearance in more or less plurality among the fragments of other sponges which I had mounted, that I determined to look for it in situ, feeling almost convinced that it was one of the Ectoeloida, but which, like Thoosa socialis, could, from its minuteness, be only sought successfully with the microscope. This was accomplished at last, but not until I had often relinquished the search as hopeless; and then the fragment was observed to consist of several dilated globular portions of transparent sarcodic membrane united together ismichially, and densely charged with the spicules of the species on their inner surface, so that when contracted in the dried state they gave the little massive appearance above mentioned. It was also in company with a minute fragment of Thoosa socialis; but from its form and approach towards the surface-apertures of the excavation in which it existed by little digital processes densely charged with the spicules of the species at their extremities, like those of Alectona Millari, there can be no doubt that this is a truly excavating sponge, for whose genus I have proposed the name of "Dotona," after another of the sea-nymphs, and "pulchella," from its great beauty. The annulation, when examined by alteration of the focus, so that both sides of the spicule may be examined, is found to be formed, as above stated, of a spiral ridge whose coils are so close together that at first they resemble annulations (fig. 24, d).

Alectona Higgini, n. sp.

(Pl. V. fig. 25, a-c.)

Lining excavated cavities in a Melobesian nodule, in the form of a sarcodic membrane charged on the inner side with the spicules of the species. Colour now that of dried sarcode—that is, yellowish. Spicules of three forms, viz.:—1, subcylindrical, slightly curved, round at the ends, sausage-like, divided irregularly throughout the body into a number of annular depressions and inflations, the latter of which are microspined, and very variable in form and length, the shortest being the thickest, 5 to 20 by 1½ to 2½-6000ths (Pl. V. fig. 25, a); 2, fine, hair-like, acerate, tending to the form of a tricurved, 12-6000ths long (fig. 25, b); 3, flesh-spicule, consisting of a straight shaft interrupted towards the centre by eight or more faintly capitate rays radiating circularly from separate points a little nearer to each other than to the extremities of
the shaft; rays equal in length to the distance between the points of radiation and the end of the shaft on each side; all parts of the spicule about the same thinness, which is almost immeasurable; all microspined and all respectively terminated by a globular inflation, 5 by 4-6000ths long (fig. 25, c). Size of largest specimen that of the Melobesian nodule which it infests, viz. 1¾ inch in diameter.

_Hab._ Marine. Excavating nodules formed of the layers of _Melobesia._

_Loc._ Gulf of Manaar.

_Obs._ Like _Alectona Millari_, this is essentially an excavating sponge; for the whole nodule is honeycombed by it; and the largest cavity exposed is one sixth of an inch in diameter, fenestrated towards the surface and in the direction of the other cavities which surround it, so that there can be no doubt of its nature any more than of that of the foregoing species. Then the spiculation being something like that of _Alectona Millari_, and especially the flesh-spicule, I have named it after my friend Mr. Thomas H. Higgin, F.L.S., of Liverpool, who has made such important additions to our knowledge of the _Spongida._

_Samus anonymus_, Gray.

This species, which is common in excavations of the Melobesian nodules, I described and figured in the 'Annals' (1879, vol. iii. p. 350, pl. xxix. figs. 1–4), afterwards stating (Journ. Roy. Microscop. Soc. i. p.) that it would probably have to be placed as a new genus among the excavating sponges. The form and frequency with which it occurs in the Melobesian nodules of the Gulf of Manaar has now (as before stated) placed this beyond doubt; therefore I will at once give its generic characters under the name " _Samus, " which was established by Dr. Gray (Proc. Zool. Soc. 1867, p. 526) upon the spicule of an unknown sponge, first figured by Dr. Bowerbank (B. S. vol. i. pl. ii. figs. 41, 42).

_Samus_, nov. gen.

_Gen. char._—Sarcodae charged with large, coarse, multifid spicules, whose prongs are more or less subdivided according to the species; filling excavated cavities in calcareous structures when fresh, and when dry contracted into masses, through which the prongs of the spicules project in a thorn-like manner; connected with filamentous processes of the same, which occupied the channels of extension; generally accompanied by a flesh-spicule.
Samus simplex, n. sp. (Pl. V. fig. 26, a–c.)

Occurring as just mentioned. Colour that of dried sarcode. Spicules of two forms, viz.:—1, a short shaft with trifid head once divided (trifurcate), the whole expanded at right angles to the shaft, 15 by 3–1800ths (Pl. V. fig. 26, a, b); 2, minute or flesh-spicule, consisting of a straight shaft spined throughout irregularly, spines most prominent towards the ends, 3–6000ths long (fig. 26, c). Size of specimen variable, concurrent with that of the excavated cavity, which may be 1–6th inch in diameter.

Hab. Marine. In excavations of the Melobesian nodules, towards the surface.

Loc. Gulf of Manaar.

Obs. This is the simplest form of Samus-spicule that I have met with; hence the designation of the sponge to which it belongs.

Samus (Pachastrella) parasiticus.

(‘Annals,’ 1876, vol. xviii. p. 410, pl. xvi. fig. 50 &c.)

This species, which I formerly called “Pachastrella parasitica” (l. c.), occurs abundantly in excavations of the Melobesian nodules, accompanied by both forms of its flesh-spicules, viz. the spined bacillar form, fig. 50, d (l. c.), and the spinispirula, fig. 50, f (l. c.). Originally I did not know the habitat of Samus parasiticus; but seeing that it so much resembled Dercitus niger, Gray, in spiculation, and finding the latter in company with a Cliona (to which I have before alluded) in excavations of marine calcareous structure (old coral) from the island of Cuba, I at once thought that Samus parasiticus must be closely allied to it, and hence gave it the generic name of “Pachastrella,” which now should be abandoned for “Samus.” At the same time I would here observe that the presence of the spicules of Dercitus niger (Hymeniacidon Bucklandi, latterly Battersbya Bucklandi, Bk., 1870) with Cliona either shows that Dercitus niger is an intruder of this kind occasionally, or that this is part of the habitat of this great, massive, liver-like black sponge so common on our shore-rocks. Be this as it may, there is so much relationship between the Pachastrella (Schmidt’s name for the deep-sea species of Dercitus, viz. P. abyssi) and Samus, that hereafter I expect it will be thought desirable to at least make them one group. Hence it also becomes questionable whether my Pachastrella intexta (‘Annals,’ l. c. p. 409, pl. xv. fig. 41 &c.) does not belong to the same category.
dorsal dots and the sides of the abdomen snow-white; antennae with ferruginous pectinations. Wings below pale emerald-green, with an indistinct discal series of sap-green spots; primaries also with a straight postmedian stripe of the same colour; veins white; fringe sap-green tipped with white: body white, yellowish in front. Expanse of wings 2 inches 5 lines.

N.E. Himalayas (Lidderdale). Type B. M.

37. Geometra grata, sp. n.

Emerald-green; wings sparsely striated with golden orange: primaries with the costal margin pinky whitish, crossed by dark brown striæ and dots; two widely separated, inarched, subparallel golden-orange lines, the inner one distinctly irregular, the outer one very slightly so; fringe tipped with white: secondaries with the costal border, abdominal margin, and the outer half of the fringe upon the outer margin snow-white; a transverse, diffused, golden-orange stripe just before the middle: palpi, antennæ, and front of collar pinky white; abdomen creamy white, greenish at base. Under surface sericeous white, the wings showing a tint of green owing to the transparency of their texture; costal border creamy; the numerous striæ of the upper surface indistinctly visible; a curved greyish line just beyond the middle; minute blackish discocecellar dots: pectus green in front. Expanse of wings 1 inch 10 lines.

Darjiling (Lidderdale). Type B. M.
Nearest to G. dentisignata of Moore.

[To be continued.]

[Continued from p. 61.]

[Plates VII., VIII.]

Geodina.

To facilitate an understanding of the complicated spiculation of a typical Geodia, and thereby to save repetition in description hereafter, the following definitions are premised, viz.:

1. The "zone-spicule." This is generally the largest of all and trid in its external extremity, where the arms, either
simple or subdivided, are for the most part spread out among
and support a layer of siliceous balls or globules on the sur-
face, called the "cortex" or petrous crust; while the shaft is
directed perpendicularly inwards; and thus, in juxtaposition,
it forms in combination around the Geodia a more or less
distinct zone, whence its name.

2. "Body-spicule." This, which is acerate, fusiform,
smooth, and curved, is generally the next in size to the zone-
nspicule, but by far the most numerous, as it is not only the
staple spicule of the body, but, when associated with the
zone-spicules, lies parallel with them, projects into the cortex,
and thus adds to the strength of the zone generally, as well
as the cortex.

3. "Forks" and "anchors." These are essentially anchor-
ing-spicules, and, from the embryo upwards, are, as a matter of
of course, projected beyond the surface. They are trifid; but
whereas in the "fork" the arms or prongs are produced, they
are recurved in the "anchor," while the shaft in both, which is
very long, depends for its length upon the distance the heads
are beyond the Geodia. From their great delicacy and brittle-
eness, they are for the most part broken off, especially
the anchor-heads; their presence among the zone-spicules
preparatory to their exertion is thus frequently the only
evidence, of their existence; and here they appear to be for
any purpose but that of "anchoring" or fixing the Geodia.
Hence their office is often overlooked.

4. "Siliceous globule." This is developed in the interior,
where it may be seen in all stages of growth till fully formed,
when it appears to be transferred to the surface, where, in
combination, it forms the cortex or petrous crust, in which
there are no young forms. In its earliest stage of develop-
ment, or when it is but just visible, it appears to be stell-
iform; the rays then become multiplied, extended, and hair-
like; after which, as they grow outwards, they become united
into a crystalline mass, which finally assumes a more or less
compressed, spheroidal, or elliptical form; meanwhile a hilous
depression becomes apparent on one side; and finally the
rest of the surface is covered by little stelliform bodies in
juxtaposition, which are respectively supported by the rays,
now undistinguishably consolidated into a crystalline mass.

5. "Stellates." There are always two forms of stellates, both
of which are very minute—but one much smaller than the
other; and this is chiefly confined to the surface, where it
densely charges and thus strengthens the pore-bearing dermal
sarcode. The other or larger form is chiefly confined to the
sarcode of the interior (for they are both flesh-spicules), where
it presents itself much less plentifully; but, from its much larger size, the less number of its rays and their greater length, together with their irregular disposition around the centre, it is for the most part easily distinguished from the smaller ones, although they may also be, in greater or less number, present in the neighbourhood; still it seems to me to be but an enlargement of the latter.

6. “Dermal acrate” or “acuate.” In addition to the dermal stellate there is frequently a minute linear spine or the surface, which may be acrate or acuate in form according to the species, and whose use, as it projects beyond the dermal sarcode, may be, as in other instances, through elevation and depression, to exert some influence over the functions of the pore.

Geodia perarmata, Bk. (Pl. VI. figs. 32, a–d, 33, a–f, 34, a–e, and 35, a–d.)

General form spheroidal. Colour grey. Surface uniformly wrinkled (now dry) and cribroform (Pl. VI. fig. 32). Pores minute and numerous in the dermal sarcode, giving to the surface its cribroform structure (fig. 34). Vents small, scattered singly or grouped here and there. Spicules of seven forms, viz.:—1, the zone-spicule, whose head consists of three arms, each of which is furcated, and all expanded at right angles to the shaft after the division of the arms, which at first are slightly inclined forwards, shaft 280 by 6-1800ths, head 50-1800ths in diameter (figs. 33, a, and 34, a); 2, bodyspicule, smooth, fusiform, acrate, curved, 200 by 4-1800ths (fig. 33, b); 3 and 4, fork and anchor, arms or prongs respectively about 5-1800ths long (fig. 33, c); 5, siliceous globule, 7-1800ths in diameter (fig. 33, d); 6 and 7, external and internal stellates respectively, the former 2-6000ths and the latter 6-6000ths in diameter, the rays in both radiating from a small body or central nucleus (fig. 33, e, f). Zone-spicules projecting beyond the petrous crust (fig. 35, c, d), and so supporting the dermal sarcode charged with its stellates (fig. 35, a) as to leave an interval of 1-30th inch between it and the former, thus traversed by the shafts of the zonespicules (fig. 35, b, d, and 32, a–e). Petrous crust 1-60th thick (fig. 32, e). The other spicules arranged as before mentioned. Size of largest specimen 1 inch in diameter.

Hab. Marine. Free or attached to hard objects.
Loc. Gulf of Manaar.

Obs. The distance between the dermal layer and the petrous crust in this species is both remarkable and instructive. It is remarkable because it is so unusual—and instructive be-
cause it points out the relation and function of this layer, which, in most specimens, is so absorbed into the petrous crust as to be undistinguishable from it; while the futility of attempting to circumscribe the uses of any thing in the Spongida is also shown by the head of the zone-spicule, generally considered to be for supporting the petrous crust, here passing beyond it so as to support alone the dermal sарcode. Of course, all that passes in through the pores must go into this subdermal interval or chamber previous to passing into the body of the sponge; moreover there are the same hourglass-shaped holes in the petrous crust as those which I so minutely described and illustrated several years ago in *Pachymatistema Johnstonia*, Bk. ('Annals,' 1869, vol. iv. p. 12, pl. ii. figs. 11, 12). It is not my object here to trace the progress of this material in through the petrous crust; but I cannot help thinking that the larger holes or vents in the dermal layer are, in all probability, the openings of the terminal canals of the excretory system, which *pass through the chamber entire*, so that their contents may not be mixed with the incoming ones through the pores.

This kind of dermal layer I described and figured many years ago in *Spongilla* under the name of "investing membrane" ('Annals,' 1857, vol. xx. p. 24, pl. i. fig. 1, b b b), showing that it is the seat of the dermal pores, while it is supported on the ends of spicules which, projecting from the parenchyma of the sponge, form a hollow space between it and the latter, into which the water and its contents are received before passing further into the interior. Moreover it is shown that the terminal canal of the excretory system is continued *through* this space or chamber entire, so that its contents may not mix with those of the chamber (ib. ib. fig. 1, g), which I have assumed to be the case in *Geodia perarmata*. And lately, again, I have represented it in a marine sponge, viz. *Halichondria simulans* ('Annals,' 1874, vol. xiv. pl. xxii. fig. 34, e e); while Dr. J. Millar has called attention to its existence over the Hexactinellida, where it is supported in a similar way, strengthened by a square lattice-work of hexagonal flesh-spicules, just as in *Geodia perarmata* it is supported on the heads of the zone-spicules and strengthened by the addition of stellate flesh-spicules.

Although these parts are not all illustrated in Dr. Bowerbank's description and illustrations of his *Geodia perarmata* (Proc. Zool. Soc. Jan. 7, 1873, p. 8, pl. ii. figs. 1 &c.), still the spiculation there given is so like that of the Manaar specimens that, taking into consideration his statement (p. 9), that the heads of the zone-spicules are "projected
through the stratum of siliceous ovaria (globules),” I think that, although the locality, being not known, may be different, there can be no doubt that the Manaar specimens are identical with it in species; and therefore I have used Dr. Bowerbank’s name. The minute acerate dermal spicule to which he alludes I have not seen.

*Geodia areolata*, n. sp.  (Pl. VI. figs. 36, a–g, and 37.)

General form globular. Colour now light cinnamon externally. Surface more or less regularly areolated by lines of minute echinating acerates fixed by one end in the dermal sarcode, otherwise charged with minute stellates and closely applied to the subjacent petrous crust, one of whose holes may frequently be seen in the centre of the areolar interstice (Pl. VI. fig. 37). Pores minute and numerous in the dermal sarcode, giving it a cribiform structure. Vents in groups, or scattered here and there singly. Internal structure consisting of the usual kind of spiculation distributed throughout an areolar sarcode, more confused and compact towards the centre, but presenting no defined nucleus. Spicules of eight forms, viz.:—1, the zone-spicule, with tridid head expanded at nearly right angles to the shaft, 200 by 5-1800ths, head 40-1800ths in diameter (fig. 36, a); 2, large, smooth, fusiform, acerate, curved, 150 by 3-1800ths (fig. 36, b); 3 and 4, fork and anchor, arms respectively about 5-1800ths long (fig. 36, c); 5, siliceous globule, 21 by 16-6000ths (fig. 36, d); 6 and 7, external and internal stellates respectively, the former 1-6000th and the latter 4-6000ths in diameter (fig. 36, e, f), in form much the same as in the last species; 8, minute dermal acerate, 60-6000ths long (fig. 36, g). Spicules arranged in the usual way, viz. the heads of the zone-spicules spread out in the inner part of the petrous crust, which is 1-35th inch in thickness. Size of largest specimen about an inch in diameter.

*Hab.* Marine. Free or attached to hard objects.

*Loc.* Gulf of Manaar.

*Obs.* This chiefly differs from the last species in the areolated form of the dermal layer, arising from the presence of reticulated lines of minute echinating acerates, its contact with the petrous crust, the form and position of the heads of the zone-spicules, and the cinnamon colour externally.

*Geodia ramadigitata*, n. sp.  (Pl. V. fig. 31, a–f.)

General form cylindrical, digital, occasionally branched (Pl. V. fig. 31). Colour grey. Surface (which is much worn)
covered here and there by the remains of a cribriform dermal membrane charged with minute stellates. Pores producing the cribriform structure of the dermal layer. Vents in groups or scattered singly here and there. Internal structure the same as that last mentioned, thickening towards the axis of the cylinder. Spicules of seven forms, viz.:- 1, zone-spicule, with trifid arms expanded at right angles to the shaft, which measures 160 by 4-1800ths, and head 24-1800ths in diameter (fig. 31, a); 2, body-spicule, acerate, curved, smooth, fusiform, 126 by 4-1800ths (fig. 31, b); 3 and 4, fork and anchor, arms respectively about 4-1800ths long (fig. 31, c); 5, siliceous globule, 10 by 8-1800ths long (fig. 31, d); 6 and 7, external and internal stellates respectively, the former 1-6000th and the latter 8-6000ths in diameter (fig. 31, e and f). The zone-spicules have their heads in the petrous crust, which is 1-16th inch in diameter. Size of largest specimen about 5 inches long, largest part of cylinder 1/3 inch in diameter.

Hab. Marine. Free or attached.

Loc. Gulf of Manaar.

Obs. This species, besides differing from the rest in shape, has larger siliceous globules and larger internal stellates. It is more or less covered by detritus (bits of shells &c.) and small calcareous organisms, which have become attached to and grown upon it, respectively, during the time it has been carried about by currents at the bottom of the sea.

Geodia globostellifera, n. sp. (Pl. VI. fig. 38, a-f.)

Globular. Colour grey. Surface more or less covered with detritus as in the last species. Spicules of seven forms, viz.:- 1, the zone-spicule, with trifid thin arms expanded laterally at right angles to the shaft, which is 122 by 1½-1800ths, and head 36-1800ths in diameter (Pl. VI. fig. 38, a); 2, body-spicule, acerate, curved, smooth, fusiform, 170 by 1½-1800ths (fig. 38, b); 3, fork (no anchor could be found), arms 8-1800ths long (fig. 38, c); 4, siliceous globule, spheroidal and oval respectively, about 5-1800ths in diameter (fig. 38, d); 5, globostellate, consisting of a spherical body covered with short conical points or rays, 1½-1800th in diameter (fig. 38, e and g); 6 and 7, external and internal stellates respectively, the former 1-6000th and the latter 8-6000ths in diameter (fig. 38, f and h). Spicules arranged as in the foregoing, and the globostellate mixed up with the siliceous globules of the petrous crust. Size of specimen about ½ inch in diameter.

Hab. Marine. Free or attached.

Loc. Gulf of Manaar,
Obs. The spiculation of this is very much like that of the last species, viz. *G. ramodigitata*; but the addition of the globostellate (no. 5), which is also present in an embryonic specimen of the same species, with an entire absence of pin-like spicules in both instances, whose presence would immediately claim for it a Hymedesmid origin, seems to indicate that it is produced by the *Geodia* itself, and thus distinguishes the latter from all other species that I have yet encountered. This form of globostellate, however, is so unusual in *Geodia*, and so common about the Manaar specimens with one or more Hymedesmids, of which it forms the basal layer (ex. gr. *H. stellivarians* &c.), that I can hardly suppose it would be present in *Geodia* under any other circumstances. Still, from what has been stated, and my inability to find any traces of a pin-like spicule in the midst of the petrous crust where these globostellates are present, I am unable to regard it otherwise than as a product of the *Geodia*, where it may be an enlarged form of the dermal stellate. Another character of this species is the great number of "fork" spicules that project through its surface, among which I have not been able to discover a single "anchorhead."

*Stelletta evastrum*, Slt. (Pl. VII. fig. 41, a-l.)

Laminiform, thin; growing parasitically over groups of *Siliquaria anguina*, and therefore presenting no definite form. Colour greyish white (Pl. VII. fig. 41). Surface even. Pores minute in the dermal sarcode. Vents in groups or scattered singly here and there. Spicules of five forms, viz.:—1, the zone-spicule, with simple trifid head or with the arms more or less divided (that is, the prongs of the furcation more or less lengthened), the whole expanded laterally at right angles to the shaft, which is from 20 to 40 by 4-1800ths, head 27-1800ths in diameter, both shaft and head being very variable in form and size (fig. 41, b); 2, body-spicule, acerate, smooth, curved, fusiform, 60 by 2-1800ths (fig. 41, c); 3, siliceous globule, discoid, irregularly elliptical, very thin, the hilous depression hardly discernible, and the stellate ends of the radiated structure scattered thickly but separately over the surface, about 17 by 9-1800ths and about 3-1800ths thick (fig. 41, d, g, k, l); 4, acerate (flesh-spicule), curved, microspined, more or less inflated in the centre (fig. 41, e, g, h); 5, stellate, 2-1800ths in diameter (fig. 41, e, g, i). Siliceous disks gathered together in a thin layer on the surface, but the rest of the spicules mixed together apparently indiscriminately and confusedly throughout the body; the zone-spicule
in form, size, and position the most irregular of all. Size of largest specimen, of which there are several, that of the group of *Siliquaria*, about 2½ inches in its long diameter, compressed.

**Hab.** Marine. Parasitic on *Siliquaria*.

**Loc.** Gulf of Manaar.

**Obs.** This species was first named by Schmidt, who obtained the specimen from Lacaze-Duthiers, who, again, got it from La Calle, on the north coast of Africa, near Algiers (Schmidt, Spong. Küste v. Algier, 1868, p. 20); no description of it, however, is given beyond the spiculation, of which I examined a mounted type specimen in the British Museum.

The disk is, *mutatis mutandis*, identical with the siliceous globule in development, structure, and location, while the imperfectly formed zone-spicule and its irregular location puts one in mind of *Pachymatismus Johnstonia* (so abundant on our coasts); still it appears to me to be more nearly allied to *Geodia* than to *Stelletta*; and therefore I have placed it, like *Pachymatismus*, among my *Geodina*. Schmidt, as above stated, has given it the generic name of "*Stelletta*," adding, by way of designation, "*euasrum,*" from the large and beautiful form which some of the stellates attain in the specimen from La Calle, but which do not occur in that of the Gulf of Manaar—although they will be seen to do so in the Australian form (fig. 42, c), which I will now describe, as it gives us more of the internal structure than is to be found on the laminiform growth over the group of *Siliquaria* (fig. 41).

*Stelletta euasrum*, Sdt., S.W. Australian specimen, Fremantle. (Pl. VII. fig. 42, a–c.)

Ovular, now wrinkled from being dry; 3 inches long by 1½ inch in diameter. Colour white externally—that is, the colour of the petrous crust,—pale yellow internally, which is the colour of the sarcode (Pl. VII. fig. 42). Surface even, dimpled, poriferous throughout (fig. 42, b b). Vents of different sizes scattered here and there (fig. 42, a a a). Dermal layer composed of the disks before mentioned, mixed with both forms of the flesh-spicule, about 1-360th inch thick, surrounding a pale yellow widely areolated body-structure charged with the spicules of the species and, if anywhere, less condensed in the centre than towards the circumference; thus, in the absence of any zonular arrangement and central condensation like that of a typical *Geodia*, this species is identical with *Pachymatismus Johnstonia*, Bk. Possessing much the same kind of spiculation as the Manaar specimen, it has, in addition, the large and beautiful stellate (fig. 42, c)
"euastrum rota," Sdt., which seems to be always quadri-
radiate with rays of equal length, viz. 12-6000ths, spined over
the outer half, and parting at the same angle from the centre
of union, where there is no body. But this spicule is confined
to the parenchymatous structure, of which there being none
or very little in the Manaar specimen from its thin, parasitic,
laminiform growth, may account for its absence there; while
the same kind of smaller and more radiated stellates, about
half the size in both specimens, are equally abundant, in the
dermal layer especially.

Besides Stelletta euastrum there are two other species with
discoid siliceous globules in the Adriatic, which Schmidt has
named respectively S. discophora and S. mamillaris (Spong.
Adriat. Meeres, 1862, pp. 47, 48, Taf. iv. fig. 5, and Taf. v.
fig. 1, respectively), of which there is a specimen (for they both
appear to me to be the same species) in the British Museum,
obtained by Mr. Saville Kent from the coast of Portugal;
and from this, together with Schmidt's illustrations, it is evi-
dent that the same kind of discophorous layer on the surface,
the absence of the zonular arrangement of the spiculation and
that of the "forks and anchors," so characteristic of Geodia,
exists in all, with a badly-developed condition of the zone-
spicule (which, as above stated, varies in the form of its head
from triform to trifurcate, and in that of its shaft from long to
short, pointed and obtuse), scattered here and there amongst
the rest of the spicules without any apparent regularity what-
ever. In short, the structure is as different from that of a
Geodia as it is specifically characteristic of Pachymatisma
Johnstonia and Caminus vulcan, Sdt. (op. et loc. cit.). All of
these, therefore, although belonging to the Geodina, should
constitute a different group from Geodia proper.

Stellettina.

The chief difference between the Stellettina and Geodina is
the total absence of the "siliceous globule" in the former,
whether spheroid or discoid, leaving nothing but the "dermal
stellates" to rest upon the zone-spicules &c., which are for
the most part similarly arranged to those of Geodia, although
seldom with such characteristic regularity.

Stelletta tethyopsis, n. sp.
(Pl. VI. fig. 39 and 40 a–f.)

General form subhemispherical and sessile, or spheroidal
and free (Pl. VI. fig. 39). Colour grey. Surface uniformly
hispid from the projection of the forks and anchors, beneath
which may be seen the heads of the zone-spicules supporting the dermal sarcode charged with its stellates. Pores in the dermal layer. Vents not seen, probably owing to contraction and dryness. Internal structure very compact on account of all the spicules lying close and nearly parallel to each other as they uninterruptedly converge from the circumference to a point in the centre, where there is no nucleus (fig. 39). Spicules of five forms, viz.:—1, the zone-spicule, consisting of an extremely long, smooth, slightly curved shaft and trifid head trifurcated, of which the three arms advance obliquely forwards at an angle of 45° with the shaft, and the rest turn off at right angles to it, shaft 625 by 5-1800ths, head about 30-1800ths in diameter (fig. 40, a a); 2, body-spicule, also extremely long, acerate, smooth, slightly curved fusiform, 625 by 4-1800ths (fig. 40, b b); 3, forks and anchors largely developed, of which the arms respectively are about 10-1800ths long (fig. 40, c); 4 and 5, external and internal stellates, the former about 1- and the latter 4-6000ths in diameter (fig. 40, e, f), both multiradiate and without central nucleus or body—that is, their rays radiate from a central point which is not differentiated,—the internal stellate, as is usual in Stelletta, very faintly developed, and the rays fewer and longer than those of the external one. Largest specimen sessile, about two inches in horizontal diameter at the base and $\frac{3}{4}$ inch high, somewhat umbonate; but a considerable portion appears to have been left on the rock where it grew.

Hab. Marine. Free or fixed.

Loc. Gulf of Manaar.

Obs. This is a very beautiful species, from the compactness and regularity of its structure internally, which also causes it to closely resemble Tethya cranium (the type of my Tethyina), hence its designation; but its spiculation is that of a Stelletta. The head of the zone-spicule is subject to great variety in form, sometimes assuming that of the “fork” greatly enlarged (fig. 40, d). It is stated above that a considerable part of the base was probably left on the rock where it grew, since I know by experience, on the S.E. coast of Arabia, that a sponge possessing this kind of structure contracts so forcibly when alive and fixed on the rock where it may be growing, that it can only be got off in portions with hammer and chisel!

Tisiphonia nana, n. sp. (Pl. VII. fig. 43, a-e.)

Laminiform, thin, or filling up the depression in the Melobesian nodule where it may be growing. Colour white. Surface even. Spicules of four forms, viz.:—1, large trifur-
cate with very short conical shaft, 6 by 3-1800ths, head 50-1800ths in diameter (Pl. VII. fig. 43, a, b); 2, acerate, smooth, fusiform, curved, 27 by 1-1800ths (fig. 43, c); 3, acerate flesh-spicule, smooth, fusiform, curved, inflated in the centre, 4-1800ths long (fig. 43, d, e); 4, stellate flesh-spicule 4-6-rayed, rays microspined, 3-6000ths (fig. 43, d, e). The large trifurcate spicule is parquetted in amongst the rest so as to form a smooth even surface over an areolar structure, whose thickness varies with the subjacent depressions of the Melobesian nodule over which the sponge is growing. Size about one third of an inch in horizontal diameter.

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaar.

_Obs._ Dwarfed as this variety is, one can see by its spiculation, although modified by its habitat on the surface of the Melobesian nodule, that it belongs to the _Stelletia._ The trifurcate head, although necessarily with an extremely short shaft, indeed hardly more than a short cone (fig. 43, b), and the acerate spicule no. 2, are equivalent to the zone- and body-spicule in _Geodia_ respectively; while the central inflation of the acerate flesh-spicule, although not microspined, and the tendency in the stellate to assume a spinispirulate form, ally it to the _Tetidea muricata_ of Bowerbank, the synonymy of which I have already published (Annals, 1878, vol. ii. p. 174); but I find that, in this article, I have omitted to mention that my dear old friend, Dr. J. E. Gray, in a note to me, dated 3rd January, 1871, foreshadowed what I have therein chiefly stated, viz. that "Bowerbank's figures of the spicules of his _Tetidea muricata_ (B. S. vol. i. figs. 304, 305) are probably those of _Tisiphonia, Wyvillethomsonia_ and _Dorvillia_ respectively," which is now proved to be the case by Dr. Bowerbank's own words and his illustrated description of _Tetidea muricata_ (Proc. Zool. Soc. 1872, p. 115, pl. v. figs. 1-6).

The first mention of the name _Tisiphonia_ for a sponge occurs in Sir Wyville Thomson's paper on _Holtentia Carpentoria_ (Phil. Trans. vol. 159, p. 712), read before the Royal Society on the "17th June, 1869," where, without more than the letters "n. g." after it, he gives it as one of the genera illustrating his "suborder Leptophleba." Subsequently we have the name " _Wyvillethomsonia_" proposed as a generic appellation for the same species by Dr. P. Wright in January 1870; and then comes Schmidt's of " _Stelletia_" in the month of May following, ending with that of " _Dorvillia_" by Mr. Saville Kent in Dec. 1870.

Now it is evident that no one but Dr. Gray had seen that
this was a form of Dr. Bowerbank’s *Tethea muricata* up to
the date above mentioned; or if so, no one ever noticed it
publicly. Still it is equally evident that *Tisiphonia = Dor-
vilia* is sufficiently different from *Tethea muricata* to re-
quire specific distinction; at the same time that *Tethea muri-
cata* is not a species of *Tethea*, but one of *Stelleta*, as Schmidt
has made it from his examination of the Florida specimen.

Furthermore, we find Dr. Bowerbank multiplying the
varieties of this sponge under the names *Ecionemia compressa, 
Hymeniacydon placentula*, and *Normania crassa* respectively
(B. S. 1874, vol. iii.), all of which specimens (now in the
British Museum) I have had the opportunity of examining.
Hence, when we find the species (varieties) of a sponge so
numerous, it becomes necessary to make a group of them
under a specific name; and as Sir Wyville Thomson’s use of
“*Tisiphonia*” claims priority in this respect, I have applied
it generically to the species above described, and shall apply
it provisionally to the two following ones, merely observing
that, while I consider them all varieties, the human mind can
never remember them without specific distinction. Nature
does not require this aid.

*Tisiphonia annulata*, n. sp. (provisional).
(Pl. V. fig. 28, a–d.)

Massive, charged with the spicules of the species, without
apparent regularity. Colour white. Spicules of three forms,
viz. :—1, quadriradiate, arms equal in size, radiating at equal
angles from a common centre, annulated throughout with
alternate inflations and depressions, the former microspined
and sometimes broken or incomplete in the annulation, arm
17 by 1-1800ths (Pl. V. fig. 28, a and d); 2, acerate, smooth,
fusiform, curved, 63 by 1-1800ths (fig. 28, b); 3, spinispirulate flesh-spicule, 3-6000ths long (fig. 28, c). Spicules
arranged confusedly in an areolated sarcode; nos. 1 and 3 in
great abundance and of various sizes, the former below and
the latter above their stated measurements respectively. Size
of specimen about 1-12th inch in diameter.

*Hab.* Marine. Growing on hard objects, in the present
instance among the minute detritus attached to the specimen
of *Stelleta euastrum* (Pl. VII. fig. 42).

*Loc.* Gulf of Manaar.

*Obs.* This sponge was found growing in the place just
mentioned. The facies of the spiculation appears to me to be
that of a variety of *Tisiphonia*; and if so, the quadriradiate
spicule is, with the exception of the annulation, like that given
by Dr. Bowerbank of *Normania crassa* (B. S. vol. iii. pl. lxxxi.
dredged up from the Gulf of Manaar.

fig. 5); but the characteristic acerate flesh-spicule (viz. microspined and centrally inflated) is absent, although the spinispirula is not, but abundantly present.

The chief interest, however, of this specimen is in the annulated quadriradiate form, on account of its resemblance to the fossil spicule from the Upper Greensand of Haldon Hill, near Exeter, which I represented in 1874 (‘Annals,’ vol. vii. pl. ix. figs. 44, 45), as it may not only throw some light on the nature of the sponge which bore this, but also on the other moniliform spicules so common in the cavities of the chalkflints of Oxfordshire and perhaps elsewhere, but first represented from some Irish specimens by Mr. Joseph Wright, F.G.S., in the Belfast Nat. Hist. Field-Club Report for 1873-74 (pl. ii. figs. 4, 5).

_Tisiphonia penetrans_, n. sp. (provisional).

(Pl. VII. fig. 44, a-d.)

Amorphous, taking the form of the excavation of the Melobesian nodule in which it may be growing. Colour white. Spicules of three forms, viz.:—1, acerate, curved, smooth, fusiform, 27 by 1-1800ths (Pl. VII. fig. 44, a); 2, the same form, but much smaller, 6-1800ths long (fig. 44, b); 3, stellate flesh-spicule, variable in the number and position of its rays, often quadriradiate, rays microspined, 4-6000ths in diameter (fig. 44, c, d). Size varying with that of the excavated cavity in which it may be growing.

_Hab._ Marine. In excavations previously made by lithodomous sponges.

_Loc._ Gulf of Manaar.

_Obs._ There is still less in this to identify directly with the spiculation of _Tisiphonia_ than in the foregoing species; but the facies here also strikes me as being allied to this genus. Although found in the excavated cavities of the Melobesian nodule, I doubt if it made the cavities itself; for they often contain a heterogeneous mixture of different forms of spicules which come from as many different kinds of sponges that in my examinations I have never met with, some of which are extremely beautiful and not less remarkable, _e.g._ figs. 29, 30 (Pl. V.). They are generally, too, enclosed in a transparent membranous investment, which must be the remains of the living organism that not only gathered them together and enclosed them, but dragged them into some of the minutest channels of the excavation in the nodule. What was the nature of that organism, Foraminiferal or Spongious, future observation may determine.
Lithistina.

In describing the Lithistids it is absolutely necessary to have specimens which possess the last-formed dermal layers in addition to a portion of the fully formed internal structure, because these are the parts which are most characteristic of the species; hence, although we may not possess the fully developed entire form, the thinnest layer, provided it contains the parts mentioned, will be sufficient to determine the species; for these will ever be the same, although the adult form of the sponge itself may be different. So that, while the specimens on the Melobesian nodules of the Gulf of Manaar are so small that, comparatively, they hardly amount to much more than traces of structure which may attain a large and definite form in the deeper sea, still, so far as they go, they will enable us to predict what they may attain in that situation.

For the most part, they have grown over the layers of Melobesia from which the nodules have been chiefly formed, while in many instances they themselves have been overgrown by one of the Microcionina that have been described; but, whether overgrown or not, as the spiculation of a Lithistid, for the most part, is so locked together that even boiling in pure nitric acid does not separate its parts, so in this way it has been easy to free the Lithistid not only from the calcareous Melobesia on which it rests, but from the Microciona covering it, to such an extent as to cause it to come out under this treatment in a clean, perfect, and beautiful form. I have stated "for the most part," because it may be easily conceived that the elements of which a Lithistid is composed are not inextricably locked together until they have undergone a certain amount of development, and therefore, being more or less united by sarcode until this occurs, they are, up to this time, separable by boiling in nitric acid. Such is more particularly the case with the Lithistids whose structure commences in disks (viz. the Discodermiae), which disks we shall hereafter find to be gradually transformed into their branched and complicated spiculation. But even here, under the boiling in nitric acid, all the separated parts can be easily retained, and, when mounted in Canada balsam, present, when thus separate, a much better view of their gradationary development than when in situ, where they lie more or less obscured in layers one over another as they are formed. The term "interlock" is here used advisedly; for whereas in the vitreous Hexactinellida the spicules are cemented together by the addition of glassy fibre, no such thing occurs in the Lithistida, whose spicules are united by mere apposition of the expanded ends of their filigreed branches (Pl. VIII.
fig. 51, i), or by an interlocking, inseparable without fracture, of the filigree of one branch with that of another (Pl. VIII. fig. 48, k k k and l). At least I have not yet seen direct union between the parts of one spicule with those of another in a Lithistid.

Although most of these Melobesian nodules present one or more growths of Lithistida upon them respectively, yet it is only in one or two instances out of the seven species that I have found that two different ones have been observed on the same nodule; while so abundant are they that it is hardly possible to mount a fragment of any other sponge on the nodule without finding in it spicules of a Lithistid.

Of the “seven species” three may be termed “Corallistes,” because they do not appear to commence their growth in discoid elements; while the opposite is the case with the other four, which will be termed “Discodermia.” Of course, in describing and illustrating them, my observations will be confined to their structure, since they must be regarded as only little growths or traces, as before stated, of the entire sponges; while the illustrations, on the other hand, must be considered as diagrams after nature, for such is the intricacy of Lithistid structure that it is almost hopeless to attempt any thing beyond catching the specific character and representing this as near to nature as possible. Having premised these remarks, we will begin with the Corallistes.

**Corallistes.**

_Corallistes aculeata_, n. sp. (Pl. VII. fig. 45, a, b.)

Surface characterized by the presence of erect spike-like processes (Pl. VII. fig. 45), which, when the structure is torn to pieces, are respectively found to be supported on three arms, which are tubercled and repeatedly subdivided into branches until they end in a filigree consisting of minute angular processes, which interlock with those of the neighbouring spicules (fig. 45, a). Spike conical, elongated, sub-sinuous, 1-333rd long by 1-120th inch in diameter at the base, more or less cononodose, tubercles more or less in circular lines round the lower two thirds of the spike (fig. 45, a, b). Internal structure composed of spicules of the usual Lithistid form, consisting of four arms, each of which is repeatedly divided and subdivided into branches until they end in the way above mentioned. Size of largest specimen about ¼ inch in horizontal diameter.

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaar.
Obs. The spike supported on three arms diadem-like and uniformly distributed over the surface is the characteristic feature of this species. There is a small specimen of it in the British Museum, about 6-12ths inch in diameter, which came from the neighbourhood of Kendrick Island, south of Japan (lat. 24° 13' N., and long. 136° 13' E.), presented by Dr. J. Gwyn Jeffreys.

_Corallistes verrucosa, n. sp._
(Pl. VII. fig. 46, a, b.)

Surface characterized by the presence of short, tuberose cones (Pl. VII. fig. 46), which, when the structure is torn to pieces, are respectively found to be supported on three arms tubercled and repeatedly subdivided into branches until they end in a filigree consisting of minute angular processes which interlock with those of the neighbouring spicules (fig. 46, a). Cone consisting of a pyramidal heap of tubercules about 1-666th inch high and 1-750th inch in diameter at the base (fig. 46, a), which is triangular and, for the most part, composed of three tubercles larger than the rest, triangularly placed and situated respectively opposite the reentering angles between the arms (fig. 46, b). Internal structure composed of spicules of the usual lithistid form consisting of four arms, each of which is repeatedly divided and subdivided into branches until they end like the one above mentioned. Size of specimen about $\frac{1}{4}$ inch in horizontal diameter.

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaar.

Obs. There is nothing particular about this species beyond the form of the surface-processes, which, at the same time that they present a distinguishing feature, afford the only remarkable difference between it and _C. aculeata._

_Corallistes elegantissima, n. sp._
(Pl. VII. fig. 47.)

The spicules of this species (if it is a distinct one) were only found in microscopic groups in two places on the same nodule as _Discoderma papillata_ (which will presently be described), where they were chiefly in the midst of, and thus protected by, the acerate spicules of a species of _Reniera_ that had overgrown them. To describe a Lithistid spicule where there is no particular character is, from its intricateness, almost impossible; therefore I must refer the reader to the illustration, which is a careful drawing to measurement of one of these elegantly beautiful objects, merely adding that
the terminations are not round like those of most Discodermia, but pointed, prong-like, and angular, as they are delineated (Pl. VII. fig. 47).

Discodermida.

Finding that the Discodermida grow by the transformation of a simple disk on the surface to the complicated structure of the interior, I have endeavoured to illustrate this in a series of figures which are taken from a portion that was boiled to pieces in nitric acid and the residue mounted in Canada balsam (Pl. VIII. fig. 48, d, &c.). Indeed all the species have been studied in this way, when the gradationary forms of the disk thus separated render it very easy, as before stated, to see and follow the changes of form which it undergoes; besides which, this may be corroborated by looking at the specimen in situ in its natural state through a microscope (Pl. VIII. fig. 48, a, b, c). In addition to the disks the Discodermida appear to be always characterized by one or more forms of minute flesh-spicules in great abundance, of which a curved acerate, or straight bacillar one, microspined, is perhaps the most prevalent (fig. 48, h, and 49, c, d); but these are not confined to the dermal sarcode in which the disks are developed and imbedded, although apparently most abundant there (fig. 48, a, &c.), but almost as plentifully distributed throughout the whole structure. Again, the filigreed ends of the branches of the full-formed spicule are not angular, but more or less spherical, like bunches of grapes interlocked with one another; after the manner of the clasping of hands (fig. 48, b). At the same time, however, I am not able to explain the fact that in Kalliapsis sidaris, Bk. (Proc. Zool. Soc. 1869, pl. xxv. fig. 2, &c.), of which I possess some good specimens in situ, and which is a genuine Discodermia, a "diadem-like" form of spicule similar in this respect to that of Corallistes aculeata, exists under the discophorous layer. I do not pretend to follow this transformation of the disk, which is succeeded, as usual, by the fully formed Lithistid spicule of the interior, but now only to announce the circumstance. In specimens of Corallistes aculeata, in situ, the spikes may be seen without any disks whatever, even when the surface is overgrown and thus protected by a Microciona; nor in the mounted residue after boiling in nitric acid of specimens of this species is there a trace of a disk under any kind of form to be observed; while in most specimens of Discodermia the Microciona grows upon the disks themselves.

In describing the structure of the different species of Discodermida, I shall commence with the disks, as these are the
first-formed parts, and follow the structure on by description and illustration to the full development of the spicule, finally giving a magnified view of the form of the filigreed termination characteristic of each species.

*Discodermia papillata*, n. sp.

(Pl. VIII. fig. 48, a–l.)

Surface even, discophorous, disks horizontal; structure papillated throughout, accompanied by a bacillar microspined flesh-spicule (Pl. VIII. fig. 48, a, b, c). Colour yellow internally. Outer layer of last-formed disks more or less circular, micropapillated in the upper, and bearing the rudiment of a spine (the shaft) in the centre of the lower surface, the smallest disk observed being circular, and about 1.300th inch in diameter (fig. 48, b and d); the next layer larger and more indented on the margin; after this the disk becomes branched, the spine or shaft fully formed (fig. 48, e), and the papillae enlarged and extended over the branches (fig. 48, f); finally the staple spicule of the interior is produced (fig. 48, i), where the shaft may be observed to be trifidly divided and subdivided until it ends in the filigree, with which it interlocks with its neighbours (fig. 48, k, k, k) on all sides by botryoidal or grape-like terminations (fig. 48, l)—the original papillae, now still more enlarged and extended over the shaft and branches, presenting over the former a wart-like appearance (fig. 48, i), probably influencing this character of the development throughout,—a similar development taking place at the inner end of the shaft, by which, both on the outer and inner side, the filigree is interlocked with corresponding portions of similar spicules; and thus the structure presents internally an increase of bulk by successive layers, as the breaking-up of a piece of fully-formed Lithistid testifies. Papillae at first microscopic, finally becoming conical (fig. 48, g). Bacillar spicule elliptical, elongated, microspined throughout, about 3-6000ths long (fig. 48, h). Largest specimen about an inch in horizontal diameter, filling up the depressions of the Melobesian nodule over which it grows, and extending into the crevices and cavities made by excavating sponges that may be underneath.

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaar.

_Obs._ I have thus summarily described the development of this discodermid sponge, so that it will not be necessary to repeat it in the other species more than the occasion demands; at the same time it should be remembered that the varieties in the structure of the elementary parts of a Lithistid are practi-
cally unlimited. Again, it frequently happens that the disco-
phorous layer has disappeared from some cause or other,
and that the surface is then formed by that condition of de-
development where the disk has passed into a branched state, in
which the branches, curving over each other, leave interspaces
charged with the bacillar flesh-spicule (Pl. VIII. fig. 48, a,
and 50 a, &c), which causes it to assume the appearance given
by Dr. Bowerbank of his Dactylocalyx Prattii (Proc. Zool. Soc.
1869, pl. v. figs. 6–11), and the same in Theonella Swinhoei,
Gray (ib. 1868, p. 565), both of which specimens, now
in the British Museum, I have examined and find the disco-
phorous layer absent. Nor is this to be wondered at, from
what I have stated of the instability of this layer until the
disks have become transformed into the interlocking spicules;
still there are no papillae on the spicules of Dactylocalyx
Prattii or of Theonella Swinhoei, which distinguishes them
from Discodermia papillata; but although the flesh-spicule is
elliptical elongate in Dactylocalyx Prattii, and bent in the middle
in Theonella Swinhoei, this is not sufficient for specific distinc-
tion between them; nor is the flesh-spicule generally to
be depended on in this respect; so, with this difference
only, I think, as Dr. Bowerbank has concluded (op. et l. cit.),
that Dactylocalyx Prattii and Theonella Swinhoei must be
considered the same species. Yet there is a large, vase-like
specimen to which I have before alluded, and which comes
from the seas about the Philippine Islands, in which the flesh-
spicules (for there are two forms) may be considered of some
specific value, since here the usual acerate curved micro-
spined and centrally inflated flesh-spicule is accompanied by
another equally plentiful, viz. a short thick ellipsoidal form
also microspined, not unlike the same kind of flesh-spicule in
Pachastrella abyssii, Sdt.

Discodermia aspera, n. sp.
(Pl. VIII. fig. 49, a–i.)

Surface even, discophorous, disks horizontal (Pl. VIII.
fig. 49, a, b). Structure asperous, spinous, accompanied by
an acerate microspined flesh-spicule (Pl. VIII. fig. 49, a, b).
Colour grey. Discophorous structure and transformation
much the same as in the last-described species, only
that the margin of the disk soon becomes denticulated
(fig. 49, c), and the papillae pass into spines, as indicated
by the four gradationary diagrams (fig. 49, g); and in the
transformed disk (fig. 49, f) the irregularly lobed and den-
ticated margin, together with the spines on the surface,
give that asperous appearance which more or less influ-
ences the subsequent development of the fully formed spicules of this Lithistid even to the end (fig. 49, h), in which the filigreed terminations are not grape-like as in the foregoing species, but subangular (fig. 49, i). Papillae at first microscopic, then enlarged, after which they become united by intervening straight linear ridges, then elevated and compressed, and finally divided into spine-like processes (fig. 49, g), which more or less characterize the fully formed spicules (fig. 49, h). Flesh-spicule acerate, curved, microspined, about 5-6000ths long (fig. 49, e), plentifully distributed over the disks (fig. 49, a) and throughout the structure. Size about 1 inch in horizontal diameter, filling up the depressions on one side of a Melobesian nodule about this size.

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaar.

_Obs._ The asperous character of the spiculation of this species, arising from a transformation of the original papillae of the disk into spinous processes, as above mentioned and illustrated (fig. 49, g, &c.), chiefly distinguishes it. As the specimen for the most part is very much worn, I should, but for the boiling in nitric acid of a portion which had been protected by having been overgrown by a _Reniera_, have been entirely ignorant of its discophorous character and the peculiar spinous transformation of the papillae of the disks to which I have alluded, which seems to continue its influence on to the fully formed structure.

_Discodermia spinispirulifera_, n. sp.

_(Pl. VIII. fig. 50, a–h.)_

_Surface even, discophorous; disks horizontal; structure loose, accompanied by two forms of flesh-spicule, viz. an acerate and a spinispirula (Pl. VIII. fig. 50, a, b, c, and e, f). Colour white. Discophorous structure and transformation much the same as in the foregoing species, only that, instead of papillae, the disk presents faint circular concentric lines (fig. 50, d), and, previously to passing into the branched form, show an irregularly lacerated margin in which the foreshadowed divisions of the full-formed spicule assume the most whimsical proportions and appearances (fig. 50, i), finally producing a branched spicule repeatedly subdivided as before until the ends become filigreed into subglobular processes (fig. 50, g). Flesh-spicule of two forms, viz.:—1, comparatively large, acerate, curved fusiform, microspined, about 20-6000ths inch long (fig. 50, e); and the other, 2, a minute spinispirula, consisting of a sinuous shaft covered with thin spines about the same length as itself, arranged over it in an echinating, spiral
manner, 3-6000ths of an inch long (fig. 50, f)—the former plentifully distributed over the disks, as before mentioned, and but little less so throughout the rest of the structure, while the latter sparsely accompanies it. Size of largest specimen about ¼ inch in horizontal diameter, and the thickness of the depression on the nodule where it may have grown, often extending into the cavities formed by excavating sponges.

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaar.

_Obs._ The remarkably shreedy character of the advanced form of disk (fig. 50, i) and the presence of the spinispirular flesh-spicule, together with the comparatively large size of its companion the acerate flesh-spicule, distinctly separate this from the other species of Discoderma. It may be remembered that the flesh-spicule of Dactylocalyx Masoni, Bk., is a spinispirula (Proc. Zool. Soc. 1869, pl. vi. fig. 4).

_Discoderma levidiscus_, n. sp.
(Pl. VIII. fig. 51, a–i.)

Surface even, discophorous, disks horizontal, structure areolar, accompanied by an acerate flesh-spicule (Pl. VIII. fig. 51). Colour yellow internally. The disks here, which also present a great number of faint lines, like those of the foregoing species, are depressed in the centre (fig. 51, b, c). They undergo similar transformation to those of the foregoing species (fig. 51, e), passing at last into the fully formed spicule of the interior (fig. 51, h, h), whose terminations appear to be more in expanded, irregular surfaces, for the sake of union by apposition with their neighbours, than in filigree processes interlocking (fig. 51, i). Flesh-spicule acerate, curved, fusiform, microspined, about 8-6000ths long (fig. 51, f, g), plentifully distributed over the disks (fig. 51, a) and throughout the interior, as in the foregoing species. Size of specimen about ¼ inch in horizontal diameter.

_Hab._ Marine. On hard objects.

_Loc._ Gulf of Manaar.

_Obs._ When viewed in situ (fig. 51) the depressions in the centres of the disks, which are rather less in diameter than those of the other species, together with the concentric lines, added to the comparative absence of filigree terminations in the fully formed spicule, and the yellow colour of the interior, are sufficient to distinguish it from the other species; while the absence of papillae on the disks causes it to
differ from *D. papillata* and *D. aspera*; the absence of the shred-like transformation of the disk (although in both instances there are no papillae on it), together with the presence of the spinispirular flesh-spicule, causes it to differ equally from *D. spinispirulifera*.

The following is a list of organisms in and about the Melobesian nodules from the Gulf of Manaar above mentioned:

**ALGÆ (calcareous).**

Melobesia (? ) polymorpha, lamini-form.
— polymorpha, nulliporiform.

Melobesia, quadrangular-celled, lamini-form, ? sp.
Flabellaria opuntia.

**FORAMINIFERA.**

*Sessile.*

Polytrema miniaceum.
— cylindricum.
— mesentericum, n. sp. Loc. unknown, not Gulf of Manaar.
Carpenteria utricularis.

Carpenteria monticularis.
Gypsina melobesioides.
— vesicularis.
— , var. spheroidalis.

**Subsessile.***

Rotalia spiculotesta.

Orbitolites marginalis.

**Free.***

Calcarina calcar, var. hispida, n. var.
Alveolina sinuosa, n. sp.
Amphistegina.
Holocladiina pustulifera, nov. gen. et sp.

Cystoedictyina compressa, nov. gen. et sp.
Ceratostegina globularis, nov. gen. et sp.
— tessellata, n. sp.

**SPONGIDA.**

Ord. ii. Ceratina.

Aplysina purpurea, n. sp.
Aplysina fusca, n. sp.

Ord. iii. Psammonemata.

Hircinia arundinacea, n. sp.
Hircinia fusca, n. sp.

Ord. iv. Rhaphidonemata.

Chalina ? sp. (young).
Desmacidon Jeffreyi, Bk.

Ord. v. Echinonemata.

*Pluriformia.*

Dictyocylindrus mansarensis, n. sp.
Dictyocylindrus sessilis, n. sp.
dredged up from the Gulf of Manaar.

Microcionina.

Microciona atrosanguinea, Bk.
—— armata, Bk.

—— complicatus, n. sp. Seychelles.

Geodina.

Geodia perarmata, Bk.
—— areolata, n. sp.
—— ramodigitata, n. sp.

Geodia globostellifera, n. sp.
Stelletta euastrum, Schmidt.
Stellettina.
Stelleta tethyopsis, n. sp.
Tisiphonia nana, n. sp.
Tisiphonia (prov.) annulata, n. sp.
— (prov.) penetrans, n. sp.

Lithistina.
Corallistes aculeata, n. sp.
— verrucosa, n. sp.
— elegantissima, n. sp.
Discoderma papillata, n. sp.
Discoderma aspera, n. sp.
— spinispirulifera, n. sp.
— laevidiscus, n. sp.

Ord. viii. Calcarea.

Spicules of unknown sponges.

Hydroidea.
Hydradendrium spinosum, nov. gen. et sp.

Actinozoa.

Alcyonaria.
Rhizoxenia, Ehr., ? sp.
Spongodes, Lesson, ? sp.

Tubipora reptans, n. sp.

Polyzoa.
A great variety of species undetermined.

Tunicata.
Synascidlae, Giard.

Tribe i. Didemnidae (with spicules).
Leptoclinum, Milne-Edwards. White, incrusting.

Gasteropoda.
Siliquaria anguina.

Type specimens of all the above organisms, dry and mounted in Canada balsam respectively, may be found in the Liverpool Free Museum, under the designation of "Manaar Collection of 1879, presented by Captain H. Cawne Warren."

Explanation of the plates.

N.B. To avoid repetition, the measurements are to be considered parts of an inch throughout.
If the scale is not given in figures, the following indications should be remembered:

"Sc. A." means 1-24th to 1-1800th inch.
"Sc. B" means 1-24th to 1-6000th.
"Sc. C" means 1-12th to 1-6000th.
"Sc. D" means 1-48th to 1-1800th.
Where the spicule is fusiform and perhaps curved, a trapezoidal figure has often been given to it for convenience in delineation, although the proportions are maintained; the detail otherwise must be sought for in the letterpress.

Dotted lines and dots are generally intended to represent spination.

**Plate IV.**

**Fig. 1.** Dictyocylindrus manaarenis, n. sp., nat. size: a, b, c, d, linear spicles; e, tricurvate; f, equianchorate (Sc. A); g, more magnified view of e and f.

**Fig. 2.** D. sessilis, n. sp., nat. size: a, b, c, linear spicles (Sc. A); d, more magnified view of c.

**Fig. 3.** Microciona bulboretorta, n. sp., spiculation of: a, b, c, d, linear spicles (Sc. A); e, more magnified view of d.

**Fig. 4.** M. quadriradiata, n. sp., spiculation of: a, b, linear spicles; c, quadriradiate (Sc. A); d, more magnified view of c.

**Fig. 5.** M. quintqueradiata, n. sp., spiculation of: a, b, c, linear spicles; d, quintqueradiate (Sc. A); e, more magnified view of d.

**Fig. 6.** M. curvispliculifera, n. sp., spiculation of: a, b, linear spicles; c, curvilinear spicle (Sc. A); d, more magnified view of c.

**Fig. 7.** M. fascispliculifera, n. sp., spiculation of: a, b, c, linear spicles; d is e fasciculated (Sc. A); e, more magnified view of b; f, bihamate (Sc. B); g, large spicles and fasciculi of c, in situ (diagram).

**Fig. 8.** Hymerhaphia unispicum, n. sp.: one form of spicule only (Sc. A).

**Fig. 9.** H. eruct, n. sp., spiculation of: a, erect linear spicle; b, caterpillar-like spicle; c, the same, but early stage, resembling the contort spicle of Hymerhaphia vermiculata, Bk. (Sc. A).

**Fig. 10.** Hymeresmia stellicivans, n. sp., spiculation of: a, linear spicle (Sc. A); b, stellate (Sc. B); c, d, e, various forms of ray, more magnified (diagram).

**Fig. 11.** H. Moorad, n. sp., spiculation of: a, linear spicle (Sc. A); b, stellate (Sc. B); a, ray, more magnified.

**Fig. 12.** H. capitastosstilifera, n. sp., spiculation of: a, linear spicle (Sc. A); b, stellate (Sc. B); c, ray more magnified.

**Fig. 13.** H. spinastosstilifera, n. sp., spiculation of: a, linear spicle; b, different forms of head (Sc. A); c, stellate (Sc. B); d, ray, more magnified.

**Fig. 14.** H. trigonostilata, n. sp., spiculation of: a, b, linear spicles (sc. 1-12th to 1-1800th); c, d, stellates (Sc. C).

**Fig. 15.** Microciona affinis, n. sp.: equianchorate, to show hook-like appearance of central arm (Sc. C).

**Plate V.**

**Fig. 16.** Remiera ? sp., white, spicule of (Sc. A).

**Fig. 17.** Remiera ? sp., yellow, spicule of (Sc. A).

**Fig. 18.** Remiera ? sp., dark brown, spicule of (Sc. A).

**Fig. 19.** Halichondria aceralospiculum, n. sp., spiculation of: a, linear, acerate, spined; b, linear, acerate, smooth, inflated in the centre; c, bihamate; d, equianchorate (Sc. B).

**Fig. 20.** Esperia serratohamata, n. sp., spiculation of: a, linear spicle; b, serrated hamate; c, tricurvate; d, inequianchorate (Sc. B).

**Fig. 21.** Suberites vestigium, n. sp., spicule of (sc. 1-12th to 1-1800th).

**Fig. 22.** S. fistulatus, n. sp., spiculation of: a, linear spicle (sc. 1-12th to 1-1800th); b, equianchorate, lateral and front views (Sc. B).
**Fig. 23.** *Thoosa socialis,* n. sp., spiculation of: *a,* sceptrelliform spicule; *b,* compressed globular spicule (Sc. C).

**Fig. 24.** *Dotona pulchella,* n. sp., spiculation of: *a,* chief spicule; *b,* fine hair-like acuate; *c,* flesh-spicule (Sc. C); *d,* portion of *a,* more magnified, to show by the dotted faint line on the opposite side that the apparent annulations form part of a spire.

**Fig. 25.** *Alectona Higginii,* n. sp., spiculation of: *a,* chief spicule; *b,* fine hair-like acerate, subtricusperate; *c,* flesh-spicule (Sc. C).

**Fig. 26.** *Samus simplex,* n. sp., spiculation of: *a,* lateral view of main spicule; *b,* horizontal view of head (Sc. A); *c,* flesh-spicule (Sc. C).

**Fig. 27.** *S. complicatus,* n. sp.: main spicule, horizontal view, upperside (Sc. A).

**Fig. 28.** *Tetraphonia annulata,* n. sp., spiculation of: *a,* annulated quadriradiate; *b,* linear acerate (Sc. A); *c,* flesh-spicule spinispirulate (Sc. C); *d,* portion of *a,* more magnified.

**Fig. 29.** Verticillately spined cylindrical spicule of unknown sponge abundant in excavated cavities of the Melobesian nodules (Sc. B).

**Fig. 30.** Pin-like spicule with spinated extremities and head turned to one side, of unknown sponge found in similar cavities of the Melobesian nodules (Sc. A).

**Fig. 31.** *Geodia ramodigitata,* n. sp., nat. size: *a,* zone-spicule; *b,* body-spicule; *c,* fork and anchor; *d,* siliceous globules, round and oval respectively; *e,* stellates of both localities, viz. external and internal (Sc. D); *f,* stellates, more magnified.

---

**PLATE VI.**

**Fig. 32.** *G. perarmata,* Bk. Section through the centre, nat. size: *a,* dermal layer; *b,* interval between the dermal layer and petrous crust; *c,* petrous crust; *d,* body or interior.

**Fig. 33.** The same, spiculation of: *a,* zone-spicule; *b,* body-spicule; *c,* fork and anchor; *d,* siliceous globules, round and oval; *e,* external and internal stellates (Sc. D); *f,* more magnified views of *e,* respectively.

**Fig. 34.** The same. Dermal layer viewed from within: *a,* head of zone-spicule; *b,* pores in dermal layer, with stellates in the lower half; the latter represented by the dots (diagram).

**Fig. 35.** The same. Vertical section of dermal layer, subdermal chamber, and adjoining part of petrous crust: *a,* dermal layer charged with stellates; *b,* subdermal chamber or interval; *c,* part of petrous crust; *d,* heads and adjoining shafts of zone-spicles (diagram).

**Fig. 36.** *G. areolata,* n. sp., spiculation of: *a,* zone-spicule; *b,* body-spicule; *c,* fork and anchor; *d,* siliceous globules, round and oval; *e,* external and internal stellates; *f,* dermal acerate (Sc. D); *g,* stellates, more magnified.

**Fig. 37.** The same, portion of surface, more magnified, to show areolation and position of dermal acerates (diagram).

**Fig. 38.** *G. globostellata,* n. sp., spiculation of: *a,* zone-spicule; *b,* body-spicule; *c,* fork (no anchor seen); *d,* siliceous globules, round and oval; *e,* globostellate; *f,* external and internal stellates (Sc. D); *g,* more magnified view of *e,* *h,* more magnified views of *f.*

**Fig. 39.** *Stellate tetraphyes,* n. sp., torn off from the base (nat. size).

**Fig. 40.** The same, spiculation of: *a a,* zone-spicule; *b b,* body-spicule;
e, fork and anchor; d, occasional form of zone-spicule; e, external stellate; f, internal stellate (Sc. D). The dotted lines at the bottom of a a and b b, respectively, are to show that they are continuations of the same spicules, which, upon this scale, are too long for the Plate.

**Plate VII.**

Fig. 41. *Stelletta eucastrum,* Sdt., parasitic on a group of *Siliquaria angulata:* a a, mouths of the *Siliquaria* (nat. size); b, zone-spicule; c, body-spicule; d, siliceous disk; e, minute acerate flesh-spicule; f, minute stellate flesh-spicule (Sc. D); g, more magnified views of d, e, and f, respectively (sc. 1-45th to 1-6000th); h, still more magnified view of acerate flesh-spicule, to show that it is microspined and inflated in the centre; i, more magnified view of ray of stellate, to show that it is microspined; k, more magnified view of portion of disk, to show form and position of stelliform points on surface; l, still more magnified views of point, lateral and direct, respectively.

Fig. 42. The same, Australian specimen: a a a, vents; b b, pores in the crust (nat. size); c, spined stellate (quadriradiate) (Sc. B).

Fig. 43. *Tisiphonia nana,* n. sp.: a, zone-spicule, viewed from above, as seen in situ; b, the same, lateral view (observe the extremely short shaft); c, body-spicule; d, acerate flesh-spicule and stellate (Sc. D); e, more magnified view of the same.

Fig. 44. *T. pedunculata,* n. sp.: e, body-spicule; b, acerate flesh-spicule and stellate (Sc. A); c, more magnified view of stellate (Sc. C); d, still more magnified view of ray of same.

Fig. 45. *Coralites aculeata,* n. sp. Oblique view of surface, showing spikes (Sc. about A): a, spike-spicule, lateral view; b, base of the spike, broken off, viewed from above (Sc. B). (Diagrams.)

Fig. 46. *C. verrucosa,* n. sp. Oblique view of surface, showing verrucous cones (Sc. about A): a, verrucous cone-spicule, lateral view; b, base of the cone, viewed from above (Sc. B). (Diagrams.)

Fig. 47. *C. elegantissima,* n. sp., spicule of (sc. 1-45th to 1-6000th).

**Plate VIII.**

Fig. 48. *Discodermia papillata,* n. sp. Portion of surface viewed from above: a, disks covered with minute, fusiform, bacillar flesh-spicules; b, the same without the flesh-spicule; c, subjacent spiculation (Sc. about D); d, five figures to show the transformation into the surface-spiculation seen at e; e, shaft of disk; f, papillae on disk; g, fully formed papillae, more magnified; h, fusiform bacillar flesh-spicule, much magnified; i, ultimate form of spicule of the interior; k k k, interlocking of the ends of the branches with those of neighbouring spicules; l, characteristic form of "interlocking," much magnified. (Diagrams.)

Fig. 49. *D. aspera,* n. sp. Portion of surface viewed from above: a, disks covered with minute, acerate, curved, fusiform flesh-spicules; b, the same without the flesh-spicule (Sc. about D); c, more magnified view of disk, showing denticulated margin and papilla; d, acerate flesh-spicule (Sc. D); e, the same, more magnified; f, more advanced form of disk, in which the papillae are transformed into spines, more or less divided; g, four diagrams, showing the transformation of the papilla into the spinous condition; h, ultimate form of spicule of the interior;
