C. grandimana, n. s.

Stamm entweder auf allen oder wenigstens den drei letzten
Segmenten mit paarigen oder unpaaren dorsalen Höckern
oder Dornen ; 2. Arm des erwachsenen Männchens kurz,
Hand desselben im Verhältniss nicht so stark entwickelt
wie bei der vorigen Art.

C. acanthifera, Leach.

"B. Hinterfühler mit Ruderhaaren. Dimorphismus wechselnd.

Stirnstaehel fehlt.

Körper ungemein bestachelt. 2. Arm kurz. *C. tuberculata*, Bate and Westwood.

— dorsal ganz glatt. 2. Arm kurz. *C. equilibra*, Say.

— nur auf Segment 5-7 bestachelt. 2. Arm des erwachsenen Männchens lang *C. linearis* (Linné) Bate.

Stirnstaehel vorhanden.

2. Arm des erwachsenen Mäusehens kurz.

Geissel des Vorderfühlers mit 19-20 Gliedern *C. septentrionalis*, Kröyer.

Geissel des Vorderfühlers mit 14 Gliedern.

Kiemen länglich. 5. und 6. Segment mit Höckern *C. dentata*, Haller.

— rund. 5. und 6. Segment glatt *C. acutifrons*, Latreille.

2. Arm des erwachsenen Männchens lang.

2. Hand desselben normal *C. attenuata*, Dana.

2. — — ungewöhnlich lang *C. inermis*, Haswell."

To this table I have added the names of the authors of the species from the accounts given by Mayer further on.

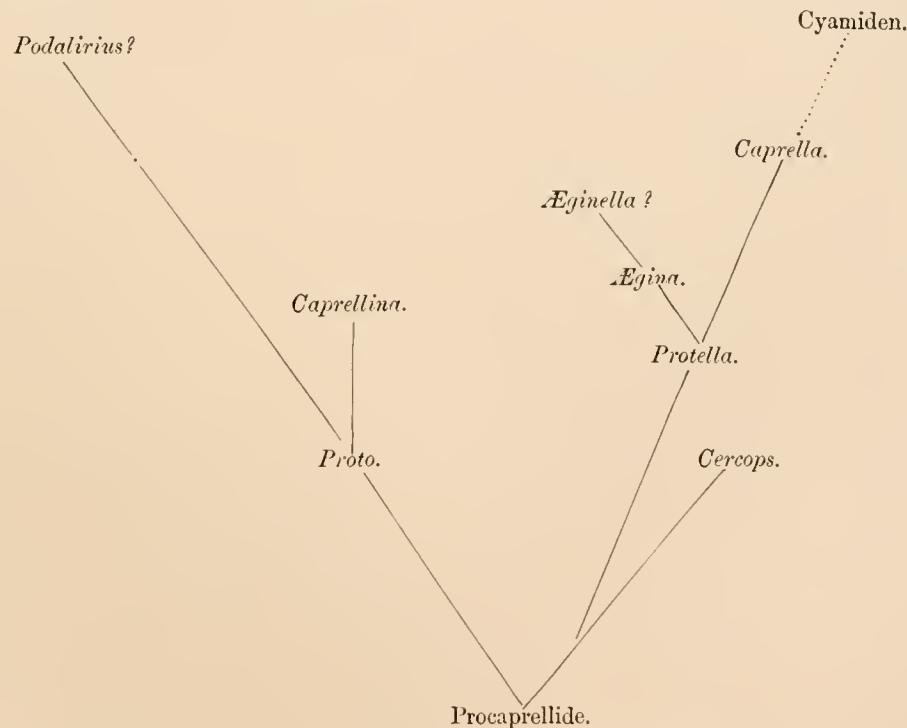

To his new species, *Caprella grandimana*, Mayer assigns the earlier "Caprella Dohrnii," Haller, as a synonym, apparently rejecting Haller's name on the ground of some uncertainty connected with his species, and what seems to be an error in the description. It must be observed also that the name *Caprella inermis*, Haswell, requires to be changed, having been already used by Grube for a different species. As it appears to be undistinguishable "from *Caprella Danilevskii*," Czerniavski, it may as well be known by that name. With *Caprella tuberculata*, Bate and Westwood, Mayer suggests the possible identification of de Quérone's *Puce de Mer arpenteuse*, Fig. A., B. (1780), which in my opinion is quite out of the question.

The genus *Podalirius*, Kröyer, receives three species, distinguished in the following table:—

" Palmarrand der Grossen Greifhand beim Männchen mit einem kleineren proximalen und einem grösseren medialen Fortsatz, .	<i>P. typicus</i> , Kröyer.
" Palmarrand der Grossen Greifhand ohne den medialen Fortsatz :	
Hinterbeine enorm verlängert, Palmarrand ohne Einschlag-	
haken,	<i>P. Kröyeri</i> , Haller.
Hinterbeine kurz, Palmarrand mit Einschlaghaken, .	<i>P. minutus</i> , n. s."

Traces of the first and second pereopods are stated to be present in "*Podalirius Kröyeri*." To *Podalirius minutus* is assigned as a synonym *Podalirius typicus*, Hock.

Under the head of Phylogenie, at page 192, the following hypothetical table of genealogy is given:—

One hundred and thirty-one works are mentioned in the Literaturliste and Nachtrag, pages 194–201, which, with a few unavoidable exceptions, have been carefully studied and are here minutely criticised by Mayer.

Taf. i., a double plate, gives figures, lateral and dorsal, of both sexes of the following species, *Proto ventricosa*, *Protella phasma*, *Podalirius kröyeri*, *Podalirius minutus*, *Caprella*

grandimana, *Caprella acanthifera*, *Caprella æquilibra*, *Caprella dentata*, *Caprella acutifrons*, all found in the Gulf of Naples. The remaining nine plates give numerous and important details of the structure both external and internal of various species. There are also various illustrations interspersed with the text.

Attention may be called to the section on the salivary gland, as Mayer says, p. 145, that "Alle Autoren ohne Ausnahme schweigen von den Speicheldrüsen."

1882. SARS, G. O.

Oversigt af Norges Crustaceer med foreløbige Bemærkninger over de nye eller mindre bekjendte Arter. (Podophthalmata—Cumacea—Isopoda—Amphipoda) (med 6 autographiske Plancher) (Christiania Videnskabsselskabs Forhandlinger 1882. No. 18. Fremlagt i Mødet den 13de Oktober).

A list is given of 294 species of northern Amphipoda, 8 of them *Hyperina*, 268 *Gammarina*, and 18 *Caprellina*. The *Gammarina* are distributed among 22 families, the subfamilies of Boeck being dropped. Forty new species are figured and described, namely; 95. *Clydonia borealis*, rather to be called *Tyro borealis*; 97. *Lysianella petalocera*, a new genus, of which the special characteristic is said to be the peculiar development of the penultimate joint of the peduncle of the lower antennæ, "insolito modo dilatato, laminari, facie interna seriebus numerosis transversis ciliorum exornata." The undivided telson brings it near to the genus *Lysianassa*, from which it is distinguished by the antennæ, the first maxillæ "lobo incisivo angusto spinis miuitis crebris armato, palpo brevi, lobo interno angusto, bisetoso," and the first gnathopods "sat breves, distincte subcheliformes, manu carpo parum longiore leviter attenuato, apice oblique truncato;" 98. *Ichnopus umbonatus*; 99. *Orchomene pectinatus*, said to be distinguished from *Orchomene serratus*, Boeck, by the pale, narrow, subsigmoid eyes, the high, compressed gibbosity on the fourth pleon-segment, and other details; 100. "*Orchomene Batei*," "= *Anonyx Edwardsii* Sp. Bate (nou Krøyer) ♀ = *Lysianassa longicornis* Sp. Bate ♂." Professor Sars says that Boeck seems not to have had this form under his notice, otherwise he could not have identified it with his *Orchomene serratus*, which is very distinct and the same as *Lysianassa crispata*, Goës. As it is not the same as Krøyer's *Anonyx edwardsii*, with which Bate had identified it, Sars renames it *Orchomene batei*, which, however, cannot rightly, I think, be made to include the species which Sp. Bate calls *Lysianassa longicornis*, Lucas; 102. *Tryphosa ciliata*, apparently very near to *Tryphosa nana*, Krøyer; 104. *Normania latimana*, provisionally referred to the genus *Normania*, but without examination of the mouth-organs; 110. *Phoxus falcatus*, "= *Phoxus simplex* Boeck non Sp. Bate," the name proposed for this species (already described by Boeck, but by him incorrectly identified with Bate's species), referring to the characteristic form of the rostrum; 112. *Stegocephalus gibbosus* said to be easily distinguishable from the two other northern species by the "Epimera 4ti paris permagna, antecedentibus junctis plus duplo majora, postice valde producta et æqualiter rotundata, distincte latiora quam altiora" and by the "segmentum 3tium corporis postici supine in gibberum acutum desinens, epiphysis in medio marginis posterioris processum acuminatum leviter recurvum formantibus, angulis inferioribus obtuse rotundatis;" 113. *Stegocephalus auratus*, said to resemble *Stegocephalus christianensis*, Boeck, but to be distinguishable by its smaller size, a broad orange stripe over the back, and the structure of the fifth peræopods with "articulus basalis permagnus, laminaris, ceteris junctis multo longior, ad marginem posticum dense serratus et deorsum in angulum valde prominentem et ultra articulum 4tum porrectum excurrens;" 114. *Andania pectinata*, said to be near *Andania nordlandica*, Boeck, but to

be distinguished from it by the first gnathopods "ungve terminali spinis 4 pectinatim ornato," the second gnathopods, "ungve terminali spinis 2 armato," the "cpiimera 4ti paris antecedentibus junctis circiter æqualia, oblique triangularia, postice obtuse producta, margine inferiore parum arcuato," and by the "pedes ultimi paris articulo basali subelliptico deorsum rotundato-producto, margine posteriore lœvi; articulo 3tio qvam in *A. nordlandica* minus dilatato;" for the relationship of this species to *Stegocephalus*, see Note on Aurivillius, 1885; 115. *Amphilochus inermis*, said to be very like *Amphilochus manudens*, Sp. Bate, but having the hand of the first gnathopods "angulo anteriore non in spinam producto," and distinguished from *Amphilochus odontonyx*, Boeck, by the second gnathopods, in which the hand is much larger than in the first pair, "apicem versus dilatata, acie arcuata calce carpi angusta et elongata ad aciem manus porrecta," and by the very elongate telson; 116. *Stegoplax longirostris*, new species of a new genus, of which Sars says "this curious little Amphipod obviously belongs to the Family Amphilochidae, but is so different from the forms hitherto known that it must be made the type of a new genus. The chief characters are the enormous development of the third and fourth pairs of side-plates, and the rudimentary structure of the two first pairs, also the narrow linear form of the basal-joint of the third and fourth pereiopods, by which it recalls the genus *Stegocephalus*." It is very near to, if not synonymous with, the earlier genus *Peltocoxa*, Catta, 1875, and the genus *Cypridida*, Haswell, 1880; see Notes on Catta and Haswell under those dates; 117. *Stenothoë tenella*, distinguished from the two other northern species of *Stenothoë* by the less strongly built body, the thin antennæ and pereiopods and light-coloured eyes; 118. *Stenothoë brevicornis*, like *Stenothoë monoculooides* in the very short antennæ, distinct in the much less developed side plates; 119. *Metopa rubrovittata*, recognised by Sars as standing very near to *Metopa alderi*, Sp. Bate, but distinguished from it by its far smaller size, the antennæ of uniform length, the hand of the second gnathopods, thus described, "pedes 2di paris robusti, manu magna, oblonga, acie brevi, fere transversa, subtiliter serrulata, inferne processu dentiformi sat prominente apici quam basi multo propiore definita;" and the colouring, "corpus pellucidum fasciis transversis angustis ex parte interruptis colore intense purpureo ornatum;" 120. *Metopa leptocarpa*, "pedes primi paris forma insolita, tenuissimi, fere filiformes, carpo valde elongato et angusto, manu apicem versus leviter dilatata, acie transversa et inferne distinctissime definita;" 122. *Metopa borealis*, synonymous with *Metopa bruzelii*, Boeck, non Goës, being distinguished, Sars says, from *Metopa bruzelii*, Goës, by its more considerable size, shorter antennæ, first gnathopods "articulo 3tio inferne parum producto, manu medio leviter dilatata carpi longitudinem æquante," and by the second gnathopods in which the palm is more coarsely serrate and the lower angle more prominent; 123. *Metopa calcarata*, distinguished by the relatively large oval eyes, the much dilated and downward produced third joint of the hinder pereiopods and by the second gnathopods in the male, which are "permagni, manu valde elongata, subarcuata, margine inferiore dense ciliata et antice eminentiam serratam præbente, nongve terminali fortissimo margine altero ciliata;" 124. *Metopa gregaria*, the hand of the second gnathopod in the male "valde praelongata, subarcuata, marginé inferiore toto dense ciliata in medio dentibus 2 et prope apicem eminentia subtiliter serrata armata, acie non definita, nongve terminali validissimo manu longiore in marginé interno ciliata;" 128. *Bruzelia tuberculata*, near *Bruzelia serrata*, but distinguished from it, Sars says, by want of any proper dorsal carina, though all the segments are raised above into protuberances, also by the blunt lateral carina, and by the lower hinder angles of the third pleon-segment, which are "acuminati et valde sinsum curvati margine inferiore serrato;" 129. *Elicherus microps*, near *Elicherus lynceus*, M. Sars, but scarcely half the size, with a shorter, less inflated rostrum, smaller eyes, second joint of upper antennæ linear, hands of the first and second gnathopods more elongate, third uropods very long; 131. *Halimedon*

megalops, distinguished by the uncommonly thick arched rostrum and large, confluent eyes; 132. *Halicreion* (?) *latipes*, only provisionally referred to Boeck's genus, as Sars recognises that the third uropods are not longer than the second, which is the case in the typical species, *Halicreion longicaudatus*, and that the proportions of the first four pairs of pereopods in the two species are very different; 133. *Paramphithoë brevicornis*, with a general resemblance to species of *Metopa*, to be distinguished from its own allies by its small size, pale colour, and unusually short antennæ; 134. *Paramphithoë assimilis*, nearest to *Paramphithoë glabra*, Boeck, but distinguished by the eyes, "magni, rotundato-triangulares," the "epimera anteriora medioreria, dente anguli infero-posterioris fere obsoleto," the two gnathopods "manu elongato-ovata in 2^{do} pari paulo majore, aeie bene definita, obliqua, margine inferiore spinis nonnullis et fasciculis pilorum ornato," and the considerably greater length of the pereopods; 136. *Iphimedia minuta*, distinguished from *Iphimedia obesa*, Rathke, by Professor Sars by its having no spine on the first joint of the upper antennæ and by the different form of the two pointed processes at the lower hinder angle of the third pleon-segment, as well as by its small size and very different colouring; distinctions of somewhat doubtful specific value, that of colour above all being untenable in face of the numerous variations which *Iphimedia obesa* undoubtedly presents; 137. *Atylus uncinatus*, very like *Atylus swammerdami*, M.-Edw., but distinguished by the very remarkable first pereopods "structura singulare, organa valida affixionis formantes, articulo 4to brevissimo, cupuliformi, 5to magno et curvato ad basin fasciculis 2 spinarum armato, ungve terminali fortissimo, falciformi," a species which appears to be synonymous with *Atylus falcatus*, Metzger, 1871; 138. *Halirages megalops*, distinguished from its ally *Halirages tridentatus*, Biuzelius, by the enormously developed eyes and the "segmenta 2 priora corporis postici supine medio in processus singulos acutos producta; segmentum 3tium ad angulum infero-posteriorem truncatum et fortiter serratum"; 139. *Halirages inermis*, to be recognised by its slender body, want of dorsal processes, thin, elongate pereopods, and the sides of the head produced downwards into conical processes; 141. *Amphitloës nodifera*, distinguished by a pair of tubercles on the back of the first, and another pair on the back of the second, pleon-segment; 143. *Tritropis inflata*; 144. *Tritropis avirostris*, which, with the preceding species, must be transferred to *Rhachotropis*, S. I. Smith; 147. *Melita pellucida*, "corpus pellucidissimum absqve pigmento. Longit. 5^{mm}."; 149. *Ampelisca gibba*, in the form of the last pereopod said to be very like *Ampelisca lærigata*, Lilljeborg, but clearly distinguished by the different form of the head, although nothing in the figures and descriptions given respectively by Sars and Boeck of *Ampelisca gibba* and *Ampelisca lærigata* seems to justify the separation of the former from the latter; 151. *Ampelisca anomala*, a species of importance as a link between the two genera *Ampelisca* and *Byblis*, even without links sufficiently close. In the general form of the body and development of the side-plates, the new species, according to Sars, is a genuine *Ampelisca*, whereas the two basal-joints of the lower antennæ are quite uncovered as in the genus *Byblis*. The last nropods extend indeed beyond the others, but still are far from being as strongly developed as is usual in species of *Ampelisca*; 153. *Byblis erythrops*, distinguished from *Byblis gaimardi* by smaller size, red eye-pigment, longer upper antennæ, and by the penultimate joint of the peduncle of the lower antennæ being distinctly shorter than the last joint; 154. *Photis tenuicornis*, the antennæ shorter and thinner than usual, sparsely pilose with short bristles, the palm of the first gnathopod obliquely excavate, of the second "bisinuate"; 156. *Gammaropsis melanops*, " = *G. erythrocephalma* Boeck, non Lilljeborg," distinguished by Sars from Lilljeborg's species by the shorter secondary flagellum of the upper antennæ, the acute antero-lateral angles of the head, and the also acute infero-posterior angle of the third pleon-segment, while, further, the eyes in this species are black, not red, as required by the

very name of Lilljeborg's species; 157. *Podocerus minutus*, a minute form distinguished by Professor Sars from *Podocerus falcatus*, Montagn, on the ground of its far smaller size, the eyes considerably larger, the slighter unciliated lower antennæ, the slenderer pereopods and the different colouring. As to the last point, "color flavescens fusco variegatum" would often precisely describe specimens of *Podocerus falcatus*. The difference in the second gnathopods of male and female is just what is found in the *pulchellus* and *variegatus* forms of *Podocerus falcatus*. Boeck speaks of having taken *Podocerus falcatus* at 20 fathoms depth, so that the occurrence of *Podocerus minutus* at a depth of 20 to 30 fathoms will not be, as Sars appears to suggest, an additional evidence of its distinctness. May it not be the *Ischyrocerus minutus* of Lilljeborg, 1851; 159. *Siphonacetes pallidus*, said to be distinguished from *Siphonacetes typicus*, Kr., and *Siphonacetes colletti*, Boeck, by its small size, pale colour, and the antennæ thus described, "1mi paris dimidio corpore longiores, articulis pedunculi sensim magnitudine deerescenibus, flagello articulis pedunculi 2 ultimos junetos longitudine aequante vel paulo superante, 6-articulato; 2di paris validæ corporis longitudinem excedentes, margine utroque valde setoso, articulo ultimo pedunculi penultimo nonnihil breviore;" 165. *Caprella ciliata*, the second gnathopods as figured and described corresponding so exactly in form and ciliation to those often met with in *Caprella acanthifera*, Leach, as to raise a presumption that Sars' specimens may belong to that very variable species. The elongate flagellum of the upper antennæ, the only other distinctive mark to which Sars himself draws attention, is likewise proper to *Caprella acanthifera*. On the other hand, the figure does not show the globose head so notable in that species, to the distinctive shape of which Sars himself calls attention in noticing *Caprella acanthifera*, and the hands of the pereopods are described and figured with "acie prope basin dente minuto armata," whereas in *Caprella acanthifera* the place of insertion of the principal spines, which defines the palm, is not, as in many Caprellæ, near the base of the hand but some way down its margin. In regard to the ciliation or hairiness of the hand of the second gnathopod, a doubt arises whether it may not be merely an adventitious growth; like the hairs depicted by Bate and Westwood on the second pereon-segment of their *Caprella tuberculata*, "die aber nichts Anderes als Pilzhypfen sind," in P. Mayer's opinion.

Besides describing new species, Professor Sars makes important observations on many old ones. He regards *Tauria abyssorum*, Boeck, as a synonym of 91. *Tauria medusarum*, Fabr., so that, combining Sars' view as to the species with that of Bovallius as to the genus, Fabricius' species should be called *Hyperia abyssorum* (Boeck); 92. *Parathemisto abyssorum*, Boeck, is obviously identical with Bate's *Hyperia obliqua*, but as this is distinct from Krøyer's *Hyperia obliqua*, which = *Hyperia galba*, Montagu, Boeck's name is retained. *Tryphana malmii*, Boeck, is referred to Dana's genus *Lycæa* as 94. *Lycæa malmii*. *Lycæa puler*, Marion, 1874, from the Mediterranean, is said to come very near the northern species. *Lysianassa plumosa*, Boeck, is said to be undoubtedly the male of 96. *Lysianassa costæ*, Milne-Edwards; *Lysianassa umbo*, Goës, which Boeck gives as *Orehomene umbo*, is considered by Sars as belonging to the genus *Lepidepecreum*, Sp. Bate. *Pontoporeia furcigera*, Bruzelius, is considered to be scarcely distinct from 105. *Pontoporeia femorata*, Krøyer, since Krøyer figures the peculiar process on the fourth pleon-segment which has suggested the name *furcigera*. The eurions 107. *Argissa typica* of Boeck is said in some degree by its general habit to recall the Ampeliscidæ, and to be slower in its movements than other members of the family Pontoporeiidæ. 108. *Bathyporeia robertsonii*, Sp. Bate, is held by Sars to be a distinct species from the closely allied *Bathyporeia pilosa*, Lindström, in which I cannot agree with him. *Montagua (Probolium) pollexiana*, Sp. Bate, is mentioned as 125. *Metopa pollexiana*. *Cressa schliödtei*, Boeck, is stated to be a synonym of 126. *Danaia dubia*, Sp. Bate. 130.

Monoculodes carinatus, Sp. Bate, is disunited from *Monoculodes affinis* of Boeck [which J. S. Schneider thinks may = *Monoculodes stimpsoni*, Sp. Bate]; 142. *Leucothoë furina*, Savigny (Sp. Bate), is thought to be easily distinguishable from *Leucothoë spinicarpa*, Abildgaard, by its slenderer body, a somewhat different form of the gnathopods, and difference of colouring. It may be doubted, notwithstanding, whether any or all of these distinctions suffice to establish the specific difference in question. *Halice grandicornis*, Boeck, is undoubtedly, Sars says, the male of 146. *Halice abyssi*, Boeck. Bate's *Ampelisca gaimardi* (originally *Tetromatus typicus*) is stated to be undoubtedly the male of 148. *Ampelisca tenuicornis*, Lilljeborg, not a separate species, *Ampelisca typica*, as Boeck makes it. But here neither Sars nor Boeck can be right, for the anterior part of the back, both in *Ampelisca tenuicornis* and in Boeck's description of *Ampelisca typica*, is round, while in Spence Bate's species "the anterior half of the animal is much more compressed than the posterior, and narrowed to an angle upon the dorsal surface, the angle increasing anteriorly to the extremity of the head." Hoek is probably right in adopting Normau's suggestion that *Ampelisca carinata*, Bruzelius, is the male of *Ampelisca æquicornis*, Bruzelius, but again neither Norman nor Hoek can be right in uniting *Ampelisca gaimardi*, Sp. Bate, to *Ampelisca carinata*, Bruzelius, for that species has the front part of the back rounded. The name *Ampelisca typica* (Bate, non Boeck) will therefore belong to *Ampelisca gaimardi* (Bate, non Kröyer), while *Ampelisca typica*, Boeck, is united to *Ampelisca tenuicornis*, Lilljeborg. The question, however, remains, whether the specific name of *Tetromatus typicus* can with propriety be retained, when the species to which it refers has been found to belong to a previously established genus. 158. *Coroplium bonelli*, M.-Edwards, is distinguished from *Coroplium crassicornis*, Bruzelius, by the rounded side-lobes of the head and the far weaker form of the lower antennae both in male and female. *Siphonacetes crassicornis*, Sp. Bate, under the title 160. *Cerapus crassicornis*, is referred without doubt to the genus *Cerapus*, Say, as characterised by S. I. Smith. It constructs, out of particles of mud, small, regularly cylindrical tubes, which it carries about with it. The species referred by Boeck to *Cerapus* belong to *Erichthonius*. The females of 163. *Dulichia monacantha*, Metzger, are said to be very like the females of *Dulichia porrecta*, Sp. Bate, while the males are clearly distinguished by the development of the side-plates of the second pair into long forward-directed spine-like processes.

1882. STREETS, THOMAS H.

A Study of the Phronimidae of the North Pacific Surveying Expedition.
Proceedings of the United States National Museum. Vol. V. 1882. pp. 3-9.
Pl. I.

Dr. Streets is of opinion that Claus combines in his description of *Phronima sedentaria* more than one species. *Phronima sedentaria* itself Dr. Streets had not had any opportunity to examine. He points out that to Claus is due the discovery that such and such a species known in the female had a male form presenting characteristic differences. He upholds *Phronima atlantica*, Guérin (fig. 1, 1a, 2), as a good species, against the researches of Claus, and also *Phronima pacifica*, Streets, fig. 3, 3a. In regard to the genus *Phronimella*, Claus, he says, "Claus states that there are 'only two pairs of styliform caudal appendages.' This is true of the female, but not of the male. In one of his plates, where the caudal extremity of a male is given, the three pairs of styliform appendages are very clearly represented." Description and figures (4, 4a, 5, 5a) are given of *Phronimella elongata*, Claus, with which Dr. Streets identifies his own *Anchylonyx hamatus*, 1877.

1882. STUXBERG, ANTON.

Evertebratfaunan i Sibiriens Ishaf. Förelöpande Meddelanden. Vega-Expeditionens Vetenskapliga Jakttagelser. Bd. I. Stockholm, 1882.

E. von Martens in the Zoological Record for 1883 says that *Stegocephalus kessleri*, sp. n., from the northern coast of Asia, is figured but not described (p. 713). Of *Acanthostephia malmgreni* (Goës) a woodcut is given and an account of its general occurrence in the Siberian glacial sea (pp. 724, 729). *Atylus carinatus* (Fab.) is mentioned (pp. 723, 729) for its occurrence in the same sea. “*Weyprechtia*, g. n., for *W. mirabilis*, sp. n., 51 mm. long. Description of the species, but no generic characters given.” (See Note on Stuxberg, 1880.)

1883. BLANC, HENRI.

Structure des eupules membraneux ou “calceoli” chez quelques Amphipodes. Zoologischer Anzeiger. VI. Jahrgang. 1883. No. 143. pp. 370-372.

For the views explained in this paper see Note on H. Blanc, 1884.

1883. CHEVREUX, ÉDWARD, born November 10, 1846 (É. C.).

Crustacés amphipodes et isopodes des environs du Croisic. Association française pour l’avanement des Sciences. Congrès de Rouen. 1883. pp. 517-520.

In this list of Amphipods from the west coast of France, forty species are mentioned, the habitat being specified from which each was obtained. The determination of the species was made with the assistance of Bate and Westwood’s well-known work, and includes “*Gossea microdeutopa* S. Bate,” but this M. Chevreux has since informed me was entered in mistake for *Calliopius norvegicus*, Rathke.

1883. CHILTON, CHARLES.

Further additions to our knowledge of the New Zealand Crustacea. (Read before the Phil. Inst. Cant., 7th September, 1882.) Notes on, and a new Species of, Subterranean Crustacea. (Read before the Phil. Inst. Cant., 5th October, 1882.) Art. II. III. Trans. and Proe. New Zealand Inst., 1882. Vol. XV. Wellington, 1883. pp. 77-92. Pl. II. III. IV.

The new species described are *Nicea egregia*, *Cypridilia* (?) *crassa*, *Mera incerta*, *Podocerus frequens*. *Cypridilia* (?) *crassa* differs so much in the form of the coxae from the other three species belonging to Haswell’s genus *Cypridilia* that, as Mr. Chilton himself suggests, it will probably have to find a generic place elsewhere.

Article III. describes and Plate IV. figures *Phreatoicus typicus*, a singular well-shrimp, of a new genus and species, which appears to be an Isopod with some remarkable Amphipodan affinities. The genus is thus defined:—“Body long, sub-cylindrical, laterally compressed. Upper antenna short, lower long, with flagellum. Mandible with an appendage. First pair of legs subchelate, others simple; first four pairs articulated to body at the anterior ends of

their segments and directed forwards, last three articulated at posterior ends of their segments and directed backwards. Abdomen long, of six distinct segments, last joined to telson. Sixth pair of pleopoda biramous, styliform. Telson large, subconical." See Note on Thomson and Chilton, 1886.

1883—GERSTAECKER, A.

1884.

Gliedfüssler: Arthropoda. Dr. H. G. Bronn's Klassen und Ordnungen des Thierreichs wissenschaftlich dargestellt in Wort und Bild. Fortgesetzt von Dr. A. Gerstaecker. Mit auf Stein gezeichneten Abbildungen. Fünfter Band. II. Abtheilung. 9.—15. Lieferung. Leipzig und Heidelberg. 1883, 1884. Siebente Ordnung. Amphipoda. Flohkrebse. pp. 279—416. Taf. XXVII.—XLVIII.

This work contains a full and clear account of the organisation and development of the Amphipoda, compiled from all the best authorities, and illustrated by figures given in facsimile from the original works. There is an introductory account of the history of the subject, and a list of authors in a chronological order determined by their first publications about the Amphipoda.

In most cases names of genera and species have been accepted from authors without criticism, it not being within the plan of the work to rectify minor details of classification. The transfer, however, of the Tanaidæ to the Amphipoda is made without reserve. See further, Note on Gerstaecker, 1886.

1883. JOSEPH, GUSTAV.

Berliner Entom. Zeitschrift. XXVII. p. 7. 1883.

The blind *Niphargus orcinus* recorded from the caves of Potis Kawez and Mrzla jama, Carniola, 51 mm. long. (Zool. Record.)

1883. MARION, A. F.

Esquisse d'une topographie zoologique du golfe de Marseille. Mémoire No 1. Annales du Musée d'histoire naturelle de Marseille.—Zoologie. Tome 1^{er}. Marseille, 1883.

In the "Description des Faunes," the occurrence of *Gammarus locusta* in several localities is recorded, and of other well-known Amphipods at different points. In the "zone émergée," of the littoral zone, it is noticed that *Gammarus marinus* wears "une livrée brunâtre, parfaitement en rapport avec la teinte des débris décomposés de zostères. Souvent, lorsque la vague accumule des débris d'algues vertes (Ulves et conferves), ces Crustacés changent, par mimétisme, de coloration" (p. 42). In the "zone littorale immergée 0 à 2 mètres," "*Melita palmata* et *Nicea nudicornis* ne sont pas rares," under stones scarcely covered by the waves, and *Gammarella brevicaudata* among Algae (pp. 46, 47). In the "Faune littorale immergée (0 à 2 mètres), dans la région des eaux vives," "les Edriophthalmes des algues encroûtées comprennent les *Caprella acutifrons*, Latr., *Caprella equilibra*, Say, *Caprella grandimana*, P. May., *Caprella dentata*, Heller, *Tanais vittatus*, Rathke, *Euryxetus erythrophthalmus*, Lij., *Leptochelia Edwardsii*, Kroy., *Podocerus pulchellus*, Leach, *Allorchestes imbricatus*, Sp. Bate (nombreuses variations mimétiques dans la coloration), *Amphithoe littorina*, Sp. Bate (coloration variée)" p. 49.

At page 84, in a footnote, Professor Marion says, "Les Amphipodes sont excessivement abondants dans nos graviers coralligènes ; ils se rapportent pour la plupart à des formes nouvelles qui devaient être le sujet d'un mémoire spécial, mais qui n'ont été décrites jusqu'ici que d'une manière préliminaire (voy. Catta : *Note pour servir à l'histoire des Amphipodes du golfe de Marseille*, Revue des Sc. natur., t. IV, no 2, septembre 1875).

"L'espèce la plus commune est le *Mæra truncatipes*, Spinn., à laquelle sont associées les *Mæra integrimana*, Heller, *Lysianassa Audouiniana*, Sp. B., *Lysianassa spinicornis*, Costa, *Melita palmata*, Leach, *Leucothoë articulosa*, Mont., *Ampelisca Belliana*, Bate, *Iphimedea obesa*, Rathke, *Liljeborgia pallida*, Bate, *Microdeutopus anomalus*, Rathke, *Protomedea hirsutimanus*, Sp. Bate, *Icridium Risoanum*, Grube et Bate ; et quelques Isopodes, *Sphaeroma curvum*, Leach, *Anceus forficularis*, Risso, *Praniza ventricosa*, Risso, etc."

1883. MARION, A. F.

Considération sur les Faunes profondes de la Méditerranée d'après les dragues opérés au large des côtes méridionales de France. Mémoire N° 2. Annales du Musée d'histoire naturelle de Marseille.—Zoologie. Tome 1^{er}. Marseille, 1883.

From the "Sables vaseux au sud de Mairé, profondeur = 65 à 70 mètres ; et vase sableuse de 75, 80 et 90 mètres, par le travers de Riou," *Lysianassa longicornis*, Lucas, is recorded (p. 16). Among the species dredged by the *Travailleur* between Marseilles and Corsica were *Leucothoë denticulata* and *Lysianassa ciliata*, and at the deepest station, "234 à 250 mètres," "*Ichnopus taurus*, *Ichnopus calceolatus*, *Ampelisca Gaymardi*."

Crustacea. The Zoological Record for 1882 ; being Volume nineteenth of the Record of Zoological Literature. London, M.DCCC.LXXXIII. pp. 1-39.

It is noted that *Iphigenia*, G. M. Thomson's name for a genus among the Corophidæ, is twice preoccupied in *Mollusca*.

1883. SCHNEIDER, J. SPARRE.

Nogle zoologiske iagttagelser fra Vardø i Øst-Finmarken. Separataftryk af Tromsø Museums Aarsberetning for 1882. Tromsø. 1883. pp. 16-34.

A list, accompanied by short notes, is given, pp. 27-30, of thirty-five Amphipods, none described as new, including two littoral forms, *Cyamus boopis* parasitic on *Megaptera boops*, and the rest from depths between five fathoms and thirty.

1883. SCHNEIDER, J. SPARRE.

Bidrag til en nøjere karakteristik af de ved Norges kyster forekommende Arter af familien Oediceridæ. Separataftryk af Tromsø Museums Aarshefter VI. Tromsø. 1883. 44 pages. 3 Pl.

The subfamily Oedicerina, Lilljeborg, 1865, Oedicerinæ, Boeck, 1870, was called by G. O. Sars, in 1882, the family Oediceridæ. This change is here accepted. Great weight is laid on the
(Zool. CHALL. EXP.—PART LXVII.—1887.)

stiliform character of the finger or last joint in the fifth pereopods, as a distinctive mark in this family. A general description is given of the head, side-plates, mouth-organs, limbs and telson. This is followed by a conspectus of the Norwegian genera and species which the family includes.

Pontocrates norvegicus, A. Boeck, is identified with *Kroyera altanarina*, Sp. Bate, instead of with *Kroyera arenaria*, Sp. Bate, with which Boeck himself made it synonymous. On this see further, Note on J. Sparre Schneider, 1885. *Monoculodes affinis*, A. Boeck, is thought to belong rather to *Monoculodes stimpsoni*, Sp. Bate, than to *Monoculodes carinatus*, Sp. Bate. A relationship is suggested between *Monoculodes grubei*, A. Boeck, and *Monoculodes longicornis*, of the same author. A species is described under the title *Halimedon saussurei*, A. Boeck ?, with the authority of Professor G. O. Sars for its being so entitled, but it is said not to agree well with the figures and description by Boeck, and both in appearance and in the structure of the mouth-organs to be unlike the genus *Halimedon*.

1883. SMITH, SIDNEY I.

List of the Crustacea dredged on the Coast of Labrador by the expedition under the direction of W. A. Stearns, in 1882. pp. 218–222. Review of the Marine Crustacea of Labrador. pp. 223–232. Proceedings of United States National Museum. Vol. VI. Washington, 1883.

In the "List," sixteen species of Amphipoda are recorded, none of them new. To *Rhachotropis aculeata*, Lepechin sp., is appended a note, "‘Πάχις et τρόπις, nom. nov., vice *Tritropis* Boeck, praeoc.’"

The review takes into account Professor Packard's papers:—"A list of the animals dredged near Caribou Island, southern Labrador, during July and August, 1880," (Canadian Naturalist and Geologist, viii., pp. 401–429 (1–29), December, 1863), and his "View of the recent invertebrate fauna of Labrador" (Memoirs Boston Soc. Nat. Hist., i. pp. 262–303, pls. 7, 8, 1867). Professor Packard's Amphipoda had been determined by various authorities, and much confusion had arisen, which Professor Smith in this paper sets himself as far as possible to correct. "In determining Professor Packard's species I have been greatly aided," Professor Smith says, "by a set of his specimens collected in 1864 and labeled by him for the Museum of Yale College."

"*Anonyx producta*, fide Boeck," Packard, 1867, is referred to *Anonyx pumilus* Lilljeborg; *Monoculodes nubilatus* Packard, 1867, to *Œdicerus lynceus* M. Sars; *Amphithonotus cataphractus* Packard, 1867, to *Pleustes panoplus* Bate (Kröyer); *Atylus vulgaris* Packard, 1867, to *Pontogenia inermis* Boeck (Kröyer); "*Atylus (Paramphitoe [—thoe]) inermis* (Kröyer, fide Boeck)," Packard, 1867, to *Halirages fulvocinctus* Boeck (M. Sars); *Gammarus mutatus* Packard, 1863, to *Gammarus locusta* Fabricius; *Gammarus purpuratus* Packard, 1863, and *Gammarus dentatus* Packard, 1867, both to *Melita dentata* Boeck (Kröyer); *Auphitonotus Edwardsii* Packard, 1867, to *Rhachotropis aculeata* Smith (Lepechin); *Ampelisca pelajica* Packard, 1863 and 1867, to *Ampelisca macrocephala* Lilljeborg; *Ampelisca Gaimardi* Packard, 1867, to *Byblis Gaimardii* (Kröyer); *Amphithoe maculata* Stimpson, 1853, Packard (*Amphithoe*), 1867, Smith, 1874, to *Amphithoe podocerooides* Rathke, 1843; *Cerapus rubricornis* Stimpson, 1853, Packard (*rubiiformis*), 1867, to *Eriichthionius difformis* Milne-Edwards; *Glauconome leucopis* Kröyer, to *Unciola irrorata*, Say.

1883. STEBBING, T. R. R.

The Challenger Amphipoda. The Annals and Magazine of Natural History.
March 1883. Ser. 5, vol. xi. pp. 203-207. London, 1883.

A few of the more striking forms among the new Amphipods brought home by the Challenger, which had been entrusted to me in the summer of 1882, are here briefly described:—in Boeek's subfamily Oedicerinae, *Acanthostepheia ornata*, n. sp., since transferred to a new genus as *Oediceroides ornata*, and *Oediceropsis rostrata*, n. sp., now called *Oediceroides conspicua*, the specific name *rostrata* having become inappropriate in the change of genus; in the subfamily Epimerinae, *Epimeria conspicua*, n. sp., with the remark that it may prove to be only a variety of *Epimeria loricata*, G. O. Sars, of which I now consider it a synonym, and *Acanthozone tricarinata*, n. sp., since transferred to a new genus as *Acanthechinus tricarinatus*; in the subfamily Gammarinae, *Amathilopsis australis*, n. sp., nearly allied to *Amathilopsis spinigera*, Heller, and *Amathilopsis affinis*, Miers; in the subfamily Stegocephalinæ, *Andania gigantea*, n. sp.; in the subfamily Iphimedinae, *Iphimeda pulchridentata*, n. sp., and *Iphimeda pacifica*, n. sp., and lastly, in the family Caprellidæ, *Dodecas elongata*, n. g. et sp.

The new genus *Dodecas* is thus defined:—"The mandibles having an elongate triarticulate palp. Six pairs of feet attached to the pereion, the fourth segment having none. Branchial vesicles at the base of the second gnathopods, the first pereiopods, and attached to the footless fourth pereion-segment, the rudimentary pleon having two pairs of biarticulate appendages."

Heller placed his new genus *Amathilopsis* between *Amathilla* and *Gammaracanthus*, two genera of the Gammarinae. In accordance with this arrangement I placed the new species, *Amathilopsis australis*, in that subfamily, but in view of the elongated palps of the maxillipeds I am now doubtful as to the propriety of this classification.

1883. WOODWARD, HENRY.

Crustacea. Cassell's Natural History. Vol. VI. London, Paris and New York, 1883.

The Class Crustacea, page 196, has for its first division the Thoracipoda, with two legions, 1. Podophthalmia, containing two orders, 2. Edriophthalmia, also containing two orders, the Isopoda and Amphipoda. The latter, pages 212-213, include the Laemodipoda as an aberrant group. No mention is made of the Hyperina. The statement that the body-rings of the Amphipoda are compressed laterally requires some limitation in regard to such genera as *Lafystius*, *Icilius* and *Corophium*. The illustrations given are "*Orchestia Darwinii*," male, and "the spectre, or skeleton shrimp (*Caprella*)" ♂ and ♀. The *Orchestia* is evidently taken from Fritz Müller's Faets for Darwin, the *Caprella* from Bate and Westwood's *Caprella tuberculata*.

"Cite les cinq espèces suivantes : *Pherusa fucicola* Leach, *Talitrus gammarellus* Lam. (*Orch. littorea* Leach), *Talitrus saltator* Edw., *Corophium longicorne* Latr., *Hyperia Latreillii* Edw." (M. Chevreux in litt.)

1884. BLANC, HENRI.

Die Amphipoden der Kieler Bucht nebst einer histologischen Darstellung der "Calceoli." Nova Acta der Ksl. Leop.-Carol. Deutschen Akademie der Naturforscher. Band XLVII. Nr. 2. Mit 5 Tafeln Nr VI-X. (*Eingegangen bei der Akademie den 25 Juni 1883.*) Halle. 1884.

According to Dr. Blanc the Amphipods of the Bay of Kiel forcibly illustrate the remark of Professor Möbius that the invertebrates of the Baltic are a degraded branch of the rich fauna of the North Atlantic and Arctic oceans.

The introduction discusses briefly the external structure, sexual differences, places of abode and length of life of Amphipods, and assigns their colouring to chromatophores in some species, and oil-drops in others, spread about in the body.

A special account of the "Calceoli" reviews the opinions of earlier writers upon them, describes their structure, and gives a preference to the view that they may be organs of hearing, rather than of clasping or smelling. The occurrence of the apparatus in the females as well as the males is urged against the suggestion that they are organs of clasping. In favour of Dr. Blanc's own view the circumstance is mentioned that the apparatus is met with in species which live in small depths, and that the number of the calceoli is greatest in those species which live on the surface, where enemies threaten most. The parts of the organ in question are the stem, the cup-shaped base with a central opening above carrying a circlet of very fine hairs, and, seated with its broader end in the cup, an ovoid bladder-like structure extremely thin-walled and marked with concentric stripes. Professor Blanc could not discover any termination of a nerve in the Calceolus or connection with the antennal-nerve, but a dark stripe within the stem he considers to be a sensory nerve-mass carrying the circlet of hairs. The so-called Riechzapfen (bâtonnets hyalins) he finds on the upper antennæ of both sexes of the Amphipoda, but Hoek's discovery of them on the lower antennæ of *Cheirocratus brevicornis* he is unable to corroborate.

Excellent figures and descriptions are given of the following species, with remarks of value upon them:—*Hyperia galba*, Montagn, found in late summer lodging in *Medusa aurita* and *Cyanea capitata*, commonly free in winter: *Orchestia littorea*, Montagu, with two forms of the male, on which light has since been thrown by Faxon's observations upon *Cambarus*; *Pontoporeia femorata*, Kröyer (with *Pontoporeia affinis*, Lindström, in the synonymy), and *Pontoporeia furcigera*, Bruzelius, which, however, should probably be named respectively *Pontoporeia affinis*, Lindstr., and *Pontoporeia femorata*, Kröyer (see Sars, *Oversigt*, p. 83, 1882); *Bathyporeia pilosa*, Lindström; *Dexamine spinosa*, Montagu; *Atylus bispinosus*, Sp. Bate, which Boeck calls *Halirages bispinosus*; *Calliopus læviusculus*, Kröyer; *Gammarus locusta*, Linné, found in almost fresh water as well as in salt water everywhere; *Cheirocratus brevicornis*, Hoek, the synonymy of which seems to be *Gammarus sundevallii*, Rathke, *Liljeborgia shetlandica*, Sp. Bate, *Protomedea whitei*, Sp. Bate, *Liljeborgia normanni*, Stebbing, so that its proper designation is *Cheirocratus sundevallii*, Rathke; "Amathilla Sabinii," Leach; *Microdeutopus gryllotalpa*, Costa, referred in accordance with Heller to the family Corophidae, subfamily Podocerinae; *Amphithoë podoceroides*, Rathke; *Podocerus falcatus*, Montagu; *Corophium longicorne*, Fabricius; *Proto ventricosa*, Müller, and lastly *Caprella linearis*, Linné, including therein, in agreement with Hoek and contrary to the view of Mayer, *Caprella hystrix* and *Caprella acuminifera* of Sp. Bate.

1884. BLANC, HENRI.

Contribution à l'histoire naturelle des Asellotes hétéropodes. Observations faites sur la *Tanais Oerstedii*, Kröyer. Avec les Planches X, XI et XII. Recueil zoologique Suisse (Dr Hermann Fol). Tome premier. No. 2. Sorti de presse le 28 février 1884. Genève-Bale. pp. 189–258.

Dr. Blanc agrees with Lilljeborg in referring the two species *Tanais rhynchites* and *Tanais balticus* of Fr. Müller, as respectively male and female forms, to the older *Tanais oerstedii*, Kröyer. The description which he proceeds to give bears on the disputed question, whether the Tanaidæ should be reckoned among the Amphipoda. In *Tanais oerstedii*, he says, the heart extends along the back from the last thoracic ring to the hinder rim of the cephalothorax. In this species, as in *Tanais savignii*, it possesses only two pairs of ostioles (venous orifices), whereas for *Tanais dubius?* Müller reckons three pairs, and Delage only one pair for *Tanais vittatus*. The ostioles are situated in the second and third free segments of the peræon. Besides these, the heart has five arteries, the cephalic artery and two abdominal arteries described by Delage, and in addition two thoracic arteries as large as the cephalic, arising, opposite one another, from the ventral part of the heart, below the two ostioles in the second free thoracic segment, and running a ventral course to the first thoracic feet.

In conclusion Professor Blaue says, "the characters which bring the Tanaidæ near to the Isopods are more numerous [than those which connect them with the Amphipoda and other groups]. The general form of the body is that of the Isopods. The body is flattened, the sixth and seventh segments of the pleon are, as in the Isopods, soldered together and form a caudal lamella, while in the Amphipods these two segments are distinct. The number of ganglia in the ventral chain of *Tanais Oerstedii* is the same as in certain Isopods, as Cymothoæ, Ligidiæ; in the Amphipods the number is less considerable, the abdominal ganglia being reduced to four or three. The five pairs of abdominal feet, as in Aneus, are all alike; since they play a part in the act of respiration, they are not the biramous feet of Amphipods. In the latter group, the urinary secretion is situated in the antennary glands and the glandular appendages of the rectum [of the midgut, according to P. Mayer]; these glands are wanting in the Tanaidæ as in the Isopods, in which the urinary secretion is situated in the fatty body. Lastly, the absence of the seventh pair of feet in the embryos of the Tanaidæ and the Isopoda is an important character which distinguishes these Crustacea from the Amphipoda, of which the embryos are born with the same number of appendages as they have when adult."

One point in this argument loses some of its force from the fact that the sixth and seventh abdominal segments are occasionally soldered among the Amphipoda, in the tribe Hyperina. The absence of lateral arteries was considered by Delage to show a nearer connection of the Tanaidæ with the Amphipoda (Gammarina) than with the Isopoda, but this point of resemblance can no longer be relied on since Professor Blanc's discovery of the lateral arteries in *Tanais oerstedii*, nor yet on the other hand can the presence of these arteries be relied on as any special link between the Tanaidæ and Isopoda, since Claus finds lateral arteries in many genera of the Amphipoda (Hyperina).

Gerstaecker, 1886, is by no means convinced by Professor Blanc's arguments, and, as will be seen, retains his conviction that the Tanaidæ ought to be classed among the Amphipoda.

1884. CHEVREUX, ÉDOUARD.

Suite d'une liste des crustacés amphipodes et isopodes des environs du Croisic.
Association française pour l'avancement des Sciences. Congrès de Blois. 1884.

Forty-four species of Amphipods are here enumerated in addition to the forty recorded by M. Chevreux in 1883. The actual number of distinct species in the list will be rather smaller, when allowance is made for the instances in which separate names have been given to the different sexes of the same species. This will be understood in most cases from the notes which M. Chevreux has appended.

1884. CHILTON, CHARLES.

Additions to the Sessile-eyed Crustacea of New Zealand. (Read before the Philosophical Institute of Canterbury, November 15th, 1883.) The Transactions of the New Zealand Institute, 1883. Vol. XVI. Wellington, 1884. Art. 14. pp. 252–265. Pls. XVII.–XXI.

Of a whale-louse, found on *Euphysetes potzii*, a species said to be "identical with *Viagia breviceps* of the northern hemisphere," Mr. Chilton writes, "I can find no important character by which these specimens can be distinguished from *Cyamus ceti*, as described and figured by Bate and Westwood. The penultimate joints of the last three pairs of legs are not quite so stout as shown in their figure, but this is evidently a character liable to variation according to age, etc. The young taken from the pouch of the female closely resemble those figured by Bate and Westwood on page 90."

Wyvillea longimanus, Haswell, is identified by Mr. Chilton with *Podocerus cylindricus*, Kirk, and renamed *Podocerus longimanus*, figured pl. xvii. fig. 2, in regard to which see Note on Haswell, 1880.

A new genus, *Teraticum*, is thus defined:—"Body small. Eyes two. Coxæ of first four segments as deep as their respective segments. Antennæ with short flagella; upper antenna with a small secondary appendage. Mandible with an appendage. First gnathopod larger than the second, subchelate; second slender, chelate. Posterior pair of pleopoda uniramous. Telson single, undivided." This must, I think, yield to *Seba* of A. Costa. The type species, *Teraticum typicum*, seems to be identical with "*Seba Saundersii*," Stebbing.

A new genus, *Paranænia*, is thus defined:—"Antennæ subequal, superior with a secondary appendage, both with multiarticulate flagella. Appendage of mandible with three broad setose joints, as in *Podocerus*. Maxillipedes with well-developed plates on ischios and meros. Gnathopoda subchelate, first small in both sexes, second small in female, very large in male. Last pair of pleopoda biramous, rami styliform. Telson single, ending posteriorly in two conical projections." This genus was instituted to receive *Paranænia typica*, n. sp. pl. xix. fig. 1, *Paranænia longimanus*, n. s., pl. xx. fig. 2, and *Mæra dentifera*, Haswell, pl. xxi. fig. 2. Of these the first and third have the coxæ of the third peræon-segment in the males "large, and produced along the inferior edge of the second segment." In the females and in the other species the coxæ are normal. In describing the genus *Gammaropsis*, Lilljeborg, Boeck does not choose the same characters as those used by Mr. Chilton, but when the description of Boeck's *Gammaropsis erythrophthalmus* (*melanops*, G. O. Sars) is added to that of the genus, and in like manner Mr. Chilton's specific descriptions are added to that of his genus, it becomes, I think, clear that *Paranænia* cannot be separated from *Gammaropsis*.

The mouth-organs and pleon seem to be in minute agreement, while the antennæ and gnathopods have a full generic correspondence.

Corophium lewissenfeldii, n. sp., pl. xx. fig. 1, is next described. This, however, cannot stand in the genus *Corophium*, since it has a secondary appendage on the upper antennæ, the first gnathopods are not subchelate, the second gnathopods are without the characteristic prolongation of the third joint, and the third uropods are biramous. The species is, moreover, now recognised as identical with *Gammarus barbimanus*, G. M. Thomson, 1879, which no doubt belongs to Haswell's genus *Haplocheira*. *Panoplaea translucens* n. s., pl. xxi. fig. 3, is next described, as closely related to, and taken in company with, *Panoplaea debilis*, Thomson, for which see Note on Thomson, 1880.

The new genus *Bircenna* is thus defined:—"Body broad, coxae very shallow. Antennæ subequal, upper without a secondary appendage. Mandibles without an appendage. Maxillipedes with well-developed plates on both basos and ischios. Gnathopoda equal, not subchelate. Last segment of pleon and its appendages rudimentary. Telson simple, not divided." The type species is *Bircenna fulvus*, n. s., pl. xxi. fig. 1 (*Bircenna fulva* at p. 265). Mr. Chilton thinks it may come near to *Phlias*, but he is very uncertain.

1884. CHILTON, CHARLES.

Notes on a few Australian Edriophthalmata. Extracted from Vol. IX., Part 4, of the "Proceedings of the Linnean Society of New South Wales." 10 pp. Pl. 46. 47. 1884.

In this paper Mr. Chilton proposes the specific name "*Coogeensis*" for a variety of *Allorchestes crassicornis*, Haswell, pl. 46. fig. 1., but this variety according to Haswell is not *Allorchestes crassicornis*, but the female of *Talorchestia quadrimana*, Dana. He describes *Glycerina affinis*, n. s., pl. 47. fig. 1., which "closely resembles *G. tenuicornis*, Haswell"; *Mæra festiva*, n. s., pl. 46. fig. 2., which, according to Mr. Haswell, belongs to *Mæra rubromaculata*; gives notes on *Megamæra (Mæra) subcarinata*, Haswell, to which he finds that *Mæra petriei*, Thomson, is a synonym, and on *Amphithoë setosa*, Haswell; discusses the relations of *Microdeuteropus mortoni*, Haswell, *Microdeuteropus tenuipes*, Haswell, *Microdeuteropus maculatus*, Thomson, with one another and with *Aora typica*, and suggests the possibility that *Paranomia typica*, Chilton, is the same as *Mæra approximans*, Haswell.

Mr. Chilton further suggests that the genera *Aora* and *Microdeuteropus* will eventually have to be combined.

He transfers *Montaguia miersii*, Haswell, which he had previously renamed *Montaguana miersii*, to Costa's genus *Probolium*, but without saying whether it has or has not mandibular palps, so that it remains uncertain whether it should be placed in the genus *Stenothoë*, Dana, of which Costa's *Probolium* is a synonym, or in *Metopa*, Boeck.

1884. CHILTON, CHARLES.

The distribution of terrestrial Crustacea. The New Zealand Journal of Science. Vol. II. No. 4. Dunedin, N. Z. July, 1884. pp. 154-157.

Arguing that similar variations may arise independently, where animals of the same family are separately subjected to new but similar conditions of life, Mr. Chilton says, "We know that this is true to a certain extent at any rate, for the terrestrial Amphipoda and Isopoda have without doubt arisen independently, and yet in both the inner antennæ have become very small—rudimentary in the Isopoda, nearly so in Amphipoda,—and in both the mandible

has lost its palp." He also remarks that "the Amphipoda appear to be only now developing terrestrial forms, and a splendid series could be made out of existing species, from *Nicea*, living wholly in the water, through *Allorchestes*, etc., which live in rock-pools, but can walk and live (leap, MS. correction) on land with great agility, *Talorchestia*, etc., living just above high-water mark, and only occasionally splashed with salt water, to species of *Orchestia* and *Talitrus*, such as *O. Sylvicola*, which live far away from the sea."

1884. CHILTON, CHARLES.

The New Zealand Journal of Science. Vol. II. No. 5. September 1884.
p. 230.

This note identifies *Mæra petriei*, G. M. Thomson, with *Megamæra (Mæra) subcarinata*, Haswell, the latter name having the priority.

1884. CLAUS, C.

Elementary Text-book of Zoology. General part and special part; Protozoa to Insecta. By Dr C. Claus. Translated and edited by Adam Sedgwick, M.A., with the assistance of F. G. Heathcote, B.A. London, 1884.

At page 405, the Arthropoda are defined as "*Laterally symmetrical animals with heteronomously segmented body and jointed segmental appendages; with brain (supræsophageal ganglia) and ventral nerve cord (ganglionic chain).*"

At page 411, Class I.—Crustacea are defined as "*Aquatic Arthropoda, which breathe by means of gills. They have two pairs of antennæ; numerous paired legs on the thorax, and usually also on the abdomen.*" It is observed that "some forms, however, can live on land, and possess respiratory organs adapted for breathing air." "The mandibles are simple but very rigid and hard masticating plates, which are usually toothed and correspond morphologically to the coxal joint of a limb, the following joints developing into a palp-like appendage (*mandibular-palp*)."
"The delicate hairs and filaments of the anterior antenna are probably olfactory organs." "The so-called shell glands of the lower Crustacea are regarded as urinary organs, as are also the glands opening at the base of the posterior antenna in the Malacostraca. In the Entomostraca the latter are only preserved during larval life. Short tubes, which correspond to the Malpighian tubes of the Tracheata, may also be present on the rectum (*Amphipoda*)."
[This correspondence, however, is denied by P. Mayer, 1882, and W. B. Spencer, 1885.]

The Crustacea are divided into four groups, Entomostraca, Malacostraca ("the higher Crustacea characterised by a definite number of segments and appendages"), Leptostraca (for *Nebalia*), and Gigantostraca. The Malacostraca include the two orders, Arthrostraca (*Amplipoda* and *Isopoda*), and Thoracostraca.

At page 449, the Arthrocostraca are defined as "*Malacostraca with lateral sessile eyes, usually with seven, more rarely with six or fewer separate thoracic segments, and the same number of pairs of legs. Without a reduplicature of the skin.*" "The head bears four antennæ, the two mandibles, four maxillæ, and a pair of maxillipeds; in all six pairs of appendages. A small bilobed plate, distinguished as the underlip, behind the pair of mandibles, marks the boundary of the primary region of the head. The two pairs of maxillæ as well as the maxillipeds are secondary cephalic appendages derived from the thoracic region of the body." I do not know how this last statement is to be reconciled with the previous

description of the Malacostraea, p. 447, "the head includes in all cases, behind the mandibular segment on which two paragnathi form a kind of underlip, the segments of two pairs of maxillæ. The latter preserve more or less the character of phyllopod feet. The head, therefore, consists of five segments, each with its pair of appendages, viz., two pairs of antennæ, one pair of mandibles, and two pairs of maxillæ. It is followed by the thorax, which is composed of eight segments." It may be noticed also that the eyes in some Amphipoda can scarcely be called lateral, and in others are apparently altogether wanting; nor is it quite accurate to say (p. 450) that "the two eyes are always sessile, compound," since in *Amphelisca* they are simple.

At p. 451 the suborder Amphipoda are thus defined:—"Arthrostraca with laterally compressed body, with gills on the thoracic feet and an elongated abdomen, of which the three anterior segments bear the swimming feet, while the three posterior bear posteriorly directed feet adapted for springing."

The plates forming the brood-pouch are here called *oostegites*. "The eggs pass into the brood-pouch and there develop. The yolk sometimes (*G. locusta* and other marine species) undergoes a complete segmentation. Sometimes (*G. pullex*), after a superficial segmentation, a peripheral cell-layer is separated, which develops into a delicate blastoderm beneath the egg membrane. A ventral primitive streak is then formed, and on the dorsal side, beneath a differentiation which has been erroneously taken for a micropyle, a peculiar globular organ makes its appearance; this is the first rudiment of the cervical gland (*dorsal organ*), which is confined to embryonic life. The appendages are developed from before backwards on the ventrally flexed body of the embryo. The young animals usually possess at hatching all their appendages and in all essential points have the structure of the adult animal, but the number of joints of the antennæ and the special form of the legs still present differences. In the *Hyperina* alone the just hatched young may be without abdominal feet, and differ so much in their form from the adult that they may be said to undergo a metamorphosis."

The following classification is made:—

"Tribe 1.—Læmodipoda. *Amphipoda with cervically placed anterior legs and rudimentary apodal abdomen.*" "The abdomen is small and reduced to a short protuberance destitute of appendages." This statement requires modification. *Caprella linearis*, L., and *Cyamus ceti*, L., are given as examples.

"Tribe 2.—Crevettina. *Amphipoda with small head, small eyes, and multiarticulate pediform maxillipeds.*" "The coxal joints of the thoracic legs have the form of broad and large epimeral plates. The abdomen has always the full number of segments. The three posterior pairs of abdominal feet (*uropoda*) are well developed and often much elongated." The epimeral plates, however, are not always large, nor are all the uropoda always well developed. Three families are assigned to the Crevettina: the Corophiidae, in which "the coxal joints of the legs are frequently very small"; the Orchestiidae, and the Gammaridae.

"Tribe 3.—Hyperina. *Amphipoda with large swollen head and large eyes, usually divided into frontal and lateral eyes. They have a pair of rudimentary maxillipeds functioning as underlip.*

"The antennæ are sometimes short and rudimentary, sometimes of considerable size, and in the male are elongated into a multiarticulate flagellum (*Hyperidae*). The posterior antennæ may in the female be reduced to the basal joint enclosing the glandular tube (*Phronima*); in the male, on the contrary, they are folded in a zigzag, after the manner of a carpenter's rule (*Platyscelinae*). A paired auditory vesicle may be present above the brain (*Oxycephalus*, *Rhabdosoma*). Three families are assigned to this group, the Hyperidae, the Phronimidae and Platyscelidae. In the description of the family Phronimidae, the statement "Head large, with projecting rostrum and large divided eye" should rather be "Head large, with projecting snout or muzzle and large pair of divided eyes."

The parenthetic statement, on p. 453, that "the presence of Arctic species [of Amphipoda] in the Swedish and Norwegian seas is very interesting," loses its point by the introduction of the word "seas" through an oversight instead of "lakes."

The Isopoda are divided into two tribes, Anisopoda and Euisopoda. The Anisopoda are thus defined:—"Body more or less resembling that of an Amphipod. The abdomen with biramous swimming feet (*Tanaïs*), which do not function as gills, or with fin-like feet (*Anceus*)."

In the "General Part" of the volume, valuable information is to be found under various headings, in regard to organs of vision, nerves, &c.

1884. D'URBAN, W. S. M.

Crustacea on the South Coast of Devon. The Zoologist. Ser. 3. Vol. VIII. London, 1884. pp. 151–153.

The capture of half a dozen species of Amphipods, not new ones, is recorded.

1884. FAXON, WALTER.

On the so-called Dimorphism in the genus *Cambarus*. From the American Journal of Science, Vol. XXVII. January 1884. pp. 42–44.

"It appears probable that the two forms of the crayfish are alternating periods in the life of the individual, the 'first form' being assumed during the pairing season, the 'second form' during the intervals between the pairing seasons." Mr. Faxon suggests that this curious discovery may explain the existence of two forms of the male in the genera *Tanaïs* and *Orchestia* pointed out by Fritz Müller (Für Darwin). It is obvious that, if the phenomenon in question should prove to be of frequent occurrence among the Crustacea, it may make necessary an extended revision of specific names.

1884. HOEK, P. P. C.

Schaaldieren van de Oosterschelde. Crustacés de l'Escaut de l'Est. Overdruk uit: Tijdschr. Ned. Dierk. Vereen., Supplementdeel I. Afl. 2. 1884. 31 pages.

This paper, in Dutch and French, records from the locality mentioned in the title fifteen species of Amphipoda, none of them new. Among them was *Atylus vellomensis*, Bate and Westwood; (also recorded from Guernsey, see Note on Koehler, 1885).

1884. KINGSLEY, JOHN STERLING.

The Standard Natural History. Vol. II. Crustacea and Insects. Boston, 1884.

Crustacea are Class I. of the Arthropoda. The Edriophthalmia are Subclass IV. of the Crustacea, and embrace two orders, Isopoda and Amphipoda. The Amphipoda, pages 72–77, include two suborders, Læmodipoda and Amphipoda genuina. The families assigned to the first suborder are the Caprellidae and Cyamidae, to the second, the Oxycephalidae, Phronimidae, Hyperidae, Cheluridae, Corophidae, Gammaridae, Orchestidae.

Species are figured under the following names, but without names of the authors of the species; fig. 96. *Caprella geometrica*; fig. 97. *Cyamus ceti*; fig. 98. *Rhabdosoma batei*; fig. 99.

Thaumops pellucida; fig. 100. *Hyperia*; fig. 101. *Cystosoma neptuni*; fig. 102. *Cerapus rubricornis*; fig. 103. *Unciola irrorata*; fig. 104. *Gammarus ornatus*; fig. 105. *Oreohestia agilis*, beach-flea; fig. 106. *Amphithoe maculata*.

Among the miscellaneous remarks it is observed that " *Unciola* does not build a tube, but takes any that it may find vacant." According to S. I. Smith's account, in 1880, "the animal apparently does not construct tubes for itself, though often found in the tubes of other Amphipoda, and in the tubes of Annelida. In the Bay of Fundy," he says, "I have found it abundantly in small holes in sandy mud near low-water mark."

Crustacea. The Zoological Record for 1883; being Volume twentieth of the Record of Zoological Literature. London, M.DCCC.LXXXIV. pp. 1-34.

1884. MIERS, E. J.

Report on the Zoological Collections made in the Indo-Pacific Ocean during the Voyage of H.M.S. 'Alert,' 1881-2. London, 1884.

A brief review is given of earlier writings dealing with the Crustaceans of Australia. "In regard to the Amphipoda," Mr. Miers says, "the affinity of the Australian with the European fauna is very remarkable; and among the few species included in the present Report instances (*Leucothoe spinicarpa*, *Caprella aequilibra*) occur where I have identified Australian examples with well-known European types, while in several other instances, the distinctions are so slight as to be scarcely of specific importance; hence I must qualify the opinion I formerly expressed as to the improbability of the species of such widely distant regions ever being actually identical."

In the determination of the Amphipoda, pages 311-321, 567-569, Mr. Miers has used Spence Bate's classification rather than Boeck's, presuming that Boeck's, being concerned with North Temperate and Arctic, would not without much modification suit the southern fauna. *Ephippiphora kröyeri*, White, which Boeck doubtfully referred to his genus *Socarnes*, is here upheld. "In the specimens from the 'Alert' collection the terminal segment is elongated, narrowing slightly to the distal extremity, with the sides straight, and is divided by a narrow median fissure." White's type specimens from Tasmania are unfortunately dry and broken, so that his species must apparently remain in some obscurity, but the imperfect terminal segments seem, Mr. Miers says, to show a structure like that of the "Alert" specimens, differing in this particular from *Lysianassa nitens*, Haswell. *Lysianassa australiensis*, Haswell, is said to come very near to *Ephippiphora kröyeri*, but to be probably distinguished from it by the telson, which Haswell leaves undescribed, as though similar to that of *Lysianassa nitens*. Mr. G. M. Thomson recorded the species from New Zealand, as "*Lysianassa Kröyeri*," but without describing the telson, so that Mr. Miers could not express an opinion on its identity. To judge by a specimen which Mr. Thomson has sent me, the New Zealand form must be quite distinct, since its telson is neither elongate, nor divided. Mr. Haswell in 1886 explains that the telson in his *Lysianassa nitens* is not, as he at first thought, simple, but deeply cleft, and in *Lysianassa australiensis* also "the telson is cleft to the base." *Leucothoe commensalis*, Haswell, is regarded as at most a variety of *Leucothoe spinicarpa*, Abildgaard, and in this Mr. Haswell appears to acquiesce. Kossmann's *Leucothoe crassimana* from the Red Sea is thought to be another synonym of the same species. A new species, *Leucothoe brevidigitata*, pl. 34, fig. A., is figured and described, which, it is said, may be regarded as in some sense intermediate between *Leucothoe novae-*

hollandiae, Haswell, on the one hand, and, on the other, *Leucothoë commensalis* with the closely allied species or varieties *Leucothoë diemenensis*, Haswell, and *Leucothoë gracilis*, Haswell. *Melita australis*, Haswell, is said to be very nearly allied to the *Melita setipes*, Dana, from Singapore. Additional particulars are given to supplement the original description by Haswell of *Mæra ramsayi*, but that species is now recognised by Mr. Haswell as a synonym of *Mæra rubromaculata*, Stimpson, which is also here described, but from imperfect specimens. A specimen, from which the head was wanting, is described under the provisional name of *Mæra crassimana*. Another imperfect specimen is described, but not named. "In the form of the anterior legs and in the coloration it resembles *Amphithoë setosa*, Haswell, from Botany Bay, but differs in the form of the palm of the second leg, and, I suppose, of the posterior uropoda." *Megamæra suensis*, Haswell?, is very fully described, and this description Mr. Haswell accepts as applying to the ordinary form of his species, so that Mr. Miers' alternative name, *Megamæra haswelli*, is not needed. *Megamæra thomsoni*, pl. 34, fig. B., is described and figured as a new species, though near to, and possibly only a variety of, *Megamæra semiserrata*, Sp. Bate, or *Megamæra brevicaudata*, Sp. Bate, which are British species. Its points of distinction from *Megamæra mastersii*, Haswell, are pointed out, but nevertheless Mr. Haswell in his latest revision considers it a synonym of that species. *Podocerus australis*, Haswell, is briefly discussed. Notes are given upon *Caprella aequilibra*, Say, and a specimen, pl. 34, fig. C., is doubtfully referred to *Caprella attenuata*, Dana, of which Mr. Haswell has since observed, "the species figured by Miers is very different from the adult *C. attenuata*, but may be an immature form."

From the Seychelles a new species is described (p. 567) and figured under the name *Mæra diversimanus*, pl. 52, fig. D. It is compared with *Mæra truncatipes* (Spinola) from the Mediterranean, and with *Mæra ramsayi*, Haswell, already noticed, and it is suggested as possible that more specimens might offer transitional characters serving to unite the two forms.

1884. SCHNEIDER, J. SPARRE.

Undersøgelser af dyrelivet i de arktiske fjorde. II. Crustacea og Pycnogonida indsamlede i Kvænangsfjorden 1881. (Aftryk af Tromsø Museums aarshefter VII.) Tromsø. 1884. pp. 56–134. Pl. I–V.

A new species is figured (Tab. I. & II.) and described under the title *Menigrates (Orchomene?) arcticus*. Complaint is made, as has been done by several authors, of the minute and over subtle distinctions on which Boeck has founded some of his numerous genera in his subfamily Lysianassinae, the result often being, as in this instance, that the author of a new species canot decide in which of the genera he ought to place it. Another new species, *Metopa sôlsbergi* (Tab. III. & IV.), here figured and described, is said to be akin to *Metopa longicornis*, A. Boeck. A species described and figured in 1883 as *Monoculodes norvegicus* is here separated from that species and recognised as a new one under the name *Monoculodes tessellatus*, Schneider, agreeing in part with *Æliceros affinis*, Goës, the last-named author being supposed to have confused two species together, one of them being *Monoculodes tessellatus*, the other *Monoculodes borealis*, A. Boeck.

Besides the description of new species, many important observations are given in regard to species already known. Among others, *Pardalisca cuspidata*, Kröyer, is discussed. Schneider, comparing his own drawings with Boeck's, finds that the maxillipeds differ somewhat, and that the second maxillæ assigned in Boeck's plate to *Pardalisca* in fact belong to *Syrrhoë crenulata*. In some points he finds that his drawings correspond far better with Boeck's description of *Pardalisca abyssi* than with that of *Pardalisca cuspidata*. In the full

description which follows, however, Schneider describes the finger of the gnathopods as oval, which will not suit *Pardalisca abyssi*, Boeck. He then speaks of the finger being two-jointed, inasmuch as it possesses a curved nail, which is obviously movable, thus making the number of joints to the limb in all seven. It may however be questioned whether this nail is anything more than a (possibly) movable spine. Were Buchholz and Schneider both right in their views as to the gnathopods of *Pardalisca cuspidata*, these limbs would have eight joints instead of the usual six.

A single damaged example of a *Melphidippa* is referred provisionally to *Melphidippa borealis*, Boeck. Figures (Tab. V.) and as full a description as circumstances would permit are given of it.

In the account of *Ampelisca eschrichtii*, Kröyer, notice is taken of the spine-bearing incision in the side of the outer branch of the second uropods, and the author remarks that he has found this peculiarity also in several species of *Onesimus*, *Tryphosa*, *Socarnes* and *Anonyx*. It occurs also in *Ichnopus*. The objection to Boeck's description of *Hippomedon holboelli*, Kröyer, that it makes the hand of the first gnathopod longer than the wrist, instead of the reverse, does not apply to the Latin account, and the error is evidently due only to the accidental omission of a word in the printing.

1884. SMITH, S. I.

Crustacea of the "Albatross" Dredgings in 1883. American Journal of Science, July, 1884, pp. 53-56. Annals and Magazine of Natural History. Ser. 5. Vol. XIV. London, 1884. pp. 179-183.

He records the capture of *Eurythenes gryllus*, Mandt, over 4½ inches long, in deep water off the middle Atlantic Coast of the United States, thus explaining the apparent anomaly of "its occurrence in the extreme arctic and antarctic seas" discussed by Lilljeborg.

1885. AURIVILLIUS, CARL WILHELM SAMUEL, born August 31, 1854 (C. W. S. A.).

Krustaeer hos Arktiska Tunikater. Härtill tre taflor. [Ur Dvega-expeditionens vetenskapliga iakttagelser, Bd. IV. Stockholm, 1885.] pp. 223-254.

Andania pectinata, Sars, 1882, is described and figured (Taf. 7, figs. 1-12). Of the four characters by which Boeck distinguishes *Andania* from *Stegocephalus*, Aurivillius observes that this species has only two. In regard to the two-jointed palp of the first maxillæ, and the undivided telson, it agrees with Boeck's description of *Andania*, but in regard to the mandibles and the palp of the second maxillæ it agrees with *Stegocephalus*. Unless a new genus were formed to receive it, Aurivillius inclines to leave it in the genus *Andania*, but its mandibles, in my opinion, decisively separate it from *Andania*, and assign it at any rate provisionally to *Stegocephalus*.

Variations are noticed in specimens of "*Aristias tumidus* Kröyer," from different localities.

1885. BOVALLIUS, CARL.

On some forgotten genera among the Amphipodous Crustacea. With one plate. Communicated to the Roy. Swedish Academy of Science, February 1885. Stockholm, 1885. Bihang till K. Svenska Vet.-akad. Handlingar. Band 10. N:o 14.

* In this acute and ingenious paper Bovallius vindicates the genus *Lanceola*, Say, 1818, as distinct from *Hyperia*, Latreille, and *Vibilia*, Milne-Edwards, and gives preliminary descriptions of the

following new species, “*Lanceola Lovéni*,” “*Lanceola Sayana*” (Fig. 1. 1a and 1b.), *Lanceola felina*, *Lanceola serrata*, *Lanceola curticeps*, “*Lanceola Clausii*.” He considers that the genus *Daira*, Milne-Edwards, 1830, is either identical with or very near to *Paraphronima*, Claus, and that *Dairinia*, Dana, is quite distinct, synonymous with *Thamyris*, Spence Bate, and belonging to Claus’ family Lycaeidæ. *Dairinia* [or rather *Dairilia*] was substituted by Dana for *Daira*, the latter being preoccupied. Bovallius describes the new species *Paraphronima clypeata* (Fig. 2), *Paraphronima californica*, “*Paraphronima Edwardsii*,” and, for the sake of comparison, *Paraphronima gracilis*, Claus, and *Paraphronima crassipes*, Claus. He argues that *Tyro*, Milne-Edwards, 1840, is the same as *Clydonia*, Dana, which the latter author placed among the Corophidæ instead of the Hyperidæ. It may be noted that G. O. Sars had already, in 1882, transferred *Clydonia* to the Hyperidæ, but without recognising its identity with *Tyro*. Bovallius gives preliminary descriptions of the new species, “*Tyro Clausii*,” *Tyro atlantica*, *Tyro marginata*, “*Tyro Sarsi*” (Fig. 3 and 3a), “*Tyro Tullbergii*.” Lastly he upholds the genus *Tauria*, Dana, 1853, as distinct both from *Hyperia*, Latreille, and *Metoecus*, Kröyer; he gives figures copied from Dana of the type species, *Tauria macrocephala*, and concludes with the following observation:—“The *Tauria medusarum* O. FABR. [A. BOECK] is to be united with the genus *Hyperia*, because the development of the carpal process is gradual through the species and no generic character. But as the name *H. medusarum* has been already given by O. F. MÜLLER to another *Hyperia*, I propose for it the name *Hyperia Kroeyeri*, the diagnosis being the same as that given by Boeck l. e. pag. 83. *Tauria abyssorum*, A. BOECK, must be named *Hyperia abyssorum*, A. BOECK.” As already observed, if G. O. Sars is right in identifying *Tauria abyssorum*, Boeck, with *Tauria medusarum*, Boeck, then *Hyperia abyssorum* will take precedence of Bovallius’s *Hyperia kroeyeri*. The remark is scarcely accurate that Spence Bate “has been deceived into transferring Hyperids with totally opposite characters to Dana’s genus,” since *Hyperia tauriformis*, Bate and Westwood, the species referred to, is not transferred to Dana’s genus at all, but I think that Bovallius is justified in dropping the specific name *tauriformis* on the ground of its misleading character, though otherwise (see Note on Norman, 1869, in Appendix) it would take precedence of the name *kroeyeri* which Bovallius proposes, as well as of Boeck’s *abyssorum*.

1885. BOVALLIUS, CARL.

Mimonectes, a remarkable genus of Amphipoda Hyperidea. With 3 Plates.
(Presented to the Royal Society of Sciences of Upsala the 10th October 1885.)
Upsala, 1885.

The name refers to the “mimicry” presented by these Amphipods; the creature offering “a striking resemblance to a little jelly-fish.” A new family is constituted as follows:—“*Mimonectidae*. Hyperids with the head and a part or the whole of the pereion developed into an enormous balloon-shaped globe. Ocelli not united but dispersed on each side of the head. The upper antennæ long, more or less straight. The lower small, four-jointed. The mandibles without palp. The maxillipeds well developed.”

The new genus *Mimonectes* is thus defined;—“*Caput magnum, latum, valde inflatum, simul cum pereio sphæram formans. Oculi parvi, dispersi. Antennæ superiores longæ, rectæ, flagello articulato. Antennæ inferiores parvæ. Pleon compressum non inflatum. Pedes uri duos ramos gerentes.*” “The genus *Mimonectes* is easily distinguished from other Hyperids by its globular shape, with all the legs, branchial sacks, ovigerous lamellæ, and the urus hanging down, similar to the filaments of a Medusa. But it differs also by some anatomical and morphological characteristics from all or most of the other Hyperids.

As important points I mention the structure of the eyes and of the nervous system, and that the interior of the pereion forms a bladder containing a fluid. With the genus *Lanceola*, Say, it agrees in the strong development of the maxillipeds, with *Cysteosoma*, Guérin, and *Tyro*, Milne-Edwards, in the form of the upper antennæ, with the true Hyperiæ in the shape of the urus and its appendages."

The type species, "*Mimoncetes Lovéni*," is very minutely described. The two other new species are called *Mimoncetes sphaericus* and "*Mimonectes Steenstrupii*." They all three come from the Atlantie, and give the impression of being specifically very closely allied. The fact that the bell or globe in the first and largest is formed by five segments, in the second by six, and in the third and smallest by seven segments of the peræon, though producing a striking difference to the eye, may well be due to age or sex, and would naturally carry with it some differences in the proportions of other parts of the animal.

1885. CARRIÈRE, JUST.

Die Sehorgane der Thiere vergleichend-anatomisch dargestellt. München & Leipzig.

According to the Zool. Jahresbericht für 1885, this paper discusses among others the eyes of *Gammarus*, *Hyperia*, and *Phronima*.

1885. CARUS, JULIUS VICTOR.

Prodromus Faunæ Mediterraneæ sive Descriptio Animalium Maris Mediterranei incolarum quam comparata silva rerum quatenus innotuit adjectis locis et nominibus vulgaribus eorumque auctoribus in commodum Zoologorum congregavit Julius Victor Carus. Vol. I. Pars II. Arthropoda. Stuttgart, 1885.

Pages 386 to 428 embrace the Amphipoda. These are classified as follows:—

- "1. Tribus. *Laemodipoda*. 1. Fam. Caprellidae. 2. Fam. Cyamidae.
- "2. Tribus. *Crevettina*. 1. Fam. Duehilidae. 2. Fam. Cheluridae. 3. Fam. Corophiidae. 4. Fam. Orchestiidae. 5. Fam. Gammaridae.
- "3. Tribus. *Hyperina*. 1. Fam. Vibiliidae. 2. Fam. Hyperidae. 3. Fam. Phronimidae. 4. Fam. Platyseelidae."

It does not seem consistent, in the definition of the Læmodipoda to give "abdomen rudimentare absque appendieibus," and to follow this by a definition of *Proto*, including "abdomen triarticulatum, pedum paribus duobus biarticulatis rudimentaribus." The epithet *triarticulatum* is not in agreement with Mayer's account of *Proto*, "die Anhänge des eingliedrigen Abdomens sind in beiden Geschlechtern 2 Paare zweigliedriger Fuss-stummel."

Caprella grandimana, Mayer, is here made a synonym of "*Caprella Dolomi*," Heller. *Cyamus erraticus*, Roussel de Vauzème, is given as a synonym of *Cyamus ceti*, contrary to Lütken's view. The genus *Cyamus* is attributed to Lamarek, instead of Latreille, the actual author.

In the "Subfam. *Coroplinae* (Dana) Cls.," are given "*Cratippus pusillus* Hell. (*Colomastix pusilla* Grube)," and *Cratippus crassimanus*, Heller, but *Colomastix*, Grube, has priority over *Cratippus*, Sp. Bate. To *Coroplium acicrusicum*, A. Costa, is attached the synonym, "? *C. crassicornis* Bruz." To *Corophium crassicornis*, Bruzelius, is attached the synonym "*C. Bonelli* Sp. B. et W., ♀." In the "Subfam. *Podohercinæ* Cls.," to the genus *Cerapus*, Say, "*Erichthonius* et *Cerapodina* M.-Edw., *Pyctilus* Dana," are given as synonyms, but the definition does not

say whether the second uropods are biramous or uniramous. *Erichthonius bidens*, A. Costa, is named *Cerapus bilens*, V. Crs. (nec Czern.). Of *Pyctilus macrodactylus*, Dana, and *Pyctilus pugnax*, Dana, referred to *Cerapus* by Czerniavski, Carus remarks, "Haæ species duæ maris orientalis (insulæ Sulu) a Czerniawski in Ponto Euxino repertæ forsitan etiam in Mediterraneo occurunt." *Elasniopus rapax*, A. Costa, is here named *Podocerus rapax*, V. Crs. *Grubia*, Czern., is placed between *Podocerus* and *Amphithoe*. "*Amphithoe Salenskii*," V. Crs., is thus described:—"Caput rotundatum, sine rostro; antennæ I. inferioribus duplo longiores, stipite biarticulato et flagello 16-articulato, antennæ II. stipite triarticulato, flagello 5-6-articulato; dorsum leviter rotundatum, absque spinis; oculi fere orbiculares; pedes I. secundis multo robustiores, ungue magno terminati; pedes VII. omnium longissimi; pedum caudalium paria tria anteriora multo longiora; telson triangulare. Habit.: Napoli (Salensky)." By the biarticulate stipes of the upper antennæ it is presumably meant that the third joint of the peduncle is indistinguishable in size from the succeeding joints of the flagellum. The first gnathopods stouter than the second, and the elongate fifth pereopods seem to point in the direction rather of *Microdeutopus* than of *Amphithoe*, but nothing is said of a secondary flagellum.

In the family *Orchestidae*, Dana, *Allorchestes*, Dana, is given, with *Hyale*, Rathke, for a synonym, and thus defined, "Antennæ I. æque longæ ac stipes inferiorum, articulis basalibus imperfecte cum fronte connatis; spina olfactoria rudimentaris; mandibulæ palpo carentes; maxillipedes uncino terminali acuminato; pedes I. et II. subcheliformes." The tenth species assigned to this genus is ? *Allorchestes punctatus*, Sp. B. (*Euone punctata*, Risso). Risso's definition of his genus is quoted. The name should be *Enone*, not *Euone*. This is followed by "Nicea Nicolet (*Hyale* Rthke., *Amphithoe* M.-Edw. p., *Allorchestes* Dana p.). Antennæ I. et II. subæquales, vix capite longiores; telson profunde divisum (aut duplex?); pedes paris I. et II. subchelati; reliquæ notæ uti in *Allorcheste*." Thirteen species are assigned to *Nicea*, ending with "*N. pontica* Catta (*Hyale pontica* Rthke.)."

In the family *Gammaridae* (M.-Edw.), Sp. B., "subfam. *Atylinæ* Cls." to *Pherusa*, Leach, is given the synonymy, "*Amphithoe* M.-Edw., *Titanethes* Schiödte, *Paramphithoe* Bruz. p." *Titanethes*, Schiödte, however, is the name of an Isopod, given in place of *Pherusa*, Koch, preoccupied. *Probotium*, A. Costa, is retained, with five species, but as the definition given of it includes "mandibulæ sine palpo," this suffices to show that the species in question, *polyprion*, Costa, *marina*, Sp. Bate, *longimana*, Sp. Bate, *megacleles*, Heller, *tergestina*, Nebeski, belong to *Stenothoe*, Dana, if in each case the character of the mandibles has been ascertained. The third of these species is entered as "*Pr. longimanum* V. Crs. (*Montagu longimana* Sp. B.)." *Amphitonotus*, Costa, is given, with *Tritropis*, Boeck, for a synonym. Among the species is included "*A. Bobretzkii* Catta. Nondum descripta. (Corpus omnino inerme.) Habit.: Marseille, Calangue de Podesta (Catta)."

In the second subfam. *Ampeliscinæ*, Lilljeb. (Sp. B.), "*A. Gaimardi* Kr." has the synonyms, "*Tetromatus typicus* Sp. B., *Araneops diadema* Costa, *Byblis Gaimardi* Boeck." "*A. brevicornis* Marion," has the synonyms "*Araneops brevicornis* A. Costa, *A. Belliana* Sp. B., *A. lavigata* Lilljeb."

In the third subfam. *Leucothoinæ*, Dana, under *Leucothoe*, Leach, is given as the second species, "*L. Richiardii* Lessona. A *L. furina* differt pari ultimo pedum spuriorum projiciente uti in *L. furina*, sed in chelam bidigitalem terminato. Thorax, antennæ et par pedum chelatum rubra, abdomen maculis rubris. Habit.: Genova, sinus (Lessona)." It is not said whether the peculiarity has been observed in more than one individual, and the description is the more puzzling, as the words "projiciente uti in *L. furina*" seem to contradict what is said in the account given of that species, "par ultimum pedum caudalium extremitatem præcedentium non superans." The account given of "*Seba* A. Costa" and of its species, "*S. innominata* A. Costa," agrees exactly with that given in the Brit. Mus.

Catal. by Spence Bate, except that to the generic account is added the fact that the upper antennæ are without accessory flagellum, and from the specific account is omitted the statement that the pereopods are subequal.

In the fourth subfam. Phoxinæ, Sp. B., is given "*Phoxus erythrophthalmus* Catta. A. Ph. Holböllii differt oculo perfecto in utroque latere. (Descriptio plenior nondum exstat.) Habit.: Marscille, Montredon (Catta); to *Pontocrates*, Boeck, is attached the synonym "*Kroyeria* Sp. B.," which should be *Kroyera*. *Acanthonotus*, Owen, is retained in preference to *Epimeria*, Costa, which, however, rightly supersedes *Acanthonotus*, preoccupied long before Owen used it. Here also Carus places "*Lilljeborgia* Sp. B." and *Guerinia*, Hope.

In the fifth subfam. Gammarinæ (Dana), Cls., the habitat of "*Mæra Blanchardi* Sp. B." is given as "Capo S. Viti, Sicilia (Milne-Edwards)," but the Brit. Mus. Catal., p. 190, gives for this species "*Hab. Cape of Santo Viti, Sicily (M. Emile Blanchard)*," and ascribes to M. Blanchard "the description as well as the figure." To *Mæra erythrophthalmus*, Heller, "*Eurystheus erythrophthalmus* Sp. B." is assigned as a synonym, although the latter species has the telson tubular, while Heller's species has "telson in partes duas triangulares, invicem imbricatas divisum." *Ceradocus*, A. Costa, is given as a synonym for *Melita*, Leach, as well as for *Mæra*, Leach, *Ceradocus orchestiipes*, A. Costa, being assigned under the latter as a synonym to *Mæra orchestiipes*, Heller. *Melita oxyura*, Catta, is thus described:—"Stipitis antennarum I. articulus 1. in extremitate spina fortis armatus; segmenta caudalia margine postero-inferiore fortiter denticulata; stili caudales posteriores graciles breves. Habit.: Marseille, Ratonneau, 10–13 org. prof. (Catta)." To *Protomedieia*, Kr., the synonyms "*Leptocheirus* Zadd., *Ptilochirus* Stimp.," are assigned. Zaddach's genus *Leptocheirus* has, however, been shown by Boeck to be distinct from *Protomedieia*. Some rearrangement therefore is necessary of the species assigned to this genus, viz. 1. *Protomedieia hirsutimana*, Sp. B. ♀. "Habit.: Marseille (var. *massiliensis*) Catta," which should be *Leptocheirus hirsutimanus*; "2. *Pr. pilosa* Sp. B. (*Leptocheirus pilosus* Zadd.)," which should be *Leptocheirus pilosus*, Zaddach; "3. *Pr. guttata* Gr. ♀," "4. *Pr. fasciata* A. Costa." The name *Protomedieia fasciata*, was used by Kröyer for the briefly described type species of his genus. Stimpson's genus is not *Ptilochirus*, but *Ptilocheirus*.

In the sixth subfam. Lysianassinæ, Dana, for the eighth species, *Lysianassa ciliata*, Grube, the synonym "? *L. aulouiniana* Sp. B." is suggested, but whereas in *Lysianassa aulouiniana*, "the central tail-piece is simple, squamiform, concave above, and rounded at the apex," which agrees with the definition of *Lysianassa* here given (telson simplex squamiforme), *Lysianassa ciliata*, Grube, on the contrary, has the telson "usque ultra medium fissum." *Egilia*, A. Costa, has been identified by Boeck with *Urothorax*, Dana, 1852. *Ichnopus calceolatus*, Heller, 1867, is identified by Boeck with his own *Ichnopus spinicornis*, 1860. "*Callisoma Barthlemyi* Hope," entered as "non descripta," has been both described and figured. See Note on Costa, 1853.

In the third tribe Hyperina, M.-Edw., in the first fam. Vibiliidæ (Dana) Cls., to "*Vibilia Jeangerarli* Lnc., are suggested as synonyms, "? *V. speciosa* A. Costa, ? *V. mediterranea* Cls." In the second fam. Hyperidæ (M.-Edw.), Sp. B., for *Lestrigonus mediterraneus*, A. Costa, is substituted *Hyperia mediterranea*, V. Crs. In the fourth fam. Platyscelidæ, Cls., and its first subfam. Typhidæ, Cls., the name *Eutyphis*, Cls., is adopted with the synonymy "*Typhis* Risso, *Thyrops* Dana ♂, *Dithyrus* Dana et *Platyscelus* Sp. B. ♀," of which, however, *Dithyrus*, Dana, has the claim of priority over *Eutyphis*. In the third subfam. Lycæidæ, Cls., to *Lycæa robusta*, Cls., a synonym is suggested in "? *L. pulex*, Marion. In the fourth subfam. Oxycephalidæ, Cls., *Oxycephalus*, M.-Edw., has the synonymy "*Natalius* A. Costa, ? *Ornithorhamphus* De Nat.," and the species *Oxycephalus similis*, Claus, is accompanied by the synonym, "? *Natalius candidissimus* A. Costa." In

this subfamily are also placed, with notes of interrogation, the genera *Carcinornis*, A. Costa; *Orio*, Cocco; *Chiropristis*, Cocco; "*Ornithorhamphus*," de Natale. It would have added to the usefulness of this exceedingly useful work, had there been an Index to this Part, in which the Latin descriptions of so large a number of genera and species are brought together. In regard to the arrangement of the group here adopted, it is not easy to see why some authors should place the Læmodipoda at the head or in the fore-front of the Amphipoda, since their structure, however well adapted to their modes of life, points very obviously to degradation, and seems as little as possible typical or representative.

1885. CHILTON, CHARLES.

On an Example of Polymorphism in the Amphipoda. The Annals and Magazine of Natural History. November 1885. Ser. 5. Vol. XVI. London, 1885. pp. 368-376. Pl. X.

Mr. Chilton gives as the synonymy of *Aora typica*, Kröyer, the following names, *Lalaria longitarsis*, Nicolet, *Microdeuteropus mortoni*, Haswell, *Microdeuteropus tenuipes*, Haswell, *Microdeuteropus maculatus*, G. M. Thomson. He supports his view by minute details and figures of various specimens, and while giving one description for the female, he describes the other sex thus:—"Male. Three forms, all differing from the female in the character of the first gnathopod, which in each has the meros produced into a long spine reaching about to the end of the carpus."

"The forms may be distinguished as follows:—

- "1. (*Aora typica*, Kröyer.)—Basos with a tooth projecting forwards on the anterior margin; carpus longer than the propodos, but of about the same breadth.
- "2. (*Microdeuteropus maculatus* ♂, Chilton.)—Carpus longer and broader than propodos; meros with small tuft of setæ on posterior margin.
- "3. (*Microdeuteropus Mortoni*, Haswell.)—Carpus longer and broader than the propodos; meros hollowed anteriorly and with each lateral margin densely fringed with setæ; dactylos as long as propodos and with two or three tufts of setæ on concave border."

He repeats an opinion previously expressed that the name *Microdeuteropus* will have to become a synonym of *Aora*.

1885. FILHOL, H.

Observations relatives aux espèces du genre *Paramithrax*, vivant en Nouvelle Zélande. Bull. Soc. Philom. IX. p. 26.

Contains notes on *Allorchestes stewarti*, n. s., and *Allorchestes campbellica*, n. s., p. 54. (G. H. Fowler, Zool. Record for 1885.)

1885. FRENZEL, JOH.

Über den Darmcanal der Crustaceen nebst Bemerkungen zur Epithelregeneration. Arch. Mikr. Anat. 25. Bd. p. 137-190. T. 8-9.

According to the Zool. Jahresbericht für 1885, *Plironima* is one of the animals investigated in regard to the subject of this paper.

1885. GIESBRECHT, W.

Zoologischer Jahresbericht für 1884. II. Abtheilung. Berlin, 1885. Crustacea. pp. 7-65.

1885. GILES, G. M.

Natural History Notes from H.M.'s Indian Marine Survey Steamer "Investigator," Commander A. Carpenter, R.N. No. 1. On the structure and habits of *Cyrtophium calamieola*, a new tubicolous Amphipod from the Bay of Bengal. [Reprinted from the *Journal of the Asiatic Society, Bengal*, Vol. LIV. Part ii. No. 1, 1885.] Calcutta, 1885.

The careful description and figures of this new species "found in the surface-net about the Palmyras shoal and the mouth of the Dhamra river on the Orissa Coast," show that it is not a *Cyrtophium*, but a *Cerapus*. Templeton's notes on *Cerapus abditus* will be recalled by the remark made upon this species, that "when alive and at ease, it would frequently turn itself inside its tube, and protrude its head from the opposite extremity." Observations made on the structure of the tube are here recorded. In this paper the appendages of the thorax are reckoned as eight pairs, the first gnathopods being called the "2nd pair of appendages" as an alternative title, and the fifth pereiopods being spoken of only as the 8th pair of appendages.

1885. GILES, G. M.

Natural History Notes from H.M.'s Indian Marine Survey Steamer "Investigator," Commander A. Carpenter, R.N. No. 2. Description of a new species of the Amphipod genus *Melita* from the Bay of Bengal. [Reprinted from the *Journal of the Asiatic Society, Bengal*, Vol. LIV. Part ii. No. 2, 1885.] Calcutta, 1885.

Two specimens, a male and female, were available for the description of the new species, named *Melita megacheles*. They were "brought up by the hempen tangles from 12½ fathoms near the Mutla Light Ship." The species is figured on pl. iii.

1885. GILSON, G.

La Cellule : Recueil de Cytologie et d'Histologie générale. Lierre, 1885.

"Spermatogénèse chez les Arthropodes (188 pp., 8 pls.) by G. Gilson; *Oniscus*, *Asellus*, *Gammarus*, p. 140 *et seq.*" (G. H. Fowler, in Zool. Record for 1885.)

1885. GUERNE, JULES DE, born August 20, 1855 (J. de G.).

Zoologie. La rade de Dunkerque. Revue scientifique (revue rose). Numéro 11. 22^e année).—14 Mars 1885.

M. de Guerne, in discussing the fauna of the buoys, says (p. 327) that upon them "au milieu des hydriaires grouille une innombrable quantité d'amphipodes (*Podocerus pulchellus*)."

"Ces petits crustacés construisent des cellules où la vase entre pour une grande part." He combats the view expressed in the British Sessile-eyed Crustacea, i. 438, that in rough weather they withdraw to the depths, by the following arguments; neither the *Podoceri* nor their nests are ever dredged in the neighbourhood of the buoys, although other Amphipods of similar size and agility are so procured; the whole *Podocerus* family is found on the buoy, showing that multiplication takes place there, and implying a permanent residence; other creatures less well endowed than the *Podoceri*, as to means of adhesion and locomotion, pass their lives on the buoys and lay their eggs there.

1885. HASWELL, W. A.

Revision of the Australian Læmodipoda. Extracted from Vol. IX., Part 4, of the Proceedings of the Linnean Society of New South Wales. 8 pp. Pls. XLVIII. XLIX. 1885.

This paper is a commencement of the revision to which Mr. Haswell proposes to subject his earlier work, now that attention has been so much drawn to the Amphipod fauna of the south, as well by Mr. Haswell's own writings, as by those of the zealous naturalists of New Zealand, Mr. G. M. Thomson, Mr. Charles Chilton, and Mr. T. W. Kirk. The paper describes and figures parts of two new species, *Proto condylata* and *Proto spinosa*. It gives additional figures and particulars relating to *Protella australis*, Haswell, and states that "it is a very well-marked species and quite distinct from *Protella gracilis* of Dana, to which Mayer is inclined to unite it, both in the form of the head and of the gnathopoda." The description is quoted which Mayer gives of "*Protella Haswelliana*," a species which has the two last segments of the peræon coalesced. *Cuprella cornigera*, Haswell, =? *Proto cornigera*, Mayer, is transferred to a new genus, *Hircella*, somewhat prematurely, on the supposition that the three anterior pairs of peræopods are rudimentary. Mayer proposed the new genus if it should prove that the appendages mentioned are in the supposed condition, but Mr. Haswell does not say whether he has or has not had an opportunity of determining this point.

1885. HASWELL, W. A.

Notes on the Australian Amphipoda. Proceedings of the Linnean Society of New South Wales. Vol. X. Part. 1. 1885. 20 pp. Pl. 10-18.

To *Talitrus sylvaticus*, Haswell, pl. x, fig. 1., *Talitrus affinis*, Haswell, is assigned as a synonym, *affinis* being evidently a mistake for *assimilis*.

Remarks are made on some of the Australian species of *Allorchestes* instituted by Dana and by Mr. Haswell respectively. Under *Neobule algicola*, pl. xi, figs. 4-6, it is suggested that the genus *Neobule*, Haswell, may be the same as *Hyale*, Rathke. Of *Aspidophoreia*, Haswell, it is said:—"This genus stands between *Allorchestes* and *Nicea*, differing from both in the large size of the anterior coxae, from *Allorchestes* also in the character of the telson, and from *Nicea* in the large size of both upper and lower antennæ, and in having the lower pair much larger than the upper."

Additional details are given as to *Stegocephalus latus*, Haswell, pl. xi, figs. 7-12, and *Ampelisca australis*, Haswell, pl. xii., figs. 7-16, and pl. xiii., figs. 1-4.

Mr. Haswell here refers *Lysianassa nitens*, pl. xii., figs. 1, 2, to the genus *Anonyx*. He would keep *Lysianassa australiensis* and *Lysianassa affinis* as distinct species, but I still think that the distinctions he mentions are insufficient to keep them separate from *Anonyx nitens*. He mentions that the telson is deeply cleft in all, a character inconsistent with the received

definition of *Lysianassa*. To *Eusirus dubius*, Haswell, he adds the account of a variety, pl. xiv., fig. 1, and a new species, *Eusirus affinis*, pl. xiv., figs. 2–4. From the information given I am inclined to group all three forms with one described in this Report under the name *Liljeborgia haswelli*. It would not, I think, be reasonable to transfer the specific title *dubius*, which was applicable enough in connection with the generic name *Eusirus*, to the undoubted position of the new species in the genus *Liljeborgia*. In the British Museum Catalogue by some accident the telson in this genus is said to be entire, a mistake corrected in Bate and Westwood's subsequent work. Probably Mr. Haswell's attention was diverted from the genus *Liljeborgia*, when he found the telson in his own species almost to the root. He accepts the view of Miers that *Leucothoë commensalis* is a variety of *Leucothoë spinicarpa*, and states that *Leucothoe gracilis* and *Leucothoe diemenensis* are to be regarded as marked varieties of the same. He describes a new species under the name *Atylus homochir*, pl. xiii., figs. 5–7, which will also be found described and figured among those brought home by the Challenger. "*Dexamine Miersii*," n. s., pl. xiii., figs. 8–12, is described. Figures, pl. xv., figs. 1–4, and description are given of "a species from Port Stephens which is very nearly related to *Megamæra suensis*, and yet differs from it in several particulars." "This species bears a considerable general resemblance also to *Mæra hamigera*, but the modification of the left posterior gnathopods in this latter species is so special as to distinguish it very clearly." *Megamæra thomsoni*, Miers, is identified with *Megamæra mastersii*, Haswell. *Mæra spinosa*, Haswell, *Mæra ramsayi*, Haswell, and *Mæra festiva*, Chilton, are identified with *Mæra rubro-maculata*, Stimpson. To this list of synonyms must no doubt be added *Megamæra serrata*, Spence Bate. Mr. Haswell speaks of "the form figured by Stimpson," but without saying where the figure is to be found. Fresh figures are given of *Xenocheira fasciata*, Haswell, pl. xvi., figs. 1–3, with the remark that "in most of its characteristics this species shows evident relationships with *Microdeuteropus*. In fact it is only the form and proportions of the gnathopoda (figs. 1 and 2) that separate it from the normal members of that genus, with which it is connected through the European *M. versicoloratus*, Spence Bate." Of *Haplocheira typica*, pl. xvi., figs. 4–8, Mr. Haswell writes that its relations are rather with the Podocerides than with the Gammaridae, "the last pair of pleopods being short, with slightly hooked spines on the outer ramus, and a very short inner ramus with a simple pointed spine, and the telson (fig. 8), being a small undivided plate with a strong hook at each of its postero-lateral angles." He says further, "the superior antennæ have small two-jointed appendages—a feature which I overlooked in my first examination. The flagellum of the inferior antennæ has three distinct joints. The anterior gnathopods (fig. 4) might be described as very imperfectly subcheliform—the propus having a small lobe at the base of the dactylus. The nearest ally of the genus seems to be *Corophium*, and *C. Lenulenfelli* of Chilton (Trans. N. Z. Inst. etc.) is probably this species." *Gammarus barbimanus*, Thomson, 1879, takes precedence as *Haplocheira barbimanus*. Of *Harmonia crassipes*, Haswell, pl. xvi., fig. 9, he writes, "The relations of this species were not correctly expressed by the position in which it was placed in the 'Catalogue of Australian Crustacea.' It is a member of the family *Corophiidae*, distinguished from *Amphithoë*, *Sunamphithoë* and *Nænia*, among other points, by the presence of an appendage on the superior antennæ, from *Cerapus* by the biramous character of the posterior pleopoda, and from *Podocerus* by the multi-articulate flagella of both pairs of antennæ. The genus may be defined as follows:—Coxæ not so deep as the corresponding segments; antennæ both with multi-articulate flagella, the superior pair with an appendage. Mandibles palpigerous. Maxillipedes unguiculate, sub-pediform, with a squamiform process on the basos only. Gnathopods sub-chelate, unequal, posterior pair very large. Posterior pleopods biramous, the outer ramus with slightly hooked spines and straight hairs, the inner with straight hairs only. Telson single, long, pointed." From

this description it seems possible that *Harmonia* may be a synonym of *Grubia*, Czerniavski, 1868, but for that genus the mouth-organs have not been described.

Cyrtophium dentatum, Haswell, pl. xvii., figs. 8-12, is transferred to a new genus, *Dexiocerella*, described as differing from Dana's genus *Cyrtophium* as defined by Spence Bate, by "the superior antennæ having a short, multi-articulate flagellum and a well-developed secondary appendage." This is obviously the same as Dana's *Plutophium*. See Note on Dana, 1852. *Dexiocerella lobata*, pl. xviii., figs. 6-8, and *Dexiocerella larvis*, pl. xviii., figs. 10-12, are described and in part figured, as new species belonging to this genus. *Cyrtophium hystrix*, Haswell, is transferred to *Læmatophilus*, Bruzelius, since the superior antennæ have no secondary appendage, and the second uropods are wanting. *Cyrtophium minutum*, pl. xviii., figs. 1-5 and fig. 9, remains as satisfying the requirements of Spence Bate's definition of *Cyrtophium*, while *Cyrtophium parasiticum*, pl. xvii., figs. 1-7, is stated to be a connecting link between the new genus *Dexiocerella* and the old *Cyrtophium*, since it "has the flagellum of the lower antennæ well-developed and indistinctly multi-articulate, but has no appendage to the superior antennæ." The genus of Bruzelius is given as *Læmatophilus*, but there cannot be any doubt about the true spelling, as Bruzelius derives it from *λαῖτμα* and *φίλος*. Some additional figures and particulars are given for *Proto novæ-hollandiæ*, pl. xviii., figs. 13-16.

1885. KOEHLER, RENÉ.

Recherches sur la Faune Marine des Iles Anglo-normandes. 70 pages. Nancy.
Extract from the Bulletin de la Société des Sciences de Nancy.

Among the 126 species of Crustacea which Dr. Koehler took in the Channel Islands, and principally in Jersey, were several Amphipods, which he enumerates. At Sark he took several specimens of *Aora gracilis*, which, however, is not, as he supposes it, rare.

A species of *Gammarella*, closely allied to *Gammarella brevicaudata*, he proposes to name *Gammarella longicornis*, from the length of the antennæ, but this is too variable a character to be any criterion of a distinct species, and the specimens, as Dr. Koehler informs me, had accidentally been dried up, before he could submit them to detailed examination. He mentions, among other common Amphipoda at Jersey, *Erysthreus edriophtalmus*, Sp. B., which is in all probability a slip of the pen for *Eurystheus erythropterus*. Thirty-two species of Amphipoda were observed. From Guernsey Dr. Koehler has since sent me a specimen of *Atylus vedlomensis*, Bate and Westwood.

1885. MARTENS, E. VON.

Crustacea. The Zoological Record for 1884; being Volume the twenty-first of the Record of Zoological Literature. London, M.DCCC.LXXXV.

In the "Biological Observations," the recorder mentions "Several new *Gregarinidæ* found in *Portunus*, *Carcinus*, *Pachygrapsus*, *Dromia*, *Nicoea* [? *Nicea*], *Phronima*, and *Caprella*; J. FRENZEL, Arch. mikr. Anat. xxiv. pp. 545-579, pl. i. figs. 1-69."

Under "Geographical Distribution," he mentions, from papers which I have not seen, the occurrence in Limfjord, Jutland, of two Caprellidæ, on the authority of "J. COLLIN, Limfjordens marine Fauna, pp. 21 & 22," and in the Baltic of eleven Amphipods, including the fresh-water *Gammarus pulex*, on the authority of "M. BRAUN, Arch. Nat. Liv. (2) x. pp. 98-102, 114, & 112."

1885. MURDOCH, J.

Seven new species of *Crustacea* and one Worm from Arctic Alaska. Proceedings of the United States National Museum. VII. Washington. pp. 518–522.

Acanthozone polyacantha, n. s., *Melita formosa*, n. s., *Melita leonis*, n. s. (G. H. Fowler, in Zool. Record for 1885.)

1885. PACKARD, A. S.

On the structure of the brain of the Sessile-eyed Crustacea. Read at Washington, April 14, 1884. Memoirs of the National Academy of Sciences. Vol. III. Part 1. 1884. Washington, 1885. pp. 97–110. 5 Plates.

The investigation appears to refer almost exclusively to Isopods, but in the section headed "Morphology of the Brain," Packard says, "the brain of the Isopods and Amphipods is a *syncerebrum*, though far less complicated than in the Decapoda. It will be remembered that Professor Lankester, in his memoir on Apus, designates the simple brain of that crustacean as an *archicerebrum*, while the composite brain of 'all crustacea, excepting Apus, and possibly some other Phyllopods,' he denominates a *syncerebrum*." "As seen in Fig. 1, the brain or supraoesophageal ganglion is a composite mass or group of four pairs of ganglia, i.e. (1) the brain proper or procerebral lobes, (2) the optic ganglia, (3) the first antennal, and (4) the second antennal lobes. These lobes are quite separate from each other in the Isopoda and Amphipoda as compared with the Decapoda."

On "the histological elements of the ganglia," he remarks that "there are in the Asellidae, as in insects and Decapods, three kinds of elements in the brain and other ganglia, viz.: (1) ganglion cells; (2) nerve fibers; and (3) Leydig's *punktsubstanz* (mark-substanz of Leydig and Rabl-Rückhard, and especially Dietl), which might be called the *myeloid* tissue or substance." "This is the central finely granular part of the brain, in which granules have short irregular fibers passing through them."

Pages 10 to 13 contain a "Bibliography of works on the nervous system of Crustacea."

1885. SARS, G. O.

Den norske Nordhavs-Expedition 1876–1878. The Norwegian North-Atlantic Expedition 1876–1878. Zoology. Crustacea. I. By G. O. Sars. With 21 Plates and 1 Map. Christiania, 1805.

Not only is the title-page of this fine work given in English as well as in Norwegian, but the two languages are employed throughout in parallel columns. The description of the Amphipoda extends from page 139 to page 233, with supplementary notes on page 270. They are figured on Plates 12 to 18, and Plate 20, Fig. 21, in this author's usual masterly manner. He reminds his readers on page 1 that the new forms to be discussed in the present work have already been briefly characterised in earlier papers, the Prodromus descriptionis of 1876, and the Crustacea et Pycnogonida of 1879. Hence, of the species here called new all belong in fact to one or other of those dates, with the exception of the very remarkable "*Hyperiopsis Voringii*."

In Tribus I. Gammarina, the genera and species are distributed and numbered as follows:—
Fam. 1. Lysianassidae. Gen. 1. *Socarnes*, Boeck, 1870, with the note, "I retain for the

present the generic subdivision proposed by Boeck, though, in my judgment, a closer revision of the family will show the need of slightly reducing the number of genera." 31. *Socarnes bidenticulatus*, Sp. Bate, with the synonymy, "*Lysianassa bidenticulata*, Sp. Bate, Ann. & Mag. Nat. Hist., Ser. 3, Vol. 1, p. 362. *Lysianassa nugar*, Sp. Bate, Cat. Amphip. Brit. Mus. p. 65. Pl. x. fig. 3 (non Phipps). *Lysianassa Vahlii*, Goës, Crust. Amphip. Spitsb. No. 2 (ex parte). *Anonyx bidenticulatus*, Miers, Spitsb. Crust. Ann. & Mag. Nat. Hist., 1877. p. 136," distinguished from the closely allied *Anonyx vahlii*, to which Goës has referred it, by the bidenticulate lateral plates of the third abdominal segment; Gen. 2. *Hippomedon*, Boeck, 1870. 32. *Hippomedon holbölli* (Kröyer), var., with the synonym, "*Hippomedon abyssi*, G. O. Sars, Prodromus descriptionis Crust., etc., No. 94 (non Goës)," a variety without eyes. Gen. 3. *Anonyx*, Kröyer, 1883 [1838]. 33. *Anonyx calcaratus*, "*Anonyx (Hippomedon) calcaratus*, G. O. Sars, Crust. & Pycnogonida nova etc., No 16." "Of the previously known *Anonyx* species, it unquestionably approximates closest *A. pumilus* Lilljeborg, but is easily recognized by the much more produced posterior lateral corners on the 3rd abdominal segment, as also the peculiar spur like projection on the basal joint of the last pair of legs, a character that suggested the specific designation. In the imperfect subcheliform structure of the 1st pair of legs, it differs from all other known species of the genus, agreeing in this respect rather with the genera *Lysianassa* and *Socarnes*." 34. *Anonyx typhlops*, carinate on the fourth abdominal segment, totally devoid of eyes. Gen. 4. *Onisimus*, Boeck, 1870, in the table of contents and index spelt *Onesimus*. 35. *Onisimus turgidus*, "*Anonyx (Onisimus) turgidus*, G. O. Sars, Crust. et Pycnogonida nova etc., No 13," "approximates closest *O. Edwardsii* Kröyer, from which however it may at once be distinguished by the remarkably clumsy and inflated form of body, a character that gives the animal greater resemblance to *O. plautus* Kröyer, which, in other respects, however, differs very decidedly." 35. *Onisimus leucopis*, "*Anonyx (Onisimus) leucopis*, G. O. Sars, Crust. & Pycnogonida nova etc., No. 14," distinguished by "the imperfect development of the eyes and the shape of the telson," which is "very faintly emarginate at extremity." Gen. 5. *Tryphosa*, Boeck, 1870. 37. *Tryphosa pusilla*, "*Anonyx (Tryphosa) pusilla*, G. O. Sars, Crust. & Pycnog. nova etc., No. 15." "The present species I refer here to Boeck's genus *Tryphosa*. In my judgment, however, both this genus and the genera *Onisimus* and *Orchomene* should, perhaps, more properly be eliminated and their species ranged under the genus *Anonyx*. From the other forms referred by Boeck to the genus *Tryphosa*, the present species may be recognised by the total absence of eyes, the remarkably slender secondary flagellum on the 1st pair of antennæ, and the form of the head." Gen. 6. *Acidostoma*, Lilljeborg, 1865. 38. *Acidostoma laticorne*, "from the only hitherto known species of this genus, viz. *A. obesum* Sp. Bate, the present is easily distinguished by the total absence of eyes, the prodigiously developed 1st pair of antennæ, and the remarkably robust 3 posterior pairs of legs. Moreover, in the rudimentary character of the last pair of caudal stylets, as also the posteriorly non-incised telson, this species differs essentially from the typical form."

Fam. 2. *Phoxidæ*. Gen. 1. *Phoxus*, Kröyer, 1842. 39. *Phoxus oculatus*, distinguished by the well-developed, darkly pigmented eyes, and from *Phoxus holbölli*, Kröyer, "by the more thickset form of body, the shorter and more obtuse frontal plate, as also by a somewhat different shape characterizing the basal joint of the last pair of legs." Gen. 2. *Harpinia*, Boeck, 1870. 40. *Harpinia abyssi*, distinguished by its size, reaching 13 mm., peculiar form of basal joint of last pair of legs, "by the obtusely rounded lateral plates on the 3rd abdominal segment, and finally by the hunched projection formed above by the succeeding segment." 41. *Harpinia carinata*, possibly males of preceding species, but differing in structure of antennæ, and also in "the distinctly keeled posterior division of

the body, the form of the 2 posterior pairs of legs and of the telson." 42. *Harpinia mucronata*, "distinguished by the strong, hook-shaped point formed posteriorly by the lateral plates of the 3rd abdominal segment, as also by the very peculiar form characterizing the basal joint of the last pair of legs." 43. *Harpinia serrata*, very near to *Harpinia plumosa*, Kröyer, but distinguished by "the anterior abdominal segments being densely pubescent above," and by the serrate basal joint of the last pair of legs. Gen. 3. *Urothoë*, Dana, 1852. 44. *Urothoë abbreviata*, length, 3 mm., "easily recognizable by its remarkably short and thickset body, the peculiar form distinguishing the first pair of antennæ, the absence of eyes, and by the short last pair of caudal stylets."

Fam. 3. Epimeridæ. Gen. 1. *Epimeria*, Costa, 1851. 45. *Epimeria loricata*, "Colour a gorgeous red. Length reaching 40 mm., distinguished from *Epimeria cornigeru*, Fabr., by "size, remarkably firm integuments, and the deviating armature of the body. Gen. 2. *Paramphithoë*, Bruzelius, 1859. 46. *Paramphithoë euacantha*, "*Pleustes euacanthus [euacanthus]*, G. O. Sars, Prodromus Crust. et Pycnog. etc., No. 110," "approximates very closely *P. pulchella* Kröyer, but is easily recognized by the thoracic segments, including the 3 anterior ones, being all of them keeled and running out as dorsal projections, whereas in the former species this is the case with the posterior ones only. Moreover, the form of the 2 anterior pairs of legs differs somewhat. The genus *Paramphithoë* is referred by Boeck to the family *Oedicerinæ*. In my judgment it should rather be classed among the Epimeridæ. Furthermore, I have seen fit to retain Sp. Bate's genus *Pleustes* for *P. panopla*, Kröyer, and the species nearest related to that form." Sars is here referring to Boeck's work of 1870, for in his posthumous volume, 1876, *Paramphithoë*, as limited by Boeck, is made a synonym of *Pleustes*, Sp. Bate, included indeed among the *Oediceriuæ*, but with the remark, "Genus *Pleustes* ad subfamiliam *Oedicerinæ* vix referendum est."

Fam. 4. Oediceridæ. Gen. *Oediceros*, Kröyer, 1842. 47. *Oediceros macrocheir*, to be "recognized by the remarkably small and non-inspissated frontal projection, the absence of eyes, and the prodigious development characterizing the 2 anterior pairs of legs."

Fam. 5. Atylidæ. Gen. *Halirages*, Boeck, 1870. 48. *Halirages quadridentatus*, very near *Halirages fulvocinctus*, M. Sars, but distinguished by size, length 24 mm., "greater number of dorsal spines, and the deviating form and armature of the lateral plates of the 3rd abdominal segment." Gen. 2. *Cleippides*, Boeck, 1870. 49. *Cleippides quadricuspis*, Heller, total length of specimens reaching 52 mm., the antennæ not included. Gen. 3. *Amphithopsis*, Boeck, 1860. 50. *Amphithopsis pulchella*, nearest *Amphithopsis latipes*, M. Sars, but "distinguished by a less thickset body, the absence of a dorsal keel, less robust ambulatory legs, as also by its colour. Moreover, the form of the 2 anterior pairs of legs is rather different."

Fam. Gammaridæ. Gen. 1. *Maera*, Leach, 1813. 51. *Maera tenera*, "*Maera tenella*, G. O. Sars, Prodromus descriptionis Crust. etc., No. 119 (non Stimpson)," "distinguished by its remarkably slender body, the evenly rounded 1st pair of epimera, the total absence of eyes, and the linear form of the basal joint of the 3 posterior pairs of legs." Gen. 2. *Melita*, Leach, 1813. 52. *Melita pallida*, "posterior margin of all abdominal segments, with exception of last, jutting out above as 2 flat, appressed spines, from between which rise two or three considerably smaller one. Lateral plates of 3rd segment produced posteriorly to a sharp point. No eyes." Gen. 3. *Amathilopsis*, Heller, 1875. 53. *Amathilopsis spinigera*, Heller, "length of largest specimens reaching 50 mm."

Fam. Syrrhoïdæ. Gen. *Bruzelia*, Boeck, 1870. 54. *Bruzelia serrata*, distinguished from *Bruzelia typica*, Boeck, "by the sharply-marked dorsal keel, with its high, compressed projections, as also by the posteriorly serrate lateral plates on the 3rd abdominal segment."

Fam. Stenothoidæ. Gen. 1. *Metopa*, Boeck, 1870. 55. *Metopa spectabilis*, "length reaching

14 mm.," very near to *Metopa alderi*, Sp. Bate, but "let alone the far greater size, it can immediately be recognized by the very unequal development of the 2 pairs of antennæ—perfectly uniform in both sexes; whereas the antennæ (in the female of *M. Alderi* at least) are about equal in length; moreover, by the armature characterizing the hand of the 2nd pair of legs; and finally, by the 3rd joint of the hindmost pair of legs being less dilated posteriorly." Sars notes that he has well-marked specimens from Hammerfest, "which are indeed a good deal smaller." 56. *Metopa æqvicornis*, "length 7½ mm.," distinguished from *Metopa spectabilis* "by its inferior size, as also by the greatly elongated and equally developed antennæ. From *M. longicornis*, Boeck, which, in the appearance of the antennæ, approximates closest the present species, it differs by the greater elongation of the 2nd joint of the 1st pair of antennæ, as also by the different form and armature of the hand of the 2nd pair of legs." Gen. 2. *Danaia*, Sp. Bate, 1862, with *Cressa*, Boeck, for a synonym. 57. *Danaia abyssicola*, differs from *Danaia dubia*, Sp. Bate, and *Danaia minuta*, Boeck, "by the total want of eyes, the remarkably elongated first pair of antennæ, and by the form of the first pair of legs." As the oral appendages could not be examined, it remains uncertain whether this species agrees with Bate's account of *Danaia* or Boeck's of *Cressa*.

Fam. Leucothoidæ. Gen. 1. *Lilljeborgia*, Sp. Bate, 1862. 58. *Lilljeborgia æqvicornis*, marked "by its want of distinctly developed eyes, by the presence of only one dorsal spine, by the uniform development of the antennæ, and finally by the peculiar structure of the first pair of legs in the male." The generic name is properly *Liljeborgia*. Gen. 2. *Tritropis*, Boeck, 1870. 59. *Tritropis appendiculata*, "the form treated of here exhibits in some respects a rather striking deviation from the other species referred to the genus *Tritropis*, and may possibly be found to constitute a separate genus." See Note on G. O. Sars, 1880. No. 27.

Fam. Ampeliscidæ. Gen. *Ampelisca*, Kroyer, 1842. 60. *Ampelisca odontoplax*, "length 24 mm.," distinguished "by its total want of eyes and the peculiar dentiform projection on each of the three anterior pairs of epimera, a character that suggested the specific designation," "presenting in its outer habitus closest resemblance to *A. spinipes*, Boeck." 61. *Ampelisca minuticornis*, "length 8 mm.," to be recognised "by the unusually small antennæ, its want of eyes, as also the considerable size of the expansion distinguishing the basal joint of the last pair of legs posteriorly." Gen. 2. *Byblis*, Boeck, 1870. 62. *Byblis abyssi*, "differs from the typical species, *B. Gaimardi* Kröyer, by the total want of eyes and the much less elongate head," and is distinguished from *Byblis crassicornis*, Metzger, "by the somewhat different structure of the antennæ and the caudal stylets," which "are all uniform in structure, with simple lanceolate and naked branches. They diminish successively in length backwards, and reach therefore, when stretched back, to about the same transverse line."

Fam. Microdeutopidæ. Gen. *Autonoë*, Bruzel, 1859. 63. *Autonoë megacheir*, "distinguished from the other two Norwegian species by its total want of eyes, the greatly elongated basal joint of the 1st pair of antennæ, and the structure characterizing the 1st, and in part too, the 3rd and 4th pairs of legs, as also by their far less dense armature of bristles."

Fam. Podoceridæ. Gen. 1. *Podocerus*, Leach, 1815. 64. *Podocerus assimilis*, nearest *Podocerus megacheir*, Boeck, "but differs from that animal in having a somewhat robuster form of body, larger epimera, the rudimentary character distinguishing the secondary flagellum of its 1st pair of antennæ, as also in the lateral plates of the 3rd abdominal segment not being angular, but obtusely rounded posteriorly." 65. *Podocerus brevicornis*, somewhat resembles *Podocerus latipes*, Kröyer, but differs "in its want of eyes, the pointed lateral corners of the head, the shorter and less abundantly bristle-beset antennæ, as also in a somewhat deviating form distinguishing the 2 foremost pairs of legs." 66. *Podocerus tenuicornis*, "*Podocerus longicornis*, G. O. Sars. Crust. & Pycnog. nova etc., No. 38 (non Heller)," "length 3 mm.," a species "distinguished from the 2 preceding ones by its remarkably elongate and slender

antennæ, furnished posteriorly with long fascicles of bristles,—by the greatly produced lateral corners of the head, and also by the comparatively feeble structure characterizing the foremost pair of legs." Gen. 2. *Erichthonius*, Edw., 1850. 67. *Erichthonius megalops*, " *Cerapus megalops*, G. O. Sars, Crust. & Pycnog. nova etc., No. 39," distinguished " by its unusually large and dark-coloured eyes, greatly elongated antennæ, and the form of the 2nd pair of legs in the male. The genus *Cerapus*, Say, of which *C. tubularis* is the type, differs essentially, as shown by Sidney Smith, from the genus *Erichthonius* Edw., belonging, as it does, to the family *Corophiidae*. The only Northern species of this genus is *C. crassicornis* (*Siphonocetes*) Sp. Bate, also met with on the coasts of Norway."

Fam. *Corophiidae*. Gen. *Unciola*, Say, 1818. "Syn: *Glaucome*, Kröyer, 1845." 68. *Unciola petalocera*, " *Glaucome petalocera*, G. O. Sars. Crust. & Pycnog. nova etc., No. 40," "length 10 mm." "The present species bears closest resemblance to *U. planipes* Norman, but it is easily recognized by its greater size and the peculiar lamellar form of the 3rd and 4th joints of the 2nd pair of antennæ in the male, as also by the structure of the 1st pair of legs. The 2nd pair of legs differs in the two sexes from those of *U. planipes*, the hind occurring vertically truncated at the extremity and with a well-defined palmar margin."

Fam. *Dulichiidae*. Gen. *Dulichia*, Kröyer, 1845. 69. *Dulichia tuberculata*, Boeck, " *Dulichia septentrionalis*, G. O. Sars. Crust. et Pycnog. nova etc., No. 41." 70. *Dulichia hirticornis*, distinguished from earlier species "by its remarkably clumsy form of body, comparatively robust and densely hirsute antennæ, and small whitish-yellow eyes." 71. *Dulichia macra*, "distinguished by its slim form of body and greatly produced limbs, rudimentary eyes, as also the peculiar form characterizing the 2nd pair of legs in the male."

Tribe 3. *Caprellina*. Fam. *Caprellidae*. Gen. *Caprella*, Lamk. 1818 [1801]. 72. *Caprella microtuberculata*, "of the previously known species, this approximates closest *C. linearis* Lin., but admits at once of being distinguished by the much more produced 1st pair of antennæ, the form of the 2nd pair of legs, and the different colouring." The last of these distinctions must be noted as of very doubtful specific value. 73. *Caprella spinosissima*, Norman, " *Caprella spinosissima*, Wyville Thomson, The Depths of the Sea, p. 126. *Caprella horrida*, G. O. Sars, Prodromus descript. Crust. & Pycnog. etc., No. 137." "On a former occasion," Sars observes, "I recorded this characteristic species under a new name, viz., *horrida*, to prevent its being confounded with Stimpson's *Aegina spinosissima*. Meanwhile, as the latter is identical with the form *Caprella spinifera*, described somewhat earlier by Bell, and must, therefore, bear the last-mentioned specific designation, I see no reason for suggesting any change in the name proposed by Norman for the species treated of here; wherefore it is now retained." As, however, the name *Caprella spinosissima* has been used by Spence Bate for the species named *Aegina spinosissima* by Stimpson in 1854 and *Caprella spinifera* by Bell in 1855, it becomes a synonym of the former, and cannot be used again for Norman's species, which will therefore revert to the name *Caprella horrida*, G. O. Sars. See also Note on C. Wyville Thomson, 1873. Gen. 2. *Aegina*, Kröyer, 1843. 74. *Aegina spinifera*, Bell, the synonymy given being *Caprella spinifera*, Bell, 1855, *Aegina spinosissima*, Stimpson, 1857. *Aegina spinosissima*, G. O. Sars, Prodromus descript. Crust. & Pycnog. No. 135. "Boeck's *Aegina echinata* differs obviously alike in the armature of the body and the structure of the 2nd pair of legs." The species is therefore, as just observed, *Aegina spinosissima*, Stimpson, 1854. Indeed, as to Stimpson's priority, I may here mention that a separate copy of Stimpson's Synopsis, which I have recently obtained, shows the following dates; on the cover, "Washington City: published by the Smithsonian Institution, January 1853.;" on the title-page, "[accepted for publication January, 1853.];" the introduction signed "William Stimpson. Smithsonian Institution, February, 1853."; on the page containing "references to the figures," "published by the Smithsonian Institution, Washington, D.C. March, 1853."

Tribe 4. Hyperiina. Fam. Hyperiidæ. Gen. *Hyperiopsis*, n. "Generic Character.—Body of the usual form in Hyperidians, tumid anteriorly, with back broad and small epimera. Head large, with upper part prominently arcuate. Eyes incompletely developed. First pair of antennæ larger than 2nd, with peduncle short and a well-developed accessory flagellum. Mandibles furnished with distinctly developed palps. The 2 foremost pairs of legs feeble in structure, simple, non-subcheliform; the 2 succeeding pairs with 3rd joint very large, compressed, lamelliform; the 3 posterior pairs slender, almost filiform, with basal joint but slightly expanded; last joint longest. Pleopods powerfully developed. The 2 foremost pairs of caudal stylets simple, two-jointed; last pair biramous. Telson rudimentary." "It is far from improbable that a closer examination will show the necessity of selecting it [*Hyperiopsis Vøringii*] as the type of a distinct group within the tribe *Hyperiina*. The most striking peculiarity in the present form is the distinct and rather large secondary flagellum on the 1st pair of antennæ, a character quite alien to Hyperidians in general." 75. "*Hyperiopsis Vøringii*," n. sp. "The specimen examined would appear, judging from the structure of the antennæ, to be a female," length 11 mm., taken off the Norwegian coast at a depth of 600 fathoms. [The fifth and sixth pleon-segments are not coalesced.]

In the *Oversigt af Norges Crustaceer*, 1882, Sars divides the Amphipoda into Tribe 1. Hyperina, Tribe 2. Gammarina, Tribe 3. Caprellina. In the present work we find Tribe 3. Caprellina, but Tribe 1. Gammarina, and Tribe 4. Hyperina, without any Tribe 2. It may be presumed that the change of order was intentional, and that the numbers would have been consecutive but for an oversight.

The appendix, p. 276, mentions that *Socarnes ovalis*, Hoek, is a synonym of *Socarnes bidenticulatus* (Sp. Bate), and that in regard to the shallow-water specimen from north of Spitzbergen referred by Hoek to *Onesimus leucopis*, G. O. Sars, the correctness of the determination is very questionable.

1885. SCHNEIDER, J. SPARRE.

Pontocrates norvegicus, Boeck, und *Dexamine thea*, Boeck, Ein Beitrag zur Kenntniss der Amphipoden des arktischen Norwegens. Tromsö. Mit 2 Tafeln. pp. 13–26.

Pontocrates norvegicus, Boeck, is described and figured in much detail, distinguished from *Pontocrates (Kroyera) arenarius*, Sp. Bate, and identified with *Kroyera altamarina*, Bate and Westwood. The genus *Pontocrates*, as defined by Boeck, is considered to be scarcely if at all distinguishable from *Monoculodes*. A very striking relationship is pointed out between *Monoculodes carinatus*, Sp. Bate, and *Pontocrates norvegicus*. Since *Monoculodes carinatus* was originally instituted as the type-species of *Kroyera*, Sp. Bate, Schneider's investigations seem to tend either to the restoration of the name *Kroyera*, with the species *carinata*, *arenaria* and *norvegica*, or to the merging of *Kroyera* and *Pontocrates* alike in *Monoculodes*. [The form *Kroyera*, instead of the earlier and more correct *Kroyera*, is uniformly used in the British Sessile-eyed Crustacea.]

Dexamine thea, Boeck, is fully described and figured. On the first maxillæ Schneider observes, "A want of symmetry in the mouth-organs is found in most Amphipoda, especially in the mandibles, but so irregular a pair of first maxillæ I have hitherto found only in *Dexamine*." It is apparently very like *Dexamine heibergi*, Boeck. "In regard to the telson, Boeck speaks of it as split to the root; I remarked to be sure," Schneider says, "a suture along the whole telson, but even under strong pressure could only make the points dehiscent. The third segment of the pleon is, just as in many Lysianassidæ, drawn out into a pointed, somewhat upward curved, hook, whereas Boeck expressly affirms the contrary."

Schneider prefers to retain the Dexaminæ (? Dexaminidæ), with the palpless mandibles, peculiarly unsymmetrical first maxillæ, and exunguiculate palps of the maxillipeds, as a separate family for the genera *Dexamine* and *Tritæta*, in contradistinction to the Atylidæ, with the genera *Atylus*, *Halirages*, *Calliopius*, *Amphitopsis* and *Laothoes*, "which in these respects are tolerably normal."

1885. SCHNEIDER, ROBERT.

Der unterirdische Gammarus von Clausthal. (*G. pulex* var. *subterraneus*.) Vorgelegt von Hrn Sehulze am 22. Oetober;—gedruckt im Bericht vom 3. Deeember [St. XLIX];—ausgegeben am 10 Deeember.) Hierzu Taf. VII. Mathematische und naturwissenschaftliche Mittheilungen aus den Sitzungsberichten der Kgl. preuss Akad. der Wissenshaften zu Berlin. Jahrg. 1885, Berlin 1885. [The cover of the separate part Heft X., Deeember 1885, bears the date 1886.]

Dr. Schneider refers to an earlier essay on "subterrane Organismen" (Abhandlung zum Programm des Königl. Real-Gymnasiums zu Berlin. Ostern 1885), in which he had already mentioned this *Gammarus*. The summary of the present paper says that the subterranean *Gammarus* from Clausthal differs from the common form of *Gammarus pulex*, and approaches the blind cavern-form in the following points:—"1. in der absoluten Bleichheit des Körpers; 2. in der beginnenden Verkümmierung des Auges; 3. in der Form des fünften Gliedes des zweiten Greiffusspaars; 4. event. in der Streckung der Vorder-Antennen." "Dazu kommen noch die Eigenthümlichkeiten der verstärkten Kalk- und Eisenaufnahme." It is not, he says, strictly a "Mittelform," but at any rate a "Vermittelungsform." The special interest of the form lies in its occurrence in the waters of mines of which the age can be more or less definitely ascertained. "Zwischen ihr und jenem Extrem, welches der völlig blinde *G. puteanus* in seinen verschiedenen Variationen darstellt, liegt unbestritten eine ungleich weitere Kluft, als zwischen eben derselben und unseren einheimischen oberirdisch lebenden Formen. Noch für menschliche Begriffe *unendlich lange* Zeiträume müssen erforderlich sein und gewesen sein, um jene vollkommen subterrane modifirte Form aus einer unserem Clausthaler Vorkommen entsprechenden Anpassungsstufe entstehen zu lassen, wenn wir bedenken, dass letztere vom Normalzustande noch nicht allzu weit differirende immerhin ein bis zwei Jahrhunderte (und vielleicht darüber) bis zu ihrem jetzigen Standpunkte gebraucht haben wird."

1885. SIMON, EUGÈNE.

Exploration scientifique de la Tunisie. Étude sur les Crustacés terrestres et fluviatiles recueillis en Tunisie en 1883, 1884 et 1885 par MM. A. Letourneux, M. Sébillot et Valery Mayet. Paris, M DCCC LXXXV.

On page 6, besides a note on *Gammarus pulex*, there is given the following description of *Gammarus tunetanus*, n. s.

"Loug. 8^{mm}. *Gammari pulicis* valde affinis, differt tegumentis corporis parcis et minutissime punctatis, capite paulo longiore et antice paululum attenuato, oculis longius reniformibus supra basin antennarum paululum superantibus (in *G. pulice* brevius ovatis et supra basin antennarum non attingentibus), antennarum superiorum ramo flagelli longiore articulum flagelli 6^{um} attingente sexarticulato, articulis 3, 4 et 5 reliquis paulo longioribus et inter se fere æquis (in *G. pulice* ramo semper triarticulato, articulo ultimo longiore setiformi, articulum flagelli 3^{um} vix æquante), antennis inferioribus flagello breviore octoarticulato articulis

cunctis paulo longioribus quam latioribus (in *G. pulice* 10-13-articulato), segmentis caudæ ultimis ut iu *G. pulice* spinis in fasciculos tres ordinatis inuuitis. Cætera ut in *G. pulice*. “*Gammari locustæ* valde affinis, oculis antennisque superioribus fere similibus, sed antennarum inferiorum flagello ruulto breviore articulis paucioribus et fere teretibus differt (in *G. locusta* flagello robustiore paulum depresso 15-20-articulato, articulis saltcm 2-5 latioribus quam longioribus).”

1885. SPENCER, WALTER BALDWIN, born 1860 (W. E. Hoyle).

The urinary organs of the Amphipoda. *Reprinted from the Quarterly Journal of Microscopical Science for April, 1885.* London, 1885. *Micr. Journ.* Vol. XXV., N.S. Pl. XIII.

The views of earlier writers on these organs are stated. Mr. Spencer has investigated them specially in *Talitrus locusta*, in which the two tubes in question open at a considerable distance from the anus and run backwards instead of forwards, as in *Gammarus*, to end blindly in the last segment. Their openings into the gut are lateral, not dorsal as in *Gammarus*. In certain specimens these tubes were found to contain very definite concretions, of which Mr. Spencer says, “distilled water does not dissolve them, nor is there any uric acid present, but I have been able to clearly detect phosphoric acid, and hence they seem to differ from those found by Nebeski in *Orchestia cavimana*, where he states that they consist of carbonate of lime.” The general result agrees with Mayer's view of these organs, which Mr. Spencer gives as follows:—

“Mayer has also described them in the Caprellidae, where he states that they are well developed in Caprella, and absent, or only very feebly developed, in Protella, Proto, and Podalirius, but when present he has never found in them characteristic concretions, and is very decided in asserting that throughout the Amphipoda these diverticula, whatever may be their function and whether they contain excretionary products or not, belong morphologically to the mid and not to the hind gut, and that hence they cannot be considered as analogous to the Malpighian tubes of insecta. He states that there is always present a sharp break in the epithelium where the mid and hind gut meet, and that the chitin lining of the latter is not continued into the tubes whose epithelium resembles that of the mid, and not that of the hind gut.”

1885. STEBBING, T. R. R.

Description of a new English Amphipodous Crustacean. The Annals and Magazine of Natural History for January 1885. Ser. 5. Vol. XV. Pl. II. pp. 59-62.

Cypridida damnoniensis, n. sp. is here described and figured, and the correspondence pointed out between the genus *Cypridida*, Haswell, 1880, and the genus *Stegoplax*, G. O. Sars, 1882. Both may have been anticipated by *Peltocoxa*, Catta. See Note on Catta, 1875.

1885. STEBBING, T. R. R.

In Narrative of the Cruise of H.M.S. Challenger. Vol. I. Second Part. London, Edinburgh, Dublin, 1885. pp. 618-622.

Figures are given of *Andania gigantea* and *Acanthozone tricarinata*, the latter of which is now transferred to a new genus, *Acanthechinus*. In this part of the Narrative also the figure by

J. J. Wild and R. von Willemoes Suhm is reproduced, which had already appeared in the Transactions of the Linnean Society, 1875, with the designation "*Cystisoma Neptunus* (*Thaumops pellucida*)," and in The Voyage of the Challenger by Sir C. Wyville Thomson, 1877, with the designation "*Cystosoma neptuni*."

1886. AURIVILLIUS, C. W. S.

Hafsevertebrater från nordligaste Tromsö amt och Vestfinmarken. Med 2 Taflor. Meddeladt den 10 Juni 1885. Bihang till k. Svenska vet.-akad. Handlingar. Band 11. N:o 4. Stockholm, 1886.

At page 41 it is mentioned that *Amphithopsis longicaudata*, A. Boeck, is found, as well as *Aristias tumulus*, Kröyer, and *Andania pectinata*, G. O. Sars, in the branchial sac of Ascidiants. A specimen, 8 mm. long, the antennæ not included, was found in *Phallusia obliqua*, Heller. On *Megaptera boopis* many specimens of *Cyamus boopis*, Lütken, were found, principally on the sides of the head, a few on the fins, and one further back on the whale's body. Curiously, out of 102 individuals only 12 were females. The largest of the male specimens was 12 mm. long, of the females 9 mm., antennæ not included.

1886. BOVALLIUS, CARL.

Remarks on the genus *Cysteosoma* or *Thaumatops*. With one Plate. Communicated to the Roy. Swed. Academy of Sciences 1885, September 16. Stockholm, 1886. Bihang till K. Svenska Vet.-Akad. Handlingar. Band. 11. N:o 9.

Bovallius considers that Guérin's *Cystisoma* must be corrected into *Cysteosoma*, and then remarks that "as the name *Cysteosoma* or *Cystisoma* has been previously given to a genus of Coleoptera by Westwood, it must be rejected and consequently the name of WILLEMOËS-SUHM *Thaumatops* be substituted." But in fact Westwood's genus is *Cystosoma*, and Guérin's name ought neither to be corrected nor rejected. *Thaumatops* is itself a correction of *Thaumops*, a correction already suggested in the Zoological Record for 1873, but these corrections only multiply synonyms needlessly, and are in my opinion very unjust to the founders of genera. If the niceties of classical philology must be attended to in the invention of new names, it would be better for authors to beware of Greek and Latin altogether and adopt Leach's device of throwing letters together into chance names like *Rocinela*, at the composition of which no scholar will be able to carp.

The family called by Willemoes Suhm *Cystisomidae* is renamed by Bovallius *Thaumatopsidae*. This, he says, "is to be ranged between the families *Mimonectidae* and *Phronimidae*. It also shows some relations to the family formed by the genus *Tyro*, MILNE-EDWARDS." He has elsewhere shown that *Tyro* is the same as the later *Clydonia*, Dana. To *Thaumatops* he assigns four species; 1. *Thaumatops neptunus*, Guérin, 1842, under which he doubtfully includes *Thaumops pellucida* (the male), Willemoes Suhm, 1874, "Phil. Trans. Roy. Soc. Lond. vol. 163, part 3, p. 637, (the male)."; 2. *Thaumatops pellucida*, Willemoes Suhm, 1874, "Phil. Trans. Roy. Soc. vol. 163, p. i. p. 629 (non p. 638), pl. 49-50, fig. 1-9a;"; 3. "*Thaumatops Lovíni*," n. s., Fig. 1-14, in which "the two first pereional segments are free, not coalesced," and "on the under-side of the head there is no shorter row of spines as in Th. Neptunus and Th. pellucida;" the single known specimen, in "length, 105 mm., was taken in the Indian Ocean; 4. *Thaumatops longipes*, n. s., Fig. 15-23, in which also "the two first pereional segments are free, not coalesced;" tho

single specimen, in "length, 57 mm., was taken off the west coast of Australia;" "through the long and coarsely denticulated legs this species," Bovallius says, "is easily distinguished from the others." Detailed descriptions are given of all the four species. Of the species described by J. C. Fabricius in 1775, under the name *Oniscus spinosus*, mention is not made.

1886. BOVALLIUS, CARL.

Amphipoda Synopidea. With 3 Plates. (Presented to the Royal Society of Sciences of Upsala the 10th May 1886.) Upsala, 1886.

Bovallius here divides the Amphipoda into five tribes, distinguished as I. Tanaidea; II. Gammaridea; III. Synopidea; IV. Hyperiidea; V. Caprellidea. In the diagnosis the distinction between the Amphipoda Gammaridea, and the Amphipoda Synopidea, is made to depend upon the eyes and the maxillipeds; in the former the eyes are described as "oculi mediocres, sessiles," in the latter as "oculi grandes, maximum partem capitis occupantes, sessiles;" but when we compare the size of the eyes in such a species as that which has been named *Calliopus grandoculis*, with the size of the eyes in the various species assigned to *Synopia*, this distinction seems untenable; the maxillipeds of the Gammaridea are said to be "non coaliti, palpus quattuor-articulatum gerentes," while those of the Synopidea are described as "plus minusve coaliti, palpus quattuor-articulatum gerentes," but surely in both tribes the maxillipeds are coalesced at the base, and in the Gammaridea the fourth joint of the palp is occasionally wanting, as in *Normania*, Boeck, and occasionally both the third and fourth joints are absent, as in *Lafystius*, Krøyer. The further character assigned to the Gammaridea, "urus mediocre, triarticulatum," is not universally applicable, since in the family Dulichidae, Dana, the uropod-bearing portion (urus) of the pleon has only two joints; and lastly, the character "telson særissime fissum," seems out of place when in so many genera the telson is not cleft.

His tribe Synopidea Bovallius divides into three families; 1. Synopidae; 2. Trischizostomatidae; 3. Hyperiopsidae. He admits that the Synopidae "resemble the true Gammarids in more points than those of the two following families do." In the diagnosis of this family, he says that "the eyes occupy the upper median part of the head, and are distinctly faceted." To the genus *Synopia*, Dana, he assigns six species, of which he gives descriptions, and, of all but the last, figures; all the species, he says, "are closely allied and seem rather to deserve the name of varieties than of species," but, "as their differences seem to be constant," he keeps them distinct under the following names; 1. *Synopia ultramarina*, Dana; 2. *Synopia caraibica*, n. s.; 3. *Synopia angustifrons*, Dana; 4. *Synopia Scheeleana*, n. s.; 5. *Synopia gracilis*, Dana; 6. *Synopia orientalis*, Kossmann. Of these *Synopia scheeleana* had long ago been figured for this Report, having been taken by the Challenger at the surface in the Pacific and elsewhere. One or two minute differences between the description by Bovallius and my own are noticed in the account of the species.

To the family Trischizostomatidae, Sars, the genus *Trischizostoma*, Boeck, is assigned without companions, and with the single species *Trischizostoma raschii*, Boeck. New descriptions and figures are given of the adult female and young male. For my opinion on the proper name for this genus, see Note on A. Costa, 1853.

The third family Hyperiopsidae has the single genus *Hyperiopsis*, Sars, and the one species "*Hyperiopsis Voerinoii*," Sars, the figures and details being borrowed from G. O. Sars' recent work on the Crustacea of the Norwegian North Atlantic Expedition 1876-1878.

1886. FORSSTRAND, CARL.

Det arktiska hafsområdets djurgeografiska begränsning med ledning af skalkräftornas (crustacea malacostraca) utbredning. Upsala, 1886. 55 pages and map.

It is mentioned in a note, p. 4, that L. K. Schmarda, in *Die geographische Verbreitung der Thiere*, Wien, 1853, calls the Arctic maritime region "Reich der Meersäugetiere und Amphipoden." The circumpolar realm is thus divided, starting eastward from Behring Strait; 1. *Amerikas ishaf*, from Behring Strait to Smith Sound and Baffin's Bay; 2. *Vestgrönlandska hafvet*, the tract of sea between the American Archipelago and mainland and Greenland; 3. *Europeiska Nordhajvet*, between East Greenland, West Finmarken and Spitzbergen; 4. *Barentz' haf*, between East Spitzbergen, Franz Joseph Land, Nova Zembla, Northern Russia and East Finmarken; 5. *Kuriska hafvet*, from the east coast of Nova Zembla to Cape Chelyuskin; 6. *Sibirien's ishaf*, from Cape Chelyuskin to Behring Strait; 7. *Beaufort's haf*, the sea immediately north of Behring Strait and south of it to the Aleutian Islands and Sea of Ochotsk.

Referring to the Royal Society Manual of the Natural History, etc. of Greenland, London, 1875, containing the "*Crustacea of Greenland by Chr. Lüthen*," he says that the West Greenland Sea has eighty species of Amphipoda, of which the following are not yet known from other seas, "*Egina longicornis* Kr., *Cercops Holboelli* Kr., *Cleippides tricuspidis* (Kr.), *Cyamus monodontis* Ltk., *mysticeti* Ltk. och *nodosus* Ltk., *Cyphocaris anonyx* Ltk., *Monoculodes affinis* (Bruz.) och *Parathemisto compressa* (Goës)." At page 36 he remarks that many species, especially pelagic and surface-living animals, such as *Themisto*, *Hyperia*, and many Copepoda, may be subject to a *passive* distribution, due to marine currents. He finishes by giving a list of 304 Crustacea, of which those numbered 135 to 304 are Amphipoda, showing their distribution in the regions above-mentioned, of which he subdivides the third into "Ö. Grönland, Ishafsdjupet, Spetsbergen." He adds for comparison two other regions, Great Britain and the Baltic. To the list of species an addendum gives "*Lanceola Clausii* Bovall," from West Greenland. Hoek's new species, 1882, are not included in the list.

1886. FOWLER, GEORGE HERBERT, born September 4, 1861 (G. H. F.).

List of the Amphipoda of the L. M. B. C. District: in the first Report upon the Fauna of Liverpool Bay and the neighbouring seas, written by the members of the Liverpool marine biology Committee, and edited by W. A. Herdman, D.Sc., F.L.S., &c. London, 1886. pp. 212-218. Pl. IV. fig. 1. [Proc. Lit. Phil. Soc. Liverpool. Vol. XL. Appendix.]

Forty-five species of Amphipoda are enumerated, with here and there a synonym and occasional notes by Mr. Fowler and Mr. A. O. Walker. "*Bathyporeia pelagica*, var. *robertsoni*, Sp. Bate," is separated from *Bathyporeia pilosa*, Lindström, by an accidental misapprehension. On *Dexamine spinosa*, Leach, the remark is made that "two very small specimens lack the characteristic tooth on the first antennæ, = *Dex. tenuicornis* ?"; on *Gammarus locusta*, Linn., "a black form is common; the red spots on the abdominal segments are not always present;" on *Gammarus marinus*, Leach, "some specimens dredged from Welshman's Gut are apparently a variety between *G. locusta* and *G. marinus*, having the first two abdominal segments rounded off, but still not agreeing with *G. campyllops* in the form of the last pair

(ZOOL. CHALL. EXP.—PART LXVII.—1887.)

Xxx 73

of feet." *Podocerus falcatus*, Montagu, *Podocerus pelagicus*, Leach, and *Podocerus pulchellus*, Leach, are given as three species, but with the statement that "the last two species may be varieties of *P. falcatus*. Figure 1 on Plate IV. is an outline of "*Protella phasma*, Dana (young)," of which Mr. Fowler observes that "none of the characteristic spines on the back are developed except that on the head; and the palm of the second cheliped is much simpler than that of the adult, exhibiting only one, not very strong, tooth."

1886. FOWLER, G. HERBERT.

The Zoological Record for 1885; being Volume the twenty-second of the Record of zoological literature. London, M.DCCC.LXXXVI. Crustacea by G. Herbert Fowler, B.A., Ph.D. 29 pages.

1886. GERSTAECKER, A.

Dr. H. G. Bronn's Klassen und Ordnungen des Thierreichs, wissenschaftlich dargestellt in Wort und Bild. Fortgesetzt von Dr. A. Gerstaecker. Fünfter Band. II. Abtheilung. Gliederfüssler; Arthropoda. 16. und 17. Lieferung. Leipzig und Heidelberg, 1886. pp. 417-512.

In this part is finished the discussion of the variety of colouring found among the Amphipoda, and mention made of the correspondence in some species between the colour of the animal and its surroundings. A section, number 3, follows on *habitat*, in which the remark is made that hitherto only a single species, *Orchestia cavimana*, Heller, has been proved (by Graeffe's experiments) to have entirely given up the water and become an air-breather like the terrestrial Isopods. It is further said that of the Gammarid group hitherto only a single species, *Pherusa fucicola*, Leach, has been observed as an inhabitant of the wrack thrown up by the sea. But surely the common Gammari, *locusta* and *marinus*, are much more frequently found in such circumstances than *Pherusa fucicola*, which along with many other species, haunts the weeds between tide marks. Section 4 describes some of the contrivances by which Amphipoda provide themselves with dwellings, giving an account, among other matters, of the investigation by which P. Mayer discovered that *Phronima sedentaria* makes use of other animals for a residence besides *Pyrosoma*. In Section 5, on the means of boring, it is suggested that the large lower antennæ of *Chelura terebrans* may be of use in removing the gnawed-off particles of wood from the passages. Section 6 is on the period of appearance of some of the Amphipoda. Section 7, on motion, describes Gerstaecker's own observations on *Gammarus pulex*. This, he says, swims never on its side except when the shallowness of the water compels it, but otherwise almost always with the back uppermost, only occasionally and for a short time back downwards. It always swims straight forward, with the last three pairs of pereiopods turned upwards, the first two pairs by their movements assisting the pleopods, the gnathopods held perfectly quiet, the antennæ for the most part kept in motion. In reference to "*Talitrus saltator*," Gerstaecker makes the suggestion that the second gnathopod may be employed in digging the hole in the sand for the creature to bury itself, though the small size and fineness of the integument of the hand of this limb are recognised as out of harmony with the suggestion. The first gnathopod would seem to be a more efficient instrument for the purpose in question. Gerstaecker suspects that the swimming movements of "*Lepidactylis (Suleator) arenaria*" must be especially

peculiar. In fact they very much agree with those of the thin and delicate *Niphargus aquilex*. Both species are to all appearance unwilling swimmers, struggling often in a more or less upright position, then swimming back downwards, and soon sinking to the bottom. Section 8, on nourishment, gives reasons for the opinion that the Amphipoda principally if not exclusively feed on animal substances, whether dead or living. Section 9, on commensalism and parasitism, distinguishes the species which have been noticed as respectively inhabitants of Sponges, of Hydrozoa, of Echinoderms, of Tunicata, of Mollusca, of Crustacea, of Fishes, of Reptilia, of Cetacea; those on Reptilia probably belonging rather to the surface growth of sea-weeds than to the animals on which the sea-weed happens to grow. Section 10 discusses the good and harm which the Amphipoda are supposed to do, the good consisting in their constituting the food of various animals of more directly obvious importance, the harm inculpating only two species, *Chelura terebrans*, which bores into submarine timber, and *Gammarus locusta*, which is supposed to destroy fishing-nets. Section 11, on parasites, mentions as internal parasites *Echinorrhynchus polymorphus*, Brems., *Echinorrhynchus proteus*, Westr., *Distomum* sp., *Gregarina longissima*, Sieb., *Zygocystis puteana*, Lachmann, *Gregarina clausi*, Frenzel, *Callyntrochlamys phronimæ*, Frenzel, *Gregarina niceæ*, Frenzel, *Gregarina caprellæ*, Frenzel, and as external parasites "*Epistylis Steini*, Wrzesn., and *Carchesium* sp., on *Gammarus pulex*; *Podophrya cyclopum*, Clap., and *Dendrocometes paradoxus*, Stein, on *Gammarus puleanus*; *Vaginicola crystallina*, on *Gammarus marinus*; *Vorticella* sp. on *Darwinia compressa* and on *Lepidactylis arenaria*; *Carchesium* sp. and *Podophrya crustaceorum* on *Caprella aquilibra*."

Chapter V. is on classification, and begins by describing successively the systems of Milne-Edwards, Dana, Spence Bate (1857 and 1862), Lilljeborg, Boeck, Nebeski and (for the *Hyperina*) Claus, but without recognising the important service rendered by Axel Boeck in laying stress upon the mouth-organs in addition to other important parts of the structure. An interesting discussion follows bearing largely upon the Tanaidea, which it seems to be a point of honour with Gerstaecker to include under the Amphipoda. The order Amphipoda itself, as distinguished from the Isopoda, he characterises "als annähernd homonom segmentirte Malacostraca mit in der Regel selbstständigem, seltener (*Laemodipoda*, *Tanaidea*) mit dem ersten Mittelleibsring verschmolzenem Kopftheil, zwei übereinander eingelenkten Fühlerpaaren, nicht facettirtem Augen-Integument, im Mittelleib gelegnem Herzschauch und lediglich der Ortsbewegung (nicht der Athmung) dienenden Hinterleibsbeinen."

He makes three suborders, thus defined:—

"Subordo I. Amphipoda genuina. Die sieben Mittelleibsringe frei, der erste nicht mit dem Kopftheil verschmolzen. Hinterleib normal ausgebildet, mit sieben (meist) selbstständigen Segmenten. Die Pedes spurii der drei hinteren Paare von denjenigen der drei vorderen formell verschieden. Lamellöse Kiemen nach innen oder hinten von mehreren Mittelleibsbeinpaaren.

"Subordo II. Laemodipoda. Der erste Mittelleibsring mit dem Kopftheil zu einem Cephalothorax verschmolzen. Hinterleib nebst den ihm entsprechenden Gliedmassen rudimentär, auf einen stummelförmigen Anhang des Mittelleibs reducirt. Dritter und vierter Mittelleibsrang mit paarigen Kiemensäcken, dagegen nur ausnahmsweise mit regulär entwickelten Beinen versehen.

"Subordo III. Tanaidea. Der erste Mittelleibsrang mit dem Kopftheil zu einem Cephalothorax verschmolzen. Hinterleib normal ausgebildet. Die Pedes spurii der fünf vorderen Paare gleich gebildet. Keine Kiemen im Anschluss an die Mittelleibsbeine. Die Seitentheile des Cephalothorax zu Athemhöhlen umgebildet."

A conspectus follows, which is not completed in this part, giving definitions of the divisions, tribes, families and most of the genera which Gerstaecker accepts. Division I. Hyperina, is

subdivided into two tribes, of which the first "Hyperina anomala, M.-Edw. (*Platyscelidæ* Claus)," follows Claus' arrangement of 1879, adding, however, *Phorcus*, M.-Edw., as a fourth genus in Fam. 3. *Pronoidæ*, Claus, whereas Claus, who omitted it in 1879, places it, in 1887, in the family *Lycaeidae*. Tribus II. *Hyperina normalia*, M.-Edw., is divided into three families. Fam. 1. *Phronimidæ*, Dana, is divided into two groups, *Phrosininae* and *Phroniminæ* (see Note on Claus, 1879), with the suggestion that *Tryphana*, Boeck, should be included in the family *Phronimidæ*, the fact escaping notice that this genus had been identified by Sars with *Lycæa*, Dana, a genus belonging to the preceding tribe. Fam. 2. *Hyperidæ*, Dana, receives the following genera, 1. " *Themisto* Guér. (*Parathemisto* Boeck)," 2. " *Cyllopus* Dana," 3. " *Cystosoma* Guér. (*Thaumopus* Willemoes)," 4. " *Tyro* M.-Edw.," 5. " *Hyperia*, Latr. (*Hiella* Straus, mas: *Lestrigonus* M.-Edw., fem: *Metocetus* Kroyer, *Tauria* Dana)," 6. " *Daira* M.-Edw. (*Dairinia* Dana)," 7. " *Mimonectes* Bovallius," with the concluding remark "hierher ferner: Gatt. *Lanceola* Say." *Cystosoma* should be written *Cystisoma*, and *Lestrigonus* is commonly regarded as the male of *Hyperia*. Fam. 3. *Vibiliidæ*, Dana (*Hyperina Gammaroidea* M.-Edw.), contains only the genus *Vibia*, M.-Edw. Division II. *Gammarina*, begins with "Tribus I. *Corophiina* (*Marcheurs* M.-Edw.)." This has five families, thus arranged:—

Fam. 1. *Chluridæ*, Allm. Genus *Chelura*, Phil. (*Nemertes*, White, *Limnoria*, Hesse).

Fam. 2. *Dulichidæ*, Dana (Dyopodidae, Sp. Bate). 1. Gen. *Dulichia*, Krøyer (*Dyopedos*, Sp. Bate, *Paradulichia*, Boeck). 2. Gen. *Læmatophilus*, Bruz. 3. Gen. *Xenodice*, Boeck. 4. Gen. *Cryptophium*, Dana (*Platophium*, Dana).

Fam. 3. *Corophiidae*, Dana. Group 1 with the rami in pairs on the first and second, single on the third uropods. 1. Gen. *Corophium*, Latr. 2. Gen. *Siphonæcetes*, Krøyer. 3. Gen. *Cerapus*, Say (*Erichthonius* and *Cerapodina*, M.-Edw., *Pyctilus*, Dana). 4. Gen. *Derothoë*, Dana (? *Cerapus*, Say, fem.). 5. Gen. *Unciola*, Say (*Glauconome*, Kroyer). 6. Gen. *Hela*, Boeck. Group 2 with pairs of rami on all the uropods. 7. Gen. *Podocerus*, Leach (*Jassa*, Leach, *Ischyrocerus*, Krøyer, *Cratophium*, Dana, *Elasmopus*, Costa). 8. Gen. *Gammaropsis*, Lilljeb. (*Eurystheus*, Sp. Bate). 9. Gen. *Aoru*, Kroyer (*Microdeutopus*, Costa, *Autonoë*, Bruz., *Lembos* et *Lonchomerus*, Sp. Bate, *Lalaria*, Nieol.). Related genus *Xenocheira*, Haswell. 10. Gen. *Stimpsonia*, Sp. Bate. 11. Gen. *Dryope*, Sp. Bate. 12. Gen. *Cratippus*, Sp. Bate (*Colomastix*, Grube, *Exunguia*, Norm.). 13. Gen. *Podoceropsis*, Boeck (*Nænia*, Sp. Bate). 14. Gen. *Amphithoë*, Leach (*Anisopus*, Templet., *Pleonexes*, Sp. Bate). 15. Gen. *Synamphithoë*, White. 16. Gen. *Protomedæia*, Krøyer (*Leptocheirus*, Zadd., *Ptilocheirus*, Stimp.). As other genera belonging here, Gerstaecker adds, without numbering, *Microprotopus*, Norm., *Gossea*, Sp. Bate, *Goësia*, Boeck, *Xenoclea*, Boeck, *Haplocheira*, Haswell, and *Amphithoides*, Kossm.

Fam. 4. *Iciliinæ*, Dana. 1. Gen. *Icilius*, Dana. 2. Gen. *Iridium*, Grube (*Pereionotus*, Sp. Bate). 3. Gen. *Phlias*, Guér.

Fam. 5. *Clydoninae*, Dana. Genus *Clydonia*, Dana.

Tribus II., *Gammarina genuina* (*Sauvage*, M.-Edw.); begins with Fam. 6. *Gammaridæ*. (The branchial vesicles in subfamilies 1–5 normally developed.)

Subfam. 1. *Lysianassina* (et *Stegocephalina*), Dana. a. Mandibles with the cutting-edge quite or almost undentate. 1. Gen. *Lysianassa*, M.-Edw. (*Ichnopus*, Costa, *Ambasia* et *Socarnes*, Boeck. 2. Gen. *Eurytenes*, Lilljeb. 3. Gen. *Anonyx*, Krøyer (*Hippomedon*, *Aristias*, *Onisimus*, *Menigrates*, *Orchomene* et *Tryphosa*, Boeck). 4. Gen. *Opis*, Krøyer (*Normania*, Boeck). 5. Gen. *Callisoma*, Costa (*Scopelocheirus*, Sp. Bate). 6. Gen. *Acilostoma*, Lillj. This is followed by three genera given as related, "verwandte Gattungen," without numbers or descriptions, namely, *Cyphocaris*, Boeck, *Egidia*, Costa, and *Glycera*, Hasw. The second group, b. having mandibles with dentate cutting-edge, contains 7. Gen. *Stegocephalus*, Kroyer (*Andania*, Boeck). 8. Gen. *Pontoporeia*, Krøyer (*Priscilla* et *Argissa*, Boeck).

9. Gen. *Bathyporeia*, Lindstr. (*Thersites*, Sp. Bate). These are followed by "Verwandte Gattungen: *Amaryllis* und *Cyproidea* Hasw."

Subfam. 2. *Plooxina*, Sp. Bate. a. Upper antennæ with secondary flagellum not rudimentary.

10. Gen. *Lepidactylis*, Say (*Pterygocera*, Latr., *Sulcator*, Sp. Bate, *Bellia*, Sp. Bate, antea).

11. Gen. *Phoxus*, Kröyer (*Harpina*, Boeck). 12. Gen. *Urothoe*, Dana. 13. Gen.

Lilljeborgia, Sp. Bate (*Microplax*, Lilljeb., *Cleirocratus*, Norm., *Iduna*, Boeck). 14. Gen.

Phædra, Sp. Bate. 15. Gen. *Tiron*, Lilljeb. (*Syrhoë*, Goës, *Tessarops*, Norm.). These are

followed by "Verwandte Gattung: *Bruzelia* Boeck." b. Upper antennæ without secondary

flagellum. 16. Gen. *Weswoodilla*, Sp. Bate. 17. Gen. *Monoculodes*, Stimp. (*West-*

woodia, Sp. Bate, *Halimedon*, Boeck). 18. Gen. *Kroyera*, Sp. Bate (*Pontocrates*, Boeck).

19. Gen. *Amphilochus*, Sp. Bate. 20. Gen. *Gitania*, Boeck. 21. Gen. *Astyra*, Boeck.

22. Gen. *Grajia*, Sp. Bate. 23. Gen. *Laphystius*, Kröyer (*Darwinia*, Sp. Bate). 24. Gen.

Œdicerus, Kröyer (*Acanthostephia*, Boeck). 25. Gen. *Œdiceropsis*, Lilljeb. 26. Gen.

Halicreion, Boeck. 27. Gen. *Pleustes*, Sp. Bate (*Amphilithonotus*, Costa). 28. Gen.

Iplimedia, Rathke (*Microcheles*, Kröyer). 29. Gen. *Odius*, Lilljeb. (*Otus*, Sp. Bate).

30. Gen. *Acanthonotus*, Owen (*Vertumnus*, White). These are followed by "Verwandte (?)

Gattung: *Epimeria* Costa."

Subfam. 3. *Prostomatæ*, Boeck. 31. Gen. *Trischizostoma*, Boeck.

Subfam. 4. *Ampeliscina*, Sp. Bate. 32. Gen. *Ampelisca*, Kröyer (*Tetrommatus*, Sp. Bate,

Araneops, Costa, *Pseudophthalmus*, Stimp.). 33. Gen. *Haploops*, Lilljeb. 34. Gen.

Byblis, Boeck.

Subfam. 5. *Gammarina*. 35. Gen. *Photis*, Kröyer (*Eiscladus*, Sp. Bate). 35. Gen. *Leucotlioë*,

Leach (*Lyesta*, Sav., ? *Seba*, Costa). 37. Gen. *Stenothoë*, Dana (*Probolium*, Costa,

Montagua, Sp. Bate, *Metopa et Cressa*, Boeck). "Verwandte Gattungen: *Aspidophoreia*,

Hasw. und *Peltocoxa* Catta." 38. Gen. *Danaia*, Sp. Bate. "Verwandte (?) Gattung:

Callimerus Stebbing." 39. Gen. *Pherusa* Leach (*Paramphithoë*, Brnz., *Amphithopsis*, Boeck).

40. Gen. *Calliope*, Leach (*Calliopus*, Lilljeb.). 41. Gen. *Atylus*, Leach (*Epilesura*, *Ponlogeneia* et *Halirages*, Boeck, *Nototropis*, Costa). 42. Gen. *Helleria*, Norm.

43. Gen. *Dexamine*, Leach (*Lampra*, Boeck). 44. Gen. *Balea*, Fr. Müll.

45. Gen. *Brandtia*, Sp. Bate. 46. Gen. *Pardalisca*, Kröyer (*Halice*, Boeck). 47. Gen.

Nicippe, Bruz. 48. Gen. *Eusirus*, Kröyer. 49. Gen. *Isæa*, M.-Edw. "Verwandte

Gattungen: *Macleayia* und *Polycheria* Hasw." 50. Gen. *Melita*, Leach (*Cerudocus*, Costa).

51. Gen. *Mæra*, Leach (*Leptothoë*, Stimp., *Megamæra*, Sp. Bate, *Elasmopus*, Costa).

52. Gen. *Crangonyx*, Sp. Bate. 53. *Gammarella*, Sp. Bate. 54. Gen. *Niphargus*, Schioedto (*Eriopis*, Bruz.). 55. Gen. *Gammarus*, Fab. (*Goplana*, Wrzesn.). 56. Gen.

Pallasea, Sp. Bate. 57. Gen. *Constantia*, Dybowsky. 58. Gen. *Melphidippa*, Boeck.

59. Gen. *Amathia*, Rathke (*Amathilla*, Sp. Bate). 60. Gen. *Gammaracanthus*, Sp. Bate.

"Verwandte Gattungen: *Weyprechtia* Stuxberg und *Amathillopsis* Heller." Here for the

present this important work makes a halt.

The above classification suggests the following comments:—

The definition of Fam. 2. *Dulichidæ*, Dana, includes the statements, "Das vierte und fünfte Hinterleibssegment mit einander verschmolzen; von den drei hinteren griffelförmigen Spaltbeinpaaren eines fehlend." But in *Platophium*, Dana, here given as a synonym of *Cylophium*, Dana, the fourth and fifth pleon-segments are not coalesced, and there are third nropods, though small and without rami.

In Fam. 3. *Corophiidæ*, Dana, *Cerapus*, Say, is identified with *Erichthionius*, M.-Edw., from which S. I. Smith has shown it to be distinct, and is included in the group which have pairs of rami on the first and second uropods, whereas the second nropods in *Cerapus* have single rami. *Derothoë*, Dana, is probably the female of *Erichthionius*, certainly not the female of *Cerapus*, Say. *Hela*, Boeck, being preoccupied, has been changed into *Neohela*.

- In the second group of the Corophiidæ, *Elasmopus*, Costa, is given as a synonym of *Podocerus*, Leach, but afterwards in the fifth subfamily of the Gammaridæ as a synonym of *Mæra*, Leach, to which it comes in fact much nearer. It is not easy to see why *Microdeutopus*, Costa, and *Autonoë*, Bruz., should become synonyms of *Aora*, Krøyer, while *Stimpsonia*, Sp. Bate, is retained as an independent genus. *Cratippus*, Sp. Bate, is of later date than *Colomastix*, Grube. The preoccupied name *Anisopus*, Templet., should rather be assigned as a synonym to *Sunamphithoë*, Sp. Bate, than to *Amplithoë*, Leach. The same may be said of *Pleonexes*, Sp. Bate, since its type species, *Pleonexes gammaroides*, is almost undoubtedly a *Sunamphithoë*. *Leptocheirus*, Zaddach, should not be made a synonym of *Protomedæia*, Krøyer; Boeck even put the two genera in different subfamilies.
- In Fam. 4. Iciliinæ, Dana, it should not be given as a generic character of *Icilius* that the second uropods are longer than the third; they are not so represented by Dana in the type species. If *Iceridium*, Grube, is the same as *Pereionotus*, Bate and Westwood, as most probably is the case, the latter name has priority. In the definition of the family, the expression "die beiden vorderen Beinpaare von den folgenden nicht formell abweichend" is inaccurate, since, at least in *Icilius*, the gnathopods have the third joint *under-riding* the wrist.
- In Fam. 5. Clydoninæ, Dana, *Clydonia*, Dana, has recently been identified by Bovallius with *Tyro*, M.-Edw.
- In Fam. 6. Gammaridæ, Subfam. 1. Lysianassina (et Stegocephalina), Dana, an attempt, with which most students will sympathise, is heroically made to reduce the number of genera, by grouping several that Boeck has established, under earlier names and comprehensive definitions. But it seems hardly just to set aside without argument results at which Boeck arrived by patient and laborious investigation. Moreover, rejected genera are very apt to make their reappearance, when fresh research and the discovery of new species makes the want of them felt, and then the earlier rejection has only the effect of complicating the synonymy. Many of Leach's genera were at one time thought superfluous, but are now firmly established. On the other hand, comprehensive definitions such as that of *Paramphithoë* by Bruzelius, are apt to introduce a confusion which it almost needs a General Council to disentangle. The preoccupied *Opis*, Krøyer, has been altered by Boeck into *Opisa*; the definition here given does not suit *Normania*, Boeck, which is made synonymous with it. *Egilia*, Costa, here given among the Lysianassina, is no doubt synonymous with *Urothoë*, Dana, given later on among the *Phoxina*, Sp. Bate. *Glycera*, Haswell, being preoccupied, has been altered to *Glycerina*.
- In the second group of this subfamily, *Andania*, Boeck, is made a synonym of *Stegocephalus*, Krøyer, but I venture to think that a comparison of the mandibles shows such a combination to be impossible; on what grounds *Priscilla* and *Argissa*, Boeck, are made synonymous of *Pontoporeia*, Krøyer, I can still less understand, since the type species of these three genera are strikingly different in outward form.
- In Subfam. 2. Phoxina, Sp. Bate, the definition begins with the words, "Kopf niedrig, schnabelförmig ausgezogen, den Ursprung der oberen Fühler kappenförmig überdachend." But the first genus assigned to the subfamily is *Lepidactylis*, in which there is no such hood-like prolongation of the head, the small acute rostrum being between the antennæ. A similar remark will apply to *Urothoë*, of which indeed Gerstaecker himself says, "Kopf nur kurz schnabelförmig ausgezogen," as well as to *Cheirocratus*, Norman, which is here given as a synonym of *Lilljeborgia* [rather *Liljeborgia*] Sp. Bate, although in fact it cannot in classification be placed even beside it, if any attention be paid to the mouth-organs. *Acanthonotus*, Owen, being preoccupied, has been altered by Boeck into *Acanthonotozoma*.
- In Subfam. 5. Gammarina, *Cressa*, Boeck, which is given as a synonym of genus 37, *Stenothoë*, Dana, has been identified by G. O. Sars with *Danaia*, Sp. Bate. *Metopa*, Boeck, a genus in which there is a mandibular palp, is also given as a synonym of *Stenothoë*, in which the

mandible has no palp. The genus *Callimerus*, Stebbing, is a synonym of *Amphilochus*, Sp. Bate. *Calliope*, Leach, being preoccupied, must yield to *Calliopius*, Lilljeborg. Of the genera *Macleayia* and *Polycheria*, Haswell, named as genera related to *Isaea*, M.-Edw., the former is a synonym of *Wyvillea* (see Notes on Haswell, 1880), the latter is synonymous with *Tritixa*, Boeck. *Ceradocus*, Costa, in which the third uropods have both rami elongate, is here given as a synonym of *Melita*, Leach, although in regard to the third uropods of that genus it is rightly said, "ihre Innenlamelle stark verkürzt." *Goplana*, Wrzesn., is made a synonym of *Gammarus*, without notice of the curious coalescence of segments which distinguishes the former genus from the latter. *Amathia*, Rathke, being preoccupied, must give place to *Amathilla*, Sp. Bate, and not *vice versa*.

1886. GIESBRECHT, W.

Zoologischer Jahresbericht für 1885. II. Abtheilung. Berlin, 1886. Crustacea. pp. 8–60.

1886. KERVILLE, HENRI GADEAU DE.

La Faune de l'estuaire de la Seine. Caen, 1886. Extrait de l'*Annuaire normand*.—Année 1886. 24 pages.

In an "aperçu de la faune actuelle de l'estuaire," the Crustacea are said to number about sixty-five species, and "parmi les plus intéressantes" are included six species of Amphipoda, none of them new. Two other species are named in the following observation, "deux espèces très affines, les *Gammarus locusta*, L. et *Gamm. pulex*, L. = *Gamm. fluviatilis*, H. Milne-Edwards, sont très abondantes dans la Seine et à son embouchure. La première de ces deux espèces, le *Gammarus locusta*, se tient constamment dans l'eau salée, tandis que le *Gammarus pulex*, très difficile à distinguer du précédent, vit à la fois, d'après mes observations, dans les eaux salées, saumâtres et douces."

1886. KOEHLER, R.

Contribution à l'étude de la Faune littorale des îles Anglo-normandes (Jersey, Guernesey, Herm et Sark). Art. N° 4. Annales des Sciences naturelles. Tome XX.—N°s 5 et 6. Paris, 1886. pp. 11–62.

This is practically the same paper as that already noticed in the Note on Koehler, 1885, p. 566. For "Erysithroœus edrioplitalmus Sp. B.," "Erysithæus erythroplithalmus Sp. B." is here read, so that *Eurystheus erythrophthalmus* is clearly intended. Some other obvious corrections of nomenclature are requisite in the lists given.

1886. KOELBEL, CARL.

Crustaceen, Pyenogoniden und Arachnoideen von Jan Mayen, gesammelt von Dr. F. Fischer, Arzt der österreichischen Expedition auf Jan Mayen. Bearbeitet von Carl Koelbel. *Mit Tafel III. und IV.* Sonderabdruck aus dem Werke: die internationale Polarforschung 1882–1883. Die österreichische Polarstation Jan Mayen. III. Band. Wien, 1886.

Out of thirty-four species of Crustacea in the collection, seventeen were Amphipods, among which the following were conspicuous for the very large number of specimens met with:—

"*Egina spinosissima* Stimp., *Tritropis aculeata* (Lepechin), *Amathilla Sabinei* (Leach), *Gammarus locusta* (Linne), *Onesimus littoralis* (Kröyer), *Themisto libellula* (Mandt)." For these and the other species synonymy is given, with brief notes in general referring almost exclusively to measurements, depths, and the various localities from which the species are recorded.

- Of "*Amathilla Sabinei*" the largest example measured, without the antennæ, 37 mm. "The young, 6 mm. long, show considerable differences from the adult, especially in regard to the antennæ, telson and uropods. The antennæ are still short and comparatively thick; the flagellum of the upper antennæ with only 6 or 7 joints, of the lower with 8 or 9; the accessory flagellum with 2. The telson is shorter than the preceding segment; the two rami of the last uropods are strikingly unequal, the inner scarcely more than a third the length of the outer. On the other hand, there is already a clear indication of the dentate dorsal carina; and on the first three pleon-segments the edges could be already perceived running obliquely downwards to the hinder angle. In the two latter points, therefore, compared with the young form described and figured by Buchholz [1874], notwithstanding the nearly equal size of the specimens examined, there was here an advance in development."
- On "*Acanthozone cuspidata* (Lepechin)," Koelbel says, "For this curious species with its rows and rows of spines, Hoeek's criticisms on the figure published by Buchholz (Die zweite deutsche Nordpolfahrt, 1874, 2. B, Taf. XI.), as well in regard to the equipment of the first joint of the peduncle of the upper antennæ as also in respect to the form of the first joint in the three hinder peræopods and to the origin of the first medio-dorsal spine, are confirmed by two very large and well-preserved specimens, which were taken at a depth of 140 Metres. The first median dorsal spine arises from the front rim of the first peræon-segment, and, running almost parallel with the longitudinal axis of the body, lies with a gently undulating curve over the head, extending beyond it with the second half of its length. Also I see the hinder end of the telson with a very shallow emargination, by no means with an acute-angled slit, as figured by Buchholz." The possibility, however, should be borne in mind, that Buchholz may have had another species or a variety under examination.

1886. NORMAN, A. M.

Museum Normanianum, or a Catalogue of the Invertebrata of Europe, and the Arctic and North Atlantic Oceans, which are contained in the collection of the Rev. Canon A. M. Norman, M.A., D.C.L., F.L.S. III. Crustacea. Printed for private distribution. Houghton-le-Spring, March, 1886.

Four tables give the numbers of Crustacea under the following heads; "I. Total Crustacea described from the World in Milne-Edwards' *Histoire des Crustacés*," including Amphipoda 130, "II. Species in Milne-Edwards from the Area of this Catalogue," Amphipoda 95, "III. Species now described from the Area of this Catalogue," Amphipoda 663, "IV. Species in the collection of A. M. N.," Amphipoda 272. A preliminary remark is made that "while, on the one hand, it is certain that very many of the forms in Column III. will hereafter prove spurious or synonymous with others; on the other hand, we know little of the Amphipoda of the Western Atlantic, and nothing of the Ostraeoda free living Copepoda and other smaller Crustacea of that district, and very little of those of some other parts of the area." The total number of species in Column III. is 3209, and Mr. Norman remarks that "the Crustacea is the class which undoubtedly embraces more forms than any other outside the Insecta." The species of Amphipoda referred to in Table IV.

are named on pages 13–18, and numbered from 528 to 799; though this is only a list of names, with synonyms occasionally given, it has its value for the student as showing the names preferred by an accomplished carcinologist.

1886. PERRIER, EDMOND.

Les Explorations sous-marines. Ouvrage illustré de 243 gravures. Bibliothèque des écoles et des familles. Paris, 1886.

On pages 194, 195, a brief popular account is given of the Amphipoda. In "Fig. 103.—*Caprelle*.—Grossie deux fois," the two antennæ are represented of equal length. It is stated that "*l'Eurythenes magellanicus*, proche parent de la Crevettine des ruisseaux, atteint sur les côtes de la Terre de Feu plus de quatre centimètres de long." But Milne-Edwards, see Note, 1848, p. 225, gives this Amphipod a length of nine centimetres by a depth of three.

On pages 288, 289, in illustration of "formes antiques [arctiques] d'Amphipodes dans les grands fonds," the figures of "*Eusirus cuspidatus*, Kroyer," and "*Caprella spinosissima*, Norman," from Wyville-Thomson's Depths of the Sea are reproduced. The rarity of deep-sea Amphipods is discussed, and in connection with the "Talisman" expedition, the remark is made that "une seule fois, sur les côtes du Soudan, le chalut est revenu de 655 mètres avec son filet presque entièrement couvert de Caprelles."

The contents of the concluding chapter embrace the following headings:—"La population de la mer s'appauvrit à mesure que la profondeur augmente.—Distinction entre la zone paléozoïque et la zone abyssale.—Hypothèse de Louis Agassiz.—Prétendue origine polaire de la faune des grands fonds.—Théorie de Fuchs: la faune de la lumière et la faune de l'obscurité.—Arguments en faveur de l'origine littorale de la faune profonde.—Tous les rivages ont pris part à sa formation."

1886. POUCHET, G., et GUERNE, J. DE.

Sur l'alimentation des Tortues marines. Comptes rendus, Paris. 12 avril 1886. 2 pages.

In the stomach of *Thalassochelys caretta*, Linné, were found among other animals "plusieurs Crustacés amphipodes (*Hyperia medusarum*), absorbés sans doute avec la Méduse dont ils étaient parasites."

1886. ROBERTSON, DAVID, born 1806 (D. R.).

Jottings from my Note-book. [Read 31st March, 1885.] The Proceedings and Transactions of the Natural History Society of Glasgow. Vol. I. (new series) part ii. pp. 130–132. Glasgow, 1886.

Experiments made with *Talitrus locusta* appear to show that with this species "a few hours close confinement in fresh water is destructive to life." In sea-water they lived for days, and when kept for many days without food they never attacked one another. Eighteen enclosed in a thin muslin bag made no attempt to perforate. Mr. Robertson therefore questions the statements of Mr. Swain quoted by Bate and Westwood, i. p. 21, as to the *Talitri* lying piled together in cartloads, yet hopping and leaping about, devouring each other as if for very wantonness, and reducing a lady's handkerchief to a piece of open-work, apparently before it could be rescued from them.

1886. STEBBING, T. R. R.

On Crustaceans from Singapore and New Zealand. Proceedings of the Zoological Society of London, January 19, 1886. pp. 4–6.

Preliminary descriptions are given of *Byblis kallarthrus*, n. s., from Singapore, and of *Talorchestia tumida*, n. s., and *Pherusa cærulea*, n. s., the two latter so named by Mr. G. M. Thomson, who discovered them in New Zealand. The suggestion that Mr. Thomson's "*Pherusa*?" should be referred to the genus *Amphithopsis*, Boeck, is withdrawn in the full report on the species, 1887.

1886. THOMSON and CHILTON.

Critical List of the Crustacea Malacostraca of New Zealand. Part I. [Read before the Otago Institute, 10th November, 1885.] Transactions of the New Zealand Institute. Vol. XVIII. Art. XXXIII., pp. 141–159.

To *Tribe I. Læmodipoda*, four species are assigned, of which the fourth is given as:—

"*Cyamus ceti*, Martens (Voy. Spitzbergen, 1671), etc., etc. Chilton (Trans. N. Z. Inst., vol. xvi. p. 252).

"Hab. Parasitic on whales (*Virgina breviceps*), C. C. It appears to be common on various whales (and sharks?). I have it from several localities in the New Zealand seas, G. M. T. On small hump-backed whale, Napier, A. Hamilton."

Tribe II. Crevettina, has sixty-five species divided between three families:—

Fam. I. Corophiidae, has species 5–17, beginning with *Corophium contractum*, Stimpson, and ending with *Iphigenia typica*, Thomson. A note on "*Corophium crassicornis*, Bruzelius," says, "This species is taken along with *C. contractum*, and it is probable that they are only male and female of the same species. *C. Bonnelli* (Milne-Edwards) is probably the same as *C. contractum*.—C. C."

Fam. II. Orchestidae, begins with species 18, *Nicea neo-zelanica*, and ends with species 32, *Talitrus brevicornis*, M.-Edw. "Following Professor von Martens' suggestion," the authors say, "the specific name *neo-zelanicus* has been adopted in place of all the various forms of the word meaning 'of' or 'from New Zealand.'" Accordingly they change *Allorchestes novi-zealandiae*, Dana, into *Allorchestes neo-zelanica*, and *Nicea novæ-zealandiae*, Thomson, into *Nicea neo-zelanica*. But these changes in my opinion are neither lawful nor expedient.

Fam. III. Gammaridae, begins with species 33, *Gammarus fragilis*, Chilton, and ends with species 69, *Probolium mirsii* (Haswell). *Pherusa novæ-zealandiae*, Thomson, is called *Pherusa neo-zelanica*, and *Œdicerus novæ-zealandiae*, Dana, is called *Œdicerus neo-zelanicus*. 43. *Aora typica*, Kröyer, has for synonyms "♀ *Microdeutopus maculatus*, Thomson," "♂ *Microdeutopus mortoni*, Haswell," "♀ *Microdeutopus tenuipes*, Haswell," and "♂ *Microdeutopus maculatus*, Chilton." After species 60, *Anonyx corpulentus*, Thomson, comes the following entry:—

"61–63. *Lysianassa* sp.

"*Lysianassa kröyeri*, Bate (Brit. Mus. Cat. Amph., p. 65, pl. 10, fig. 4). Thomson (Trans. N. Z. Inst. vol. xi., p. 237).

"The above identification is extremely doubtful; the species referred to it has been found at Dunedin Harbour and Stewart Island, G. M. T. I have at least three species of the genus from Lyttelton and elsewhere, none of them referable to *L. kröyeri* without considerable doubt, C. C. [Descriptions of these are not published pending the publication of the *Challenger* report on the Amphipoda.]

"[In the 'Zool. Coll. of H.M.S. Alert,' p. 312, Mr. Miers refers to this genus and species as *Ephippiphora krögeri* (White), the original designation. Meanwhile the limits of the genus and the characters of the species require complete revision]." Compare Note on Miers, 1884.

To Tribe III. Hyperina, two families are assigned, embracing between them five species.

Fam. I. Phronimidae, contains *Phronima neo-zelandica*, altered from *Phronima novae-zealandia*, Powell, and *Themisto antarctica*, Dana, for which see Note on Thomson, 1879.

Fam. II. Platyscelidae, receives the species *Platyscelus intermedius*, Thomson, *Oxycephalus edwardsii*, Thomson, and *Phreatoicus typicus*, Chilton, with the following remarks upon the last:—"The systematic position of this singular crustacean is doubtful. In general appearance, I was inclined to place it among the *Amphipoda*, but from the fact of the first five pairs of *pleopoda* acting as branchial organs, and from the absence of any such organs attached to the *pereion*, Mr. Chilton places it among the *Isopoda*.—G.M.T." The list continues with "Suborder II.—Isopoda. Tribe I. Anisopoda. Fam. I. Tanaidæ," and probably the affinities of *Phreatoicus* will eventually prove to be rather with the Tanaidæ than with the Hyperina. I do not know what are the special reasons for classing it among the Platyscelidae.

1887. BARROIS, THÉODORE CHARLES, born February 10, 1857 (T. C. B.).

Note sur quelques points de la morphologie des ORCHESTIES suivie d'une liste succincte des amphipodes du Boulonnais. Lille, 1887. 20 pages, with plate.

The various forms assumed by the second gnathopods of *Orchestia deshayesi*, Audouin, are described and figured. The lower antennæ in that species have calceoli, whereas in "*Orchestia littorea* Montagu," Blanc's observation that they are not to be found is confirmed. *Orchestia brevidigitata*, Bate and Westwood, is shown to be in all probability only a young, though somewhat abnormal, form of *Orchestia littorea*. The list of species includes three Orchestidæ, eleven Gammaridæ, nine Corophiidæ, two Hyperidæ, four "Læmodiopodes," but it is recognised that several of the names given are probably synonyms.

1887. BOVALLIUS, C.

Systematical List of the Amphipoda Hyperiidea. Communicated to the Royal Swedish Academy of Sciences, 1885. Dec. 9. Bihang till K. Svenska Vet.-Akad. Handlingar. Band. 11. N:o 16. Stockholm, 1887. 50 pages.

For the group Bovallius gives the following diagnosis:—

"Head free, not coalesced with the first pereional segment.

"Eyes mostly large, often occupying the whole surface of the head.

"First pair of antennæ without secondary flagellum.

"Maxillipeds coalesced into a kind of operculum, without palps.

"Uropoda more or less laminar, forming natatory organs.

"Telson undivided."

The expression "more or less laminar" applied to the uropoda will only be accurate if understood to include some forms that are narrowly elongate and some that are prismatic. The group is divided into sixteen families, thus:—

Fam. I. TYRONIDÆ.

Gen. 1. *Tyro*, M.-Edw., 1840, with ten species, definitions being given of *Tyro cornigera*, M.-Edw., 1830, *Tyro pacifica*, n. s., *Tyro marginata*, Bovallius, 1885.

Fam. 2. LANCEOLIDÆ.

Gen. 1. *Lanceola*, Say, 1818, with six species, omitting Bovallius' own *Lanceola curticeps*, 1885, and changing "*Lanceola Clausii*," Bovallius, 1885, into "*Lanceola Clausi*."

Fam. 3. VIBILIDÆ, Claus, 1872.

Gen. 1. *Vibilia*, M.-Edw., 1830, with fifteen species, definitions being given of *Vibilia macropis*, n. s., *Vibilia gibbosa*, n. s., *Vibilia robusta*, n. s., "*Vibilia Kroeyeri*," n. s., *Vibilia longipes*, n. s., *Vibilia viatrix*, n. s., *Vibilia gracilis*, n. s., *Vibilia gracilenta*, n. s., *Vibilia armata*, n. s., *Vibilia pyripes*, n. s.

Fam. 4. CYLLOPODIDÆ.

Gen. 1. *Cyllopus*, Dana, 1852, with six species, of which the first is *Cyllopus magellanicus*, Dana, 1852, the second "*Cyllopus Batei*," a new name for the *Cyllopus magellanicus*, so called by Spence-Bate. *Cyllopus armatus*, n. s., and *Cyllopus levius*, n. s., are described. The genus *Cyllopus* is followed by "? Gen. 2. *Cyllias*, n. g. Typus: *Hyperia tricuspidata*, Streets," thus defined:—

"Head large, irregularly quadrangular from a lateral view. Flagellum of first pair of antennæ ovate, acute at the apex. Carpus of first pair of pereiopoda dilated, twice as broad as metacarpus. Carpus of second pair narrow, not produced into a process; metacarpus slightly produced into a pointed process on either side of the dactylus. Dactylus of seventh pair?" The single species is "*C. tricuspidatus*, H. Streets, 1877."

Fam. 5. PARAPHRONIMIDÆ.

Gen. 1. *Paraphronima*, Claus, 1879, with five species, of which the fourth, *Paraphronima pectinata*, n. s., is described; the fifth is given as "? *P. Gaberti*, H. Milne-Edwards, 1840," the reference being to Milne-Edwards' "*Daira Gabertii*." No mention is here made of "*Paraphronima Edwardsii*," Bovallius, 1885.

"Fam. 6. THAUMATOPSIDÆ, C. Bovallius, 1886."

"Gen. 1. *Thaumatops*, R. v. Willemoes-Suhm, 1874," with four species.

Fam. 7. MIMONECTIDÆ, C. Bovallius, 1885.

Gen. 1. *Mimonectes*, C. Bovallius, 1885, with three species.

Fam. 8. HYPERIIDÆ, Dana, 1852.

Gen. 1 *Hyperia*, Latreille, 1825, with ten species, "1. *H. medusarum*, O. F. Müller, 1776;" "2. *H. Latreillei*, H. Milne-Edwards;" "3. *H. Gaudichaudi*, H. Milne-Edwards, 1840;" "4. *H. Fabrei*, H. Milne-Edwards, 1840;" "5. *H. fera*, Dana, 1852;" "6. *H. rubescens*, Dana, 1852;" "7. *H. galba*, Montagu, 1813;" "8. *H. agilis*, Dana, 1852;" [9] "9. *H. minuta*, Edward, 1868;" "10. ? *H. mediterranea*, A. Costa, 1865."

Gen. 2. *Iulopis*, n. g., is thus defined:—

"Body hirsute. Head very large, deeper than long. Antennæ as in Hyperia. Pereional segments raised, forming rolls. The first two pairs of pereiopoda subcheliform, the spoon-like earpal processes compressed, narrow. Carpi of third and fourth pairs not dilated. Three last pairs subequal, metacarpi short but broad. Epimerals distinct. Uropoda short and broad. Telson large." To this genus are assigned two species, "*Iulopis Lovéni*," n. s., and *Iulopis mirabilis*, n. s.

Gen. 3. *Hyperoche*, n. g., is thus defined:—

"Body smooth. Head large, deeper than long. Antennæ as in Hyperia. Pereional segments even. First two pairs of pereiopoda cheliform, the carpal processes long, knife-like. Carpi of third and fourth pairs not dilated. Last three pairs subequal, metacarpi not elongated, narrow. Epimerals distinct. Uropoda tolerably short and broad. Telson large." To this genus five species are assigned as follows:—"1. *H. Kroeyeri*, C. Bovallius, 1885;" "2. *H. abyssorum*, A. Boeck, 1870;" "3. *H. Luethkeni*, n. sp;" "4. *H. Martinezi*, Fritz Müller, 1864;" "5. *H. prehensilis*, Spence Bate and Westwood, 1868." A definition is given of *Hyperoche Luethkeni*, the new species.

Gen. 4. *Tauria*, Dana, 1852, has one species, *Tauria macrocephala*, Dana.

Gen. 5. *Hyperiella*, n. g., is thus defined:—

“Body smooth. Head large, deeper than long, flattened anteriorly, antennæ as in Hyperia. Pereional segments even. Two first pairs of pereiopoda subcheliform, carpal processes as in Hyperia. Carpi of third and fourth pairs not dilated. Fifth pair longer than the following, with elongated metacarpns. Two last pairs with short metacarpi. Epimerals distinct. Uropoda elongated. Telson mediocre.” This genus has three species, “1. *H. antarctica*, n. sp.” with a definition; “2. *H. fusca*, Dana, 1852;” “3. ? *H. pupa*, A. Costa, 1853.”

Gen. 6. *Parathemisto*, A. Boeck, 1870, receives six species, “1. *P. abyssorum*, A. Boeck, 1870;” “2. *P. obliqua*, Kroeyer, 1838;” “3. *P. compressa*, A. Goës, 1865;” “4. *P. longipes*, n. Type. *Hyperia obliqua*, SPENCE BATE (nec KROEYER), 1862;” “5. *P. trigona*, Dana, 1852;” “6. *P. japonica*, n. sp.” of which a definition is given.

Gen. 7. *Euthemisto*, altered from *Themisto*, Guérin, 1828, which is preoccupied, receives the following six species, “1. *E. Gaudichaudi*, Guérin, 1828;” “2. *E. libellula*, Mandt, 1822;” “3. *E. antarctica*, Dana, 1852;” “4. *E. Guerini*, Spence Bate, 1860;” “5. *E. bispinosa*, A. Boeck, 1870;” “6. *E. Nordenskiöldi*, n. sp.” which is defined.

Gen. 8. *Thiemistella*, n. g., is thus defined:—

“Body smooth. Head mediocre, deeper than long. First three joints of flagellum of first pair of antennæ provided with olfactory processes. The second pair like that in Hyperia. First two pairs of pereiopoda subcheliform, with narrow, gauge-shaped carpal processes. Carpi of third and fourth pairs not dilated. Fifth pair are the longest, the following decreasing in length. Metacarpi of last three pairs somewhat elongated. Epimerals not distinct. Uropoda long and narrow. Telson mediocre.” This genus receives the single species, “*Th. Steenstrupi*, n. sp.”

Gen. 9. *Phronimopsis*, Claus, 1879, receives two species, “1. *Ph. spinifer*, Claus, 1879;” “2. *Ph. Sarsi*, n. sp.” the new species being as usual defined.

Fam. 9. PHRONIMIDÆ, Dana, 1852, is divided into two subfamilies.

“Subfamily 1. Dairellinae. *Diagn.* Head almost round. All the pereiopoda are simple, walking legs. Epimerals marked but not articulated.”

“Gen. 1. *Dairella*, n. g., is thus defined:—

“First and second pairs of pereiopoda simple, with straight, short dactyli. Carpi of all the pereiopoda elongated. Peduncles of uropoda very broad, with distant rami. Telson very short and broad.” It receives two species, “1. *D. californica*, C. Bovallius, 1885,” the reference being to Bovallius’ *Paraphronima californica*; “2. *D. latissima*, n. sp.”

“Subfamily 2. Phroniminæ. *Diagn.* Head conical. Fifth pair of pereiopoda are transformed into a strong prehensile organ. Epimerals coalesced with the pereional segments.”

“Gen. 2. *Phronima*, Latreille, 1802,” receives five species, “1. *Ph. sedentaria*, Forskål, 1775;” “2. *Ph. atlantica*, Guérin-Méneville, 1836;” “3. *Ph. Novæ Zealandiæ*, Powell, 1877;” “4. *Ph. spinosa*, n. sp.;” “5. *Ph. Colletti*, n. sp.”

“Gen. 3. *Phronimella*, Claus, 1872?” has the species “1. *Ph. elongata*, Claus, 1863;” “2. *Ph. filiformis*, n. sp.”

Family 10. ANCHYLOMERIDÆ.

Gen. 1. *Anchylomera*, M.-Edw., 1830, with six species. “Gen. 2. *Plrosina*, Risso, 1826,” receives the species “1. *Ph. seminulata* [semilunata], Risso, 1822;” “2. *Ph. Nicetensis*, H. Milne-Edwards, 1830;” “3. *Ph. longispina*, Spence Bate, 1862.” Gen. 3. *Primno*, Guérin-Méneville, 1836, has the one species “*P. macropa*, Guérin-Méneville, 1836.”

Fam. 11. “*Phorcinae*, Spence Bate, 1860 [1862].”

Gen. 1. *Phorcus*, M.-Edw., 1830, receives the species, “1. *Ph. Reynaudi*, H. Milne-Edwards, 1830;” “2. *Ph. hyalocephalus*, Dana, 1852;” “3. *Ph. Lovéni*, n. sp.” Gen. 2. *Lycognopsis*,

Claus, 1879, receives the species "1. *L. themistoides*, Claus, 1879;" "2. *L. Lindbergi*, n. sp."

Fam. 12. "TRYPHLENIDÆ, A. Boeck, 1870."

"Gen. 1. *Tryphæna*, A. Boeck, 1870," receives the species "1. *T. Malmi*, A. Boeck, 1870;" "2. *T. Nordenskiöldi*, n. sp." It will be noticed that Boeck's family Tryphanidæ and genus *Tryphæna* are here altered in spelling evidently on philological grounds, an improvement which in my opinion is both lawful and inconvenient, as multiplying synonyms and making the authority for the names uncertain. Sars' identification of Boeck's *Tryphæna* with *Lycea*, Dana, is tacitly rejected. Gen. 2. "*Thamyris*, Spence Bate, 1860," receives six species, "1. *Th. rapax*, Claus, 1879;" "2. *Th. globiceps*, Claus, 1879;" "3. *Th. eruscum*, Spence Bate, 1860;" "4. *Th. antipodes*, Spence Bate, 1860;" "5. *Th. inæquipes*, Dana, 1852;" "6. *Th. elegans*, n. sp." But the position of Dana's *Dairilia* *inæquipes* in this genus seems to warrant the transfer of all the six species to *Dairilia*, Dana, 1852, with the species *inæquipes* for the type. In Dana's work, under *Daira*, M.-Edw., for which Dana further on substituted *Dairilia*, the first species given is *Daira ? debilis*, the second is *Daira ? depressa*, the third *Daira inæquipes*. As apparently none of these belong to Milne-Edwards' genus, it is reasonable to take the species unmarked by a note of interrogation as the type of Dana's own genus.

"Gen. 3. *Thamneus*, n. g.," is thus defined:—

"Head small, depressed. Body broad, depressed. First two pairs of pereiopoda similar to those in *Thamyris*. Femora of fifth and sixth pair small. Seventh pair perfectly developed, with claw-formed dactylus. Telson distinctly articulating with last ural segment." This has the species "1. *Th. rostratus*, n. sp.;" "2. *Th. debilis*, Dana, 1852," the reference being to *Daira ? debilis*, Dana. Of Dana's *Daira ? depressa*, Bovallius does not seem to take account. Gen. 4. *Lycea*, Dana, 1852, has the following seven species, "1. *L. ocellacea*, Dana, 1852;" "2. *L. pulex*, Marion, 1875;" "3. *L. similis*, Claus, 1879;" "4. *L. robusta*, Claus, 1879;" "5. *L. nasuta*, Claus, 1879;" "6. *L. serrata*, Claus, 1879;" "7. *L. Stebbingi*, n. sp." It is not explained why the *Lycea pulex* of Marion and the *Lycea robusta* of Claus are upheld as distinct species. Gen. 4 [5]. *Paralycea*, Claus, 1879, has the species "1. *P. gracilis*, Claus, 1879;" "2. *P. Newtoniana*, n. sp.," definitions being given of both. Gen. 5 [6]. *Pseudolycea*, Claus, 1879, has one species, "*P. pachypoda*, Claus, 1879." Gen. 7. *Simorhynchus*, Claus, 1871, has the species, "1. *S. antennarius*, Claus, 1871;" "2. *S. Lilljeborgi*, n. sp."

Fam. 13. OXYCEPHALIDÆ, Spence Bate, 1862.

Gen. 1. *Glossocephalus*, n. g., is thus defined:—"Head anteriorly produced into a thick, rounded, tongue-shaped rostrum. Tibia, carpus, and metacarpus of fifth pair of pereiopoda very dilated, not tumid. Uropoda short and broad." This receives the species, "1. *G. Milne-Edwardsi*, n. sp.;" "2. *G. spiniger*, n. sp."

Gen. 2. *Oxycephalus*, M.-Edw., 1830, receives the species, "1. *O. piscator*, H. Milne-Edwards, 1830;" "2. *O. Clausi*, n. sp.;" "3. *O. tuberculatus*, Spence Bate, 1862;" "4. *O. pectinatus*, n. sp.;" "5. *O. latirostris*, Claus, 1879;" "6. *O. porcellus*, Claus, 1879;" "7. *O. pronoides*, n. sp.;" "8. *O. Steenstrupi*, n. sp.;" "9. *O. longiceps*, Claus, 1879;" "10. *O. typhloides*, Claus, 1879;" "11. *O. scleroticus*, H. Streets, 1878."

Gen. 3. *Leptocotis*, Streets, 1877, has the species, "1. *L. Lindströmi*, n. sp.;" "2. *L. tenuirostris*, Claus, 1871."

Gen. 4. *Tullbergella*, n. g., is thus defined:—"Head anteriorly produced into a short, sharp, wedge-shaped rostrum. Body thick and broad. First two pairs of pereiopoda strongly chelate. Femora of fifth and sixth pairs broadly dilated. Seventh pair rudimentary. Uros and uropoda short; interior rami not coalesced with the peduncles." This has one species, "*T. cuspidata*, n. sp."

Gen. 5. *Calamorhynchus*, H. Streets, 1878, has the one species, " *C. pellucidus*, H. Streets, 1878."

" Gen. 6. *Rhabdonectes*, n.," a name substituted for *Rhabdosoma* preoccupied, is thus defined:—" Body very elongated, rod-like. Head elongated, with a distinct neck, and a very long, needle-shaped rostrum. Tibiae and carpi are linear, but periodically intumesced in the female. Seventh pair rudimentary. Ovitectrices wanting. Peduncles of uropoda very elongated and narrow. Telson very long, needle-shaped."

The species assigned are " 1. *Rh. armatus*, H. Milne-Edwards, 1840;" " 2. *Rh. Whitei*, Spence Bate, 1862," the definitions given being inconsistent with Claus' view that the latter species is not distinct, but the male of the former. The name *Macrocephalus*, given to this genus by Spence Bate in 1858, had been used several times before, and therefore, like *Rhabdosoma*, must yield to *Rhabdonectes*.

Fam. 14. PRONOIDE, Claus, 1879.

Gen. 1. *Pronoë*, Guérin-Méneville, 1836, has the single species " *P. capito*, Guérin-Méneville, 1836." Gen. 2. *Eupronoë*, Claus, 1879, has five species, " 1. *E. maculata*, Claus, 1879;" " 2. *E. minuta*, Claus, 1879;" " 3. *E. brunnea*, Dana, 1852," (it being apparently taken for granted that *Eupronoë armata*, Claus, is the same species); " 4. *E. macrocephala*, n. sp.;" " 5. *E. ornata*, n. sp." Gen. 2 [3]. *Amphipronoë*, Spence Bate, 1862, has the one species " *A. cuspidata*, Spence Bate, 1862." *Amphipronoë serrulata*, Streets, 1877, is not noticed. " Gen. 3 [4]. *Parapronoë*, Claus, 1879," receives four species, " 1. *P. crustulum*, Claus;" " 2. *P. parva*, Claus, 1879;" " 3. *P. agilis*, n. sp.;" " 4. *P. atlantica*, n. sp."

Fam. 15. PARASCELIDÆ, Claus, 1879.

Gen. 1. *Thyropus*, Dana, 1852, is tacitly substituted for the genus *Tanyscelus* of Claus, and receives three species, " 1. *Th. diaphanus*, Dana, 1852;" " 2. *Th. sphæroma*, Claus, 1879," [this being Claus' *Tanyscelus sphæroma* (*Thyropus diaphanus*, Dana?)]; 3. " *Th. atlanticus*, n. sp."

Gen. 2. *Parascelus*, Claus, 1879, has the species " 1. *P. Edwardsi*, Claus, 1879;" " 2. *P. typhoides*, Claus, 1879;" " 3. *P. parvus*, Claus, 1879;" " 4. *P. nasutus*, n. sp."

Gen. 3. *Schizoscelus*, Claus, 1879, has the species " 1. *S. ornatus*, Claus, 1879;" " 2. *S. rapax*, H. Milne-Edwards, 1830," the reference being to Milne-Edwards' *Typhis rapax*.

Gen. 4. *Euscelus*, Claus, 1879, has one species, " *E. robustus*, Claus, 1879.

Fam. 16. EUTYPHIDÆ, Dana, 1852.

" Gen. 1. *Eutyphes*, Claus, 1879," (a note on the name, with which I by no means agree, explaining that " *Typhis* must be corrected to *Typhes*"), contains five species, " 1. *E. ovoides*, Risso, 1816;" " 2. *E. armatus*, Claus, 1879;" " 3. *E. globosus*, Claus, 1879;" " 4. *E. ferus*, H. Milne-Edwards, 1830," [*Typhis ferus*, M.-Edw.]; " 5. *E. forfex*, n. sp."

" Gen. 2. *Dithyrus*, Dana, 1852," which Claus makes a synonym of *Eutyphes*, is here re-established as a separate genus, tacitly superseding *Hemityphis*, Claus, of which it is made to include both the species; it receives in all four species, " 1. *D. faba*, Dana, 1852;" " 2. *D. tenuimanus*, Claus, 1879;" " 3. *D. crustulum*, Claus, 1879;" " 4. *D. stellatus*, n. sp."

" Gen. 3. *Paratyphes*, Claus, 1879," has the spelling altered from *Paratyphes*, Claus. It receives the species " 1. *P. maculatus*, Claus, 1879;" " 2. *P. Théhi*, n. sp."

Gen. 4. *Tetrathyphus*, Claus, 1879, has three species, " 1. *T. forcipatus*, Claus, 1879;" " 2. *T. rectangularis*, n. sp.;" " 3. *T. inscriptus*, n. sp."

Gen. 5. *Amphithyphus*, Claus, 1879, receives four species, the fourth being " *A. inermis*, n. sp."

The new genera here constituted are nine in number, independently of those re-established or named afresh. Short descriptions are given of forty-five new species. The work contains diagnoses of the several families, which it will be more convenient to notice in the descriptive part of this Report.

1887. BOVALLIUS, C.

Arctic and Antarctic Hyperids. With eight Plates. [Ur "Vega-expeditionens vetenskapliga iakttagelser," Bd. IV., Stockholm, 1887.] pp. 545-582.

In the introductory part Bovallius says, "In my opinion the limits of the zoo-geographical regions must be taken more generally with regard to truly pelagic animals than regarding the inhabitants of the depths and the shores. Therefore I shall fix the southern limit of the Arctic region at Lat. 60° N., and the northern limit of the Antarctic region at Lat. 50° S. Certainly a part of the Gulf Stream will thus be included within the limits of the Arctic region, but this seems to do but little harm, as is shown by the diagram of the geographical distribution of the species given below." Then tracing the history of the discovery of Arctic and Antarctic Hyperids, he says, "after reducing the various synonyms to the names, which in my opinion are the true ones, we find in the above cited literature altogether 15 species mentioned from the arctic region, viz., *Tyro borealis* G. O. Sars. *Lanceola Lovéni* C. Bovallius. *Lanceola Clausi* C. Bovallius. *Hyperia medusarum* O. F. Müller. *Hyperia Latreillei* H. Milne-Edwards. *Hyperia galba* Montagu. *Hyperoche Kroeyeri* C. Bovallius. *Hyperoche abyssorum* A. Boeck. *Parathemisto obliqua* Kröyer. *Parathemisto compressa* A. Göes. *Parathemisto abyssorum* A. Boeck. *Euthemisto libellula* Mandt. *Euthemisto bispinosa* A. Boeck. ? *Euthemisto Nordenskiöldi* C. Bovallius. *Tryphæna Malui* A. Boeck. From the antarctic region 10 species, viz., *Cylopus magellanicus* Dana. *Cylopus Lucasii* Spence Bate. *Cylopus Danae*, Spence Bate. *Tauria macrocephala* Dana. *Parathemisto trigona*, Dana. *Euthemisto Gaudichaudii* Guérin. *Euthemisto antarctica*, Guérin [Dana]. *Anchylomera abbreviata* Spence Bate. *Anchylomera antipodes* Spence Bate. *Thamyris antipodes* Spence Bate." In this paper the number of the Arctic species is raised to twenty-two, and the Antarctic to thirteen.

In the descriptive part, *Clydonia borealis*, Sars, 1882, becomes *Tyro borealis*. Brief descriptions are given of "*Tyro Clausi*," Pl. 40, figs. 1-3, "Syn. 1885. *Tyro Clausii*, C. Bovallius;" "*Tyro Tullbergi*," Pl. 40, figs. 4-10, "Syn. 1885. *Tyro Tullbergii*, C. Bovallius;" "*Lanceola Clausi*," Pl. 41, figs. 11-14, "Syn. 1885. *Lanceola Clausii*, C. Bovallius;" "*Lanceola Lovéni*, C. Bovallius," 1885; "*Lanceola serrata*, C. Bovallius," 1885; "*Vibilia Kroeyeri*, C. Bovallius," 1887; "*Cylopus magellanicus*, Dana, 1852;" "*Cylopus Lucasii*, Spence Bate, 1862. *Syn. 1862. Cylopus Lucasii*, Spence Bate;" "*Cylopus Danae*, Spence Bate, 1862;" "*Cylopus armatus*, C. Bovallius, 1887. Pl. 41, fig. 15-25;" "*Thaumatops longipes*, C. Bovallius, 1886," on which Bovallius remarks, "One specimen taken just at the southern limit of the Arctic region, at Lat. 59° 38' N.; Long. 5° 24' W. The other known specimen is taken off the western shore of the Australian mainland. Indeed a wide distribution for the species;" "*Mimonectes Steenstrupi*," Pl. 47, figs. 111-115. "Syn. 1885. *Mimonectes Steenstrupii*, C. Bovallius;" "*Hyperia medusarum*, O. F. Müller, 1776. Pl. 42, fig. 26-33;" "*Hyperia Latreillei*, H. Milne-Edwards, 1830. Pl. 42, fig. 34-39; Pl. 43, fig. 40-46; *Hyperia galba*, Montagu, 1813. Pl. 43, fig. 47-54;" "*Hyperoche Kroeyeri*, C. Bovallius, 1885," which would rather seem to be entitled to the name *Hyperoche medusarum*, since Bovallius gives as its earliest synonym "*Metocetus medusarum*, Kroyer," 1838; "*Hyperoche abyssorum*, A. Boeck, 1870. Pl. 44, fig. 55-62," the opinion of Sars, 1882, that this is the same species as the preceding, not being noticed; "*Hyperoche Luetkeni*, C. Bovallius, 1887. Pl. 44, fig. 63-71;" "*Hyperiella antarctica*, C. Bovallius, 1887. Pl. 45, fig. 72-80;" "*Parathemisto abyssorum*, A. Boeck, 1870. Pl. 45, fig. 81-89;" "*Parathemisto compressa*, A. Göes, 1865," transferred from *Themisto* by Boeck in 1870; "*Parathemisto obliqua*, Kroeyer, 1838," transferred from *Hyperia* by Bovallius in 1887; "*Parathemisto trigona*, Dana, 1852," in like manner transferred by

Bovallius from *Hyperia*; “*Euthemisto Gaulichauli*, Guériu, 1828,” with the synonym “*Euthemisto [Themisto] Gaulichaudii*, Guérin;” “*Euthemisto libellula*, Mandt, 1822. Pl. 46, fig. 90–96;” “*Euthemisto bispinosa*, A. Boeck, 1870. Pl. 46, fig. 97–103;” “*Euthemisto antarctica*, Dana, 1852;” “*Euthemisto Nordenskiöldi*, C. Bovallius,” 1887, with the synonym “*Euthemisto Nordenskiöldii*, C. Bovallius,” 1887, the observation being made that “possibly the *Hyperia Cyanex* Spence Bate (not Sabine) is identical with this species;” “*Anchylomera abbreviata*, Guérin-Méneville, 1836;” “*Anchylomera antipodes*, Spence Bate, 1862;” “*Tryphæna Malmi*, A. Boeck, 1870,” with the synonyms “*Tryphæna Malmii*, A. Boeck,” and “*Lycæa Malmii*, G. O. Sars;” “*Tryphæna Nordenskiöldi*, C. Bovallius, 1887;” “*Thamyris antipodes*, Spence Bate, 1862.”

As far as Bovallius has himself observed, the Arctic and Antarctic Hyperids do not include species of the Paraphronimidae, Phronimidae, Phorcidae, Oxycephalidae, Pronoidae, Scelididae, or Typhidae. From his whole review he draws the conclusions, that:—

- “ 1:o) the genus *Euthemisto* (and possibly also *Hyperia*) is common to both the arctic and the antarctic regions; as it has only few representatives in the Northern and Southern temperate regions and none in the tropical, its centra of development are most likely to be searched for in both the frigid zones;
- “ 2:o) the genus *Lanceola* is a true arctic form with only a few emigrants in the Northern temperate region;
- “ 3:o) the genera *Hyperia* and *Parathemisto* are cosmopolites, probably to be found in all the seas;
- “ 4:o) the genus *Cyllopus* is a true antarctic form with its centre in the American Antarctic Ocean;
- “ 5:o) the genus *Hyperiella* is a connecting link between *Hyperia* and *Euthemisto*, with same centre as *Cyllopus*;
- “ 6:o) the genus *Hyperoche* is an arctic form with its centre in the European Arctic Ocean;
- “ 7:o) the genera *Vibiliæ*, *Tharmatops*, *Mimonectes* and *Tryphæna* are occasional immigrants into the arctic region from the tropical and temperate regions, probably to be found occasionally also in the antarctic region (except *Mimonectes*);
- “ 8:o) the genera *Anchylomera* and *Thamyris* are occasional immigrants into the antarctic region, not likely to be found in the arctic realm.”

The Challenger collection, I may observe, shows the genus *Lanceola* to have an immensely wider range than that given above. One specimen was obtained, along with a specimen of *Plironima*, in lat. 50° 1' S.; another specimen was taken in lat. 8° 37' S. Bovallius himself records *Lanceola curticeps* from Cape Verde Islands and *Lanceola felina* from Tristan da Cunha. The genus *Hyperoche* is represented at the Cape of Good Hope.

For *Hyperia medusarum*, O. F. Müller, the following synonymy is given:—*Pulex cancriformis antennis brevissimis*, H. Ström, 1762; *Cancer medusarum*, O. F. Müller, 1776; *Gammarus medusarum* [O. F. Müller], J. C. Fabricius, 1779; *Plironima*, Latreille, 1818; *Talitrus cyanex*, Sabine, 1824; “*Hyperia Lesueurii*, Latreille,” in Desmarest, 1825, and in Milne-Edwards, 1840; *Hyperia spinipes*, A. Boeck, 1861 [1860] and 1872; *Hyperia exulans*, var., A. Goës, 1866 [1865].

To *Hyperia Latreillei*, M.-Edw., 1830, the synonyms assigned are *Lestrigonus exulans*, Kröyer, 1838; *Hyperia Latreillei*, M.-Edw., 1840; “*Hyperia galba* [Moutagu] Spence Bate,” 1862; “*Lestrigonus Kinahani*, Spence Bate,” 1862; *Hyperia exulans*, Kröyer (e. p.). Goës,” 1865; “*Lestrigonus Kinahani*. Spence Bate,” in Bate and Westwood, 1868; “*Hyperia medusarum* [O. F. Müller.] A. Boeck,” 1872.

To *Hyperia galba*, Montagu, 1813, the synonyms given are “*Hyperia galba*, Moutagu,” 1813, (which should rather be *Cancer Gammarus galba*); “*Lestrigonus exulans*. [Kröyer]. Spence Bate,” 1862; “*Hyperia medusarum* [O. Fabricius] Spence Bate,” 1862; “*Lestrigonus*

exulans. [Kroeyer]. Spence Bate and Westwood," 1868 [1863]; " *Hyperia galba*. Montagu. Spence Bate and Westwood," 1868 [1863].

To " *Hyperoche Kroeyeri*, C. Bovallius," the synonyms are *Metoecus medusarum*, Kröyer, 1838; *Hyperia medusarum* (O. Fabr.). Spence Bate, 1862; *Metoecus medusarum* (O. Fabr.), A. Boeck, 1870; *Tauria medusarum* (O. Fabr.), A. Boeck, 1872; " *Hyperia Kroeyeri*, C. Bovallius," 1885. Thus Bate's *Hyperia medusarum* is cited for two genera.

1887. CHEVREUX, ÉDOUARD.

Sur les Crustacés amphipodes de la côte ouest de Bretagne. 3 Janvier 1887. Paris. ("Communication faite à l'Académie de Paris, le 3 Janvier 1887.")

A short account is given of Amphipods obtained on the coast or by dredging "entre la pointe de Penmarch et l'embouchure de la Loire," an extent of about 100 marine miles. "La baie du Croisic" was specially examined, a locality prolific in forms in proportion to the varied nature of the ground which its waters cover. *Elasmopus latipes*, Boeck, was found by M. Chevreux to be a commensal of *Maia squinado*, together with *Isxa montagui*, M.-Edwards. Twenty other species, he says, are found more or less often on this crab. The total number of known species obtained in the region examined amounted to 115, to which are to be added three new forms, briefly described under the names *Ptilochirus tricristatus*, *Microprotopus longimanus*, *Microdeutopus armatus*. The last of these appears to come very near to *Stimpsonia chelifera*, Sp. Bate; see Ann. and Mag. Nat. Hist., ser. 5, vol. i. pl. v., 1878.

Incidentally "*Stenothoe monoculoides* Mont., *Atylus Swammerdamii* Milne-Edwards, *Amathilla Sabini* Leach" are recorded from the coast of Algeria.

1887. CHEVREUX, ÉDOUARD, et GUERNE, JULES DE.

Notes sur les Amphipodes des Côtes de France. (Extrait des *Procès-verbaux des séances de la Société Zoologique de France*, t. XI. séance du 28 décembre 1886.)

Fuller descriptions are here given by M. Chevreux of *Ptilochirus tricristatus*, n. s., *Microprotopus longimanus*, n. s., and *Microdeutopus armatus*, n. s., from the south-west of Brittany. M. de Guerne gives a list of thirty species of Amphipods from the north of France, but he notes that the *Podocerus falcatus*, Montagu, and the *Janassa variegata*, Leach, which he includes in the number mentioned, are regarded by Nebeski as the male and female of a single species. In my opinion the *Amphithoë podoceroides*, Rathke, and *Amphithoë rubricata*, Montagu, are also a single species, though some specimens are green and others red. Probably also the species named in the list *Podoceropsis rimapalmata*, Sp. Bate, and *Podoceropsis excavata*, Sp. Bate, are identical.

1887. CHEVREUX, E.

Catalogue des Crustacés Amphipodes marins du Sud-ouest de la Bretagne, suivi d'un aperçu de la distribution géographique des Amphipodes sur les côtes de France. (Planehe V.). Extrait du Bulletin de la Société Zoologique de France. t. XII. 1887. Paris, 1887. 54 pages.

Among the weeds and Hydroid zoophytes which commonly grow on the carapace of *Maia squinado*, M. Chevreux has been able to discover no less than twenty-three species of

Amphipods, the list beginning with "*Isaxa Montagu* Edw." and "*Laphystius sturionis* Kröy," and ending with "*Podalirius typicus* Kröy." Altogether the Catalogue enumerates 123 species, with notes principally on synonymy and locality. *Bathyporeia robertsoni*, Spence Bate, is upheld as a distinct species, with the remark that "chez ce dernier type, et quelle que soit sa taille, les articles du fouet des antennes inférieures sont assez allongés, et garnis de volumineuses baguettes olfactives, tandis que chez les *B. pelagica* de toutes tailles, ils sont extrêmement courts et ne présentent pas de baguettes olfactives bien apparentes." This distinction between specimens, however interesting in itself, is not, I think, of specific importance apart from other distinguishing characters. On *Urothoë marina*, Sp. Bate, M. Chevreux observes, "e'est certainement à tort que Meinert considère *U. marina* comme le mâle d'*U. brevicornis* Sp. Bate; chez toutes les *Urothoë*, les mâles se distinguent des femelles par leurs longues antennes inférieures. M. le Professeur Giard a signalé, il y a longtemps déjà, ce caractère sexuel. J'ai trouvé du reste un certain nombre d'*U. marina* portant des œufs." Of *Urothoë elegans*, Sp. Bate, he says, "e'est très probablement la forme mâle d'*U. marina*."

Of *Monoculodes longimanus*, Bate and Westwood, the antennæ are described and figured, Pl. V. figs. 1-2, and the suggestion is made that this species ought perhaps to be placed in a new genus.

"*Guernea*, nov. gen." in place of *Helleria*, Norman, preoccupied, is thus defined:—"Antennæ superiores flagello appendiculari instructæ. Pedes 1st et 2nd paris manu subcheliformi. Pedes 7th paris setis longis plumosis instructi. Segmentum abdominis 5th et 6th coalita. Pedes saltatorii ultimi paris 2 ramosi. Appendix caudalis laminiformis, profunde fissa." Of the type species, "*Guernea coalita* Norman," figures are given in the text on page 5, though referring to the description of the female on page 16.

Of *Elasmopus latipes*, Boeck, found on *Maia squinado*, it is remarked, page 21, that the male differs from the female (which Boeck describes) in the hand of the second gnathopods, which is much larger, and carries two or three large obtuse teeth on the lower margin, while in the female it is smooth. The hand of the male is represented, fig. 3, on page 6.

Protomedea pectinata, Norman, and *Protomedea hirsutimanus*, Spence Bate, are here referred to the genus *Ptilochirus*, Stimpson.

Ptilochirus tricristatus, n. s., is described at some length, parts of it being represented on page 6, fig. 4, and on Pl. V. figs. 3, 4.

Microprotopus longimanus, n. s., is likewise described, with illustrative figures on Pl. V. figs. 5-10, and fig. 5 on page 8 of the text.

Of *Microdeutopus armatus*, n. s., the two sexes are described, and illustrated by fig. 6 and fig. 7 on page 9 of the text, and Pl. V. figs. 6, 7.

Boeck's *Janassa variegata*, Leach, is here regarded as an independent species, with "♂ *Podocerus capillatus* Sp. Bate and Westwood," for a synonym.

Under "Erichthonius Edwards," a species is entered as "*Erichthonius abditus* Templeton, Trans. Eut. Soc. (*Cerapus*).—Sp. Bate and Westwood, Brit. sess. Crust. (*Cerapus*)."

"*E. bidens*, Costa, Cros. amfp. del. Regno di Napoli.

"♀ *Dercothoe punctatus* Sp. Bate and Westwood, Brit. sess. Crust.;" and a second species as, "*E. difformis* Edwards, Hist. des Crust.—Sp. Bate and Westwood, Brit. sess. Crust. (*Cerapus*)."

But from Templeton's description of the tube and habits of his species, it is probable that he had in view a true species of *Cerapus*. On the other hand I believe that the forms named respectively *Cerapus abditus*, *Cerapus difformis*, and *Dercothoe* (*Cerapus* ♀) *punctatus*, in the British Sessile-eyed Crustacea, are all synonyms of *Erichthonius difformis*, Milne-Edwards. I have found them all at Ilfracombe nesting together on tufts of *Chondrus crispus* in the same small rock-pool. There can be little doubt that the so-called *Cerapus abditus* of this family group is the most fully developed male; *Dercothoe punctatus* is

certainly the female, and *Cerapus difformis* is probably the male in a less advanced stage, or possibly a form assumed between the pairing seasons. The account given by Gosse of the tubes of his "*Cerapus Whitei*" taken at Ilfracombe (see Notes on Gosse, 1853 and 1855, and Brit. Sess. Crust., i. p. 468) induces me to suppose that his species ought not to be referred to *Siphonæcetes* but to be made an additional synonym of *Erichthonius difformis*.

Dryope irrorata, Sp. Bate, and *Dryope erenatipalmata*, Sp. Bate, are entered as separate species, but recognised as "deux formes très voisines." The fact that they were dredged together tends to confirm my opinion that they are forms of a single species.

In the Second Part, M. Chevreux gives, he says, "un résumé de tous les documents que j'ai pu réunir sur la répartition géographique des Amphipodes de nos côtes." In the notes he observes that Sp. Bate has not described any species of the name *Megamæra subserrulata*, as in Grube's list from Saint-Vaast-la-Hongre, 1869. Grube no doubt intended the species *Megamæra semiserrata*, Sp. Bate. Of the existence of the true *Microdeutopus anomalus* on the French coasts M. Chevreux is not certain; but in regard to the females of the genera *Microdeutopus*, *Aora*, and *Stimpsonia*, he promises soon to publish differentiating characters, based on the examination of living specimens at the moment of reproduction.

In "la liste des Amphipodes recueillis sur le littoral des Alpes-Maritimes par M. Adrien Dollfus," two new species are included:—" *Stenoiohoe Dollfusi* n. sp.", thus described:—" *Antennæ prælongatæ, subæquales; etiam inferiores flagellum elongatum gerentes. Pedes 2di paris manu elongata, plus quam duplo longiore quam lata, palma valde excavata, in parte anteriore dentibus duobus instructa* (fig. 8)," on page 10 of the text.

"*Guernea lavis* n. sp." thus described:—" *G. coalitæ valde affinis, sed carina segmentorum abdominis duorum posteriorum non denticulata differt.*" If there be no other distinction between the species than that here mentioned, I should be inclined to regard *Guernea lavis* as a synonym of *Guernea coalita*.

The "relevé général de nos espèces de la Méditerranée" includes the names of 75 species, beginning with "*Vibiliæ Jeangerardi* Lucas" and ending with "*Cyamus ceti*".

The "Distribution géographique et bathymétrique" is given in a tabular form, the "liste des espèces marines signalées sur les côtes de France" in this table numbering 174. As to the bathymetric distribution M. Chevreux says, "Enfin, le fait le plus frappant est la capture par l'*Expedition Norvégienne* 1876–1878, de l'*Hippomedon Holboelli*, dragué par 1215 brasses (2284 m.) de profondeur. Cette forme ne diffère de celle qui habite les fonds de 5 à 10 m. de la baie du Croisic que par l'absence des organes de vision." He remarks in a note that adult specimens of *Podoerurus falcatus*, *Amphithoe rubricata*, and *Proto ventricosa* coming from depths of 80 to 100 m. are much smaller than shore-specimens; but this observation cannot, I think, have any very general application.

The "Index bibliographique" contains sixty-six entries, beginning with Risso, 1816, and ending with J. de Guerne, 1887.

1887. CLAUS, C.

Die Platysceliden. Mit 26 lithographirten Tafeln. Wien, 1887.

The preface notices that hitherto sufficient attention has not been paid to sexual dimorphism and metamorphosis occurring in the Hyperina, and that accurate details in regard to the mouth-organs and inner structure of the Platyscelidæ have been entirely wanting.

The description of families, genera and species, pages 30 to 75, corresponds closely with that already published by Claus in 1879; see Note on Claus under that date. But the value of that description is here enormously increased by the addition of the beautifully executed and highly instructive plates.

The introduction, pages 3 to 29, comprises eight sections, as follows:—

1. Allgemeine Charaktere. Among these are noted the very striking differences presented by the antennæ in the two sexes, the absence of palp-appendages from the maxillæ as well as the maxillipeds, and the limitation of the triarticulate mandibular palp to the male sex.
2. Acusser Erscheinung und Körperform. Claus knows of no instance in this group in which the epimera or side-plates are absorbed in the segment as in the *Phronima*-group. The fifth and sixth pleon-segments are always coalesced, and sometimes the telson is united to them without suture.
3. Gliedmassen. The upper or front antennæ never have an accessory flagellum; observers have been misled by the produced peduncle in *Phorcus* to regard the principal flagellum as accessory. The second or hinder antennæ have the peduncle and flagellum not sharply defined the one from the other. In almost all cases the first or coxal joint is absorbed into the integument of the head. Claus notices that there are fine setæ along all the joints except the first of the folding antennæ of the male, but of their function he is not quite certain. The left mandible has a tooth-like process of considerable size, which is either absent or as a rule very weakly indicated on the right mandible. The first joint of the mandibular palp, which is generally small in the Gammarina, is generally large, and sometimes enormous, in the Platyscelidae. For the terminal part of the gnathopods various expressions are used, *Greifhand (Zange)* for a subchelate, *Scheere* for a chelate, hand and finger, *doppelte Scheere* when the chelate hand and finger are applied against an immovable process of the wrist, and *zusammengesetzte Scheere* when the chela is formed by a simple hand and finger applied against the process of the wrist. The marsupial plates of the female are generally lanceolate, yet widening at the free end, and occasionally so much so as to be like a stalked leaf.
4. Integument und Hautdrüsen.
5. Nervensystem und Sinnesorgane. The ganglia of the first two pereon-segments are drawn together and taken up into the group of the suboesophageal ganglion. The last pereon-ganglion is relatively small and united with the preceding, while the fourth pleon-ganglion, which provides for the hinder section of the pleon and in the Gammarina remains separate, is much reduced, united with the third ganglion, and placed in the third pleon-segment. In the more elongate species lateral nerves issue not only from the ganglion-masses, but also from the longitudinal commissures in the pereon-part of the ganglionic chain. In the genera *Eutyphis*, *Thamyris*, *Simorhynchus*, and the Oxycephalidae there are centrally from the origin of the great front antennary nerves two short nerves, each of which provides for a sense-organ lying just in front of the brain, which is evidently an organ of hearing. The contents of the vesicle in question are a clear watery fluid and what is obviously an otolith.

Of the eyes Claus says:—"Eine Facettenbildung der Cuticularbekleidung habe ich in keinem Falle beobachtet, vielmehr bildet, wie bei *Phronima*, die zarte durchsichtige Körperdecke über dem Auge eine gleichmässige Cornea. Immerhin tritt bei tiefer Einstellung eine sechseitige facettenähnliche Felderung hervor, bedingt durch den optischen Querschnitt der paarigen Krystallkegelzellen, deren zwei grosse Kerne erhalten bleiben. Oberhalb der Krystallkegelzellen breitet sich eine deutlich nachweisbare Hypodermis als Matrix der Cornea aus, welche der schon von *Claparède* vertretenen und von *Grenacher* aufrecht erhaltenen Auffassung entgegensteht, nach welcher überall die Bildungszellen der Krystallkegel (mit den Semper'schen Kernen) zugleich die Matrixzellen der Chitin Haut seien."

On the Spürfäden or Riechhaare he says that here and there the end is open in consequence of the breaking off of the point, and that this may have led to the erroneous view "als besäßen die Riechhaare an der Spitze Oeffnungen." For the latter view see Note on Leydig, 1878, with whom Hoek, 1879, agrees.

6. Darmcanal und Anhangsdrüsen. Among many other statements of importance, Claus says, "der Mitteldarm, in welchen der Vormagen oft mit verengtem Trichter einführt, beginnt überall mit der Einmündung eines einzigen Paars von Leberschläuchen, deren Umfang und Form im Verhältniss zu dem medianen Darmrohre mannigfach wechselt," and "Anhänge des Afterdarmes oder am Ende des Mitteldarmes sind mir in keiner Gattung bekannt geworden."
7. Herz, Gefäss-system und Athmung. In the Platyscelidæ the heart has only two pairs of venous ostia, the slits being wanting in the second peraeon-segment; besides the two aortas it has three pairs of lateral arteries, occurring respectively in the third, fourth and fifth segments. Of the branchial vesicles Claus says, "mit Ausnahme der männlichen *Rhabdosomen*, welche nur zwei Paare von Kiemen am fünften und sechsten Beinpaaren der Brust tragen, finde ich die Fünfzahl der Kiemenpaare überall eingehalten." *Lycæopsis*, as Claus himself subsequently shows, is another exception, but whether that genus should hold a position among the Platyscelidæ he is doubtful. Bovallius places it in the family Phorcidae.
8. Geschlechtsorgane. Entwicklung. Claus mentions by the way that he is unable to corroborate the statement of Fr. Müller that the young of *Hyperia* leave the egg-sheath without abdominal feet. From a comparison of young with adult forms he draws the conclusion that the Hyperidæ have developed from the Gammarina, and that from the Hyperidæ have sprung the Platyscelidæ as an aberrant offshoot.

1887. HANSEN, H. J., and HOLM, TH.

Oversigt over de paa Dijmphna-Togtet indsamlede Krebsdyr af H. J. Hansen, in Dijmphna-Togtets zoologisk-botanische Udbytte. Avec des résumés en français. Udgivet paa Bekostning af Ministeriet for Kirke- og Undervisningsvaesenet af Kjøbenhavns Universitets zoologiske Museum ved Dr Chr. Fr. Lütken. Kjøbenhavn, 1887.

The account of the Amphipoda extends from page 210 to page 234, and is illustrated on Plates XXI. and XXII., of which the *explicatio* is given on pages 282, 283. Spence Bate's view is adopted that the so-called epimera are the first joints of the thoracal legs, the joints of which are accordingly in the descriptions numbered from one to seven, not, as many authors prefer, from one to six. Forty-one species are mentioned. *Onisimus caricus*, n. s. (Tab. xxi, Fig. 6-6e), is said to be very near to *Onisimus edwardsii*, Krøyer (Tab. xxi, Fig. 8, 8a), but distinguished from it by its superior size, and among other things especially by the second gnathopods, thus described, "in utroque sexu articulo sexto quam articulo quinto vix duplo breviore, subtriangulo, ad apicem versus nonnihil dilatato, dimidio longiore quam latiore, margine anteriore quam posteriore nonnihil longiore, apice emarginato; unguis (e articulo septimo et ungue vero formato) sat robusto, valde curvato, ut intervallum inter unguem et articulum sextum praestet." Besides the differences of the antennæ in the male, female, and young of the Lysianassidæ, Dr. Hansen says that much difference may be found between the second gnathopod of the male and that of the female. This he illustrates by *Onisimus brevicaudatus*, n. s. (Tab. xxi, Fig. 7-7e), in which the female has the second gnathopod nearly as in the closely allied *Onisimus caricus*, while in this limb of the male "articulus sextus alio modo formatus est, non triangulus, marginibus ad apicem versus subparallelis, apice oblique truncato, ut margo anterior brevior quam margo posterior evadat, 'ungue' breviore et graciliore in medio margine apicali sito." *Onisimus affinis*, n. s. (Tab. xxi, Fig. 9, 9a), is said to be very near to *Onisimus edwardsii*, the distinctions being apparently only drawn from measurements of

the second gnathopods and telson. "*Eusirus Holmii*, n. s. (Tab. xxii, Fig. 1-1b), is said to be very like *Eusirus cuspidatus* in respect to the carina and dentation of the back and in the form of the hands, while it much resembles *Eusirus longipes* by the length of its legs, which, however, are considerably longer than in the last-named species, but it is said to differ from both the species mentioned by its specially long upper antennæ, by the size and form of the three first pairs of epimera, and in several other respects. The length of an adult female was 53 mm. *Microdentopus arcticus*, n. s. (Tab. xxii, Fig. 3), is also remarkable for its size, attaining a length of 29 mm. Dr. Hansen was under the impression moreover that none of his specimens were full grown.

A description and figures are given (Tab. xxi, Fig. 5-5c) of the maxillæ and maxillipeds of *Socarnes bidenticulatus* (Sp. Bate). Of "*Stegocephalus ampulla* (Phipps) (Tab. xxi, Fig. 10-10c)" the mandibles and maxillæ are described and figured. In a footnote, however, Dr. Hansen says that, judging by the length in comparison with the depth of the fourth side-plate, and by the form of the widened second [first free] joint of the fifth pereopod in Phipps' figure, as well as by the size of the animal, Phipps' species must be the same as *Stegocephalus kessleri*, Stuxberg. His own specimens ought therefore, he says, to have been named *Stegocephalus inflatus*, Krøyer. Dr. Hansen also states that *Stegocephalus kessleri*, Stuxberg, is pretty certainly the same as *Stegocephalus ampulla*, forma altera, Goës.

Of "*Acanthostephia Malmgrenii* (Goës) (Tab. xxi, Fig. 11, 11a.)," the maxillæ are described and figured.

"? *Oediceros microps* G. O. Sars (Tab. xxi, Fig. 12)," is thought to be possibly an intermediate form between *Oediceros microps*, Sars, and *Oediceros macrocheir*, Sars.

Boeck's *Acanthonotozoma* is altered into *Acanthonotosoma* for the three species, *cristatum* (Owen), *serratum* (O. Fabr.), and *inflatum* (Krøyer). Of the last species Hansen's largest specimen was "18,5 mm" in length, and the postero-lateral angles of the first two pleon-segments were acute, making it doubtful whether Boeck's *Acanthonotozoma inflatum*, 6,5 mm long, and with these angles rounded, is really the same as Krøyer's species.

To *Acanthozone cuspidata* (Lepechin) the synonyms assigned are "*Oniscus cuspidatus* Lepechin," "*Amphithoe Hystrix* Krøyer," "*Acanthozone cuspidata* Boeck," and the species is said to be easily distinguishable from all other Amphipods, without notice of the doubt thrown upon this point by E. J. Miers. See Note on Lepechin, 1780.

Of "*Gammarus Locusta* (Lin.). (Tab. xxii, Fig. 2-2b.)" the maxillæ and maxillipeds are figured, with a view more particularly to show the basal joints.

Melita dentata (Kr.) is recorded, and "*Gammarus dentatus* forma altera Goës" is described as a new species "*Melita Goësi* n. s. (Tab. xxi, Fig. 13)." It is a little singular, if the two forms are really distinct, that a single specimen of each should have been obtained at the same spot, the two specimens also closely agreeing in size; but the differences are said to be numerous.

"*Melphidippa spinosa* (Goës)" is identified with "*Gammarus spinosus* Goës," but doubtfully with Boeck's *Melphidippa spinosa*.

A female *Podocerus* is named "(?) *Podocerus brevicornis* G. O. Sars." Nine specimens of "*Egina spinosissima* Stimpson" were obtained, and Dr. Hansen observes that the species from the "Vega" expedition named *Egina echinata* is obviously this species.

Of "*Caprella spinosissima* Norman (Tab. xxii, Fig. 4, 4a.)" the maxillæ are described and figured, and the statement made that on the second pair and three hindmost pairs of legs there is a short but well chitinized and movable first joint. This species should rather be called *Caprella horrida*, Sars. See p. 571, in Note on Sars, 1885.

The other species here recorded are named "*Parathiemisto abyssorum* A. Boeck;" "*Socarnes Vahlii* (Kr.);" "*Anonyx lagena* Kr.;" "*Anonyx gulosa* Kr.;" "*Orchomene pectinatus* G. O. Sars;" "*Harpinia plumosa* (Krøyer);" "*Halicreion latipes* G. O. Sars;" "*Aceros*

phyllonyx (M. Sars);” “*Atylus Smittii* (Goës);” “*Halirages fulvocinctus* (M. Sars);” “*Tritropis Helleri* Boeck;” “*Tritropis fragilis* (Goës);” “*Tritropis inflata* G. O. Sars;” “*Gammaracanthus loricatus* (Sab.);” “*Ampelisca Eschrichtii* Kr.;” “*Ampelisca macrocephala* Lilljeb.;” “*Haploops tubicola* Lilljeb.;” “*Haploops laevis* Hoek;” “*Byblis Gaimardi* (Kr.);” “*Autonoë longipes* (Lilljeb.)” “*Unciola irrorata* Say.”

The “Résumé,” pp. 508–511, mentions three other species, “*Orchomene minutus* (Kr.);” “*Aristias tumidus* (Kr., non Boeck);” “*Amphithopsis glacialis* n. sp.,” to be described in a work on the Malacostraca of West Greenland. In discussing the second maxillæ of the Malacostraca, Dr. Hansen says, “dans les Amphipodes, les éléments de la mâchoire sont un peu réduits: le quatrième article fait défaut, ou bien se confond avec le troisième, qui se prolonge en un grand lobe.” Of the first maxillæ he says, “le premier article, dans les types que nous venons de nommer (excepté dans les *Caprella*), est muni d'un puissant lobe, et la partie basale de ce lobe se continue, dans les *Boreophausia*, *Mysis*, et *Diastylis*, en un prolongement lamelliforme dirigé en dehors, sur la face inférieure de la mâchoire. Le second article est toujours petit et sans lobe; le troisième est grand et se prolonge en un grand lobe. La mâchoire n'a pas plus d'articles dans les Isopodes et les *Mysis*; dans les *Diastylis* et les *Boreophausia*, on trouve un quatrième article sous forme d'une palpe dirigée en avant ou (dans les *Diastylis*) en arrière; les Amphipodes présentent un quatrième et cinquième article comme une palpe biarticulée, dirigée en avant.”

M. Th. Holm, who accompanied the expedition, gives at pp. 495, 496 interesting notes on the colours of the living Amphipods. *Socarnes bidenticulatus* “blanchâtres avec une coloration rouge foncée sur le milieu du dos et descendant un peu des deux côtés du corps.” *Stegocephalus inflatus* “était le plus souvent d'un brun de bronze reluisant, avec des taches blanches sur les anneaux du corps et sur les épimères.” *Acanthonotosoma inflatum* “attirait l'attention surtout par sa belle couleur cramoisie, avec ou sans des ceintures transversales plus claires. *Gammarus locusta* “était presque blanc, aux yeux noirs.” *Acanthozone cuspidata* “se distingue . . . par . . . sa couleur bigarrée, blanchâtre avec des ceintures transversales d'un brun foncé, et par ses grands yeux d'un rouge clair.” *Acanthonotosoma serratum* is “blanc avec des bandes transversales d'un rouge jaunâtre, l'*Halirages fulvocinctus*, d'un blanc de neige avec une large ceinture transversale d'un rouge vif au milieu du thorax.” “*Acanthostephia Malmgreni*, gris.” “*Eusirus Holmii*, d'un rose pâle, presque diaphane.” Their abundance in the region explored (about lat. 71° N., long. 62° E.) may be estimated from the fact which he mentions that, “quand on descendait, jusqu'au fond, des chiens morts et qu'on les remontait au bout de vingt-quatre heures, non seulement ces derniers, mais encore le grand sac de toile à voiles où ils étaient placés, étaient garnis de *Socarnes bidenticulatus* et de deux ou trois espèces d'*Onisimus* si bien qu'on ne pouvait, littéralement parlant, distinguer ni chien, ni sac.”

[A few papers which have not been described in their proper places will be found recorded in the Appendix.]

DESCRIPTION OF GENERA AND SPECIES.

Class CRUSTACEA.

Subclass MALACOSTRACA.

Thoracipoda, H. Woodward.

Order EDRIOPHTHALMA, Leach, 1815.

Tetradécapodes, de Blainville, 1816.

Arthrostraca, Burmeister, 1837.

Choristopoda, Dana, 1846.

Suborder AMPHIPODA, Latreille, 1816.¹

Tribe I. AMPHIPODA GAMMARINA.

Head not coaleseed with the first segment of the peræon.

Peræon of seven distinct segments, very rarely reduced to six (*Dulichia*) by the coalescence of the last two.

Pleon of six distinct segments bearing appendages, and the telson; rarely with two (*Atylus*), or with three (*Goplana*), of the segments coalesced, or with only five distinct segments and five pairs of appendages (*Dulichidæ*); the telson (probably) never absent.²

Eyes generally two, sometimes four (*Ampelisca*) or none (*Byblis abyssi*, Sars, &c.), seldom very large or projecting much above the surface of the head; generally with many component ocelli, sometimes simple (*Ampeliscidæ*).

Antennæ, two pairs; the proportions not constant; the upper often having a secondary flagellum, well-developed or rudimentary, but very rarely (*Gammarus sarmatus*, Dybowsky) of great length.

Maxillipeds generally with two pairs of plates, neither pair coaleseed, and a four-jointed palp; the palp rarely with only three joints (*Normania*), or only two (*Lafystius*).

¹ For definitions, see Glossary, and Notes on Latreille, 1816 (p. 95), 1817 (p. 95), 1829 (p. 137); Burmeister, 1837 (p. 170); Milne-Edwards, 1840 (p. 184); Dana, 1852 (p. 256); Claus, 1880 (p. 508), 1884 (p. 553); Gerstaecker, 1886 (p. 579).

² But see, in Bibliography, Notes on *Iridium*, Grube, 1864 (p. 348), *Ichthyomyzocetus*, Hesse, 1873 (p. 417, and in Appendix), the *Orchestidæ*, Zaddach, 1878 (p. 485).

The side-plates of the peraeon varying greatly in size, but those of the sixth and seventh segments never very large.

Pleopods generally having the inner angle of the peduncle armed with two or more small coupling spines, and the first joint of the inner ramus furnished with some apically-cleft spine-like setæ.

Family ORCHESTIDÆ, Leach, 1814.

The following is the definition of the family by Boeck, 1872 :—

“ *Upper Lip* strong, rounded at the apex.

“ *Mandibles* very strong, curved, much dentate at the apex, carrying a row of plumose spines; inner appendage strongly dentate; molar tubercle very prominent; palp wanting.

“ *First Maxillæ* armed with strong pectinate teeth; inner plate clongate, narrow, with two plumose setæ at the apex; palp small or wanting.

“ *Second Maxillæ* with broad plates.

“ *Maxillipeds* with the outer plate small, broad, ovate, having on the margin slender spines or setæ; the inner plate elongate, broad, apically truncate, armed with three strong teeth; palp strong and broad, the last joint sometimes wanting.

“ *Body* compressed; back rounded; side plates well developed.

“ *Upper Antennæ* more or less shorter than the lower, without accessory flagellum.

“ *Lower Antennæ* with the two anterior joints very short but pretty broad.

“ *Uropods* short and strong; the first and second biramous, the last pair one-branched.

“ *Telson* short and thick.”

Genus *Orchestia*, Leach, 1813.

Leach, in 1813, in the first division of his family Gammarini, defines *Talitrus* as having “Anterior pair of feet larger than the second pair; no hands,” and *Orchestia* as having “Two anterior pair furnished with a movable thumb, which is capable of being bent on the edge of the hand; second pair largest, having a compressed hand.” For further definitions, see Notes on Leach, 1815 (p. 90), Friedrich Müller, 1848 (p. 226), J. F. Brandt, 1851 (p. 244), Dana, 1852 (p. 257). Boeck’s definition, 1872, includes “*Maxillæ 1mi paris palpo destitutæ*,” but some species of *Orchestia*, if not all, have a rudimentary palp on the first maxillæ; it also includes “*pedes maxillares palpis per-brevibus latis; articulo palpi 2do sursum dilatato, 4to absenti*,” in which statement it would probably be more accurate to substitute *rudimentari* or *tuberculiformi* in the place of the word *absenti*.

Orchestia selkirkii, n. sp. (Pls. I., II.).

The Head is somewhat longer than the first segment of the pleon; rostrum rudimentary. Peræon moderately dilated; beyond its fourth segment the body tapers rather rapidly to the telson. Segments not greatly differing in length; first of the pleon the longest. The first three pleon-segments are postero-laterally squared, the angles very slightly outdrawn, and the margins above them serrate upwards.

Eyes roundish to oval, conspicuously black in the spirit specimens; distance between the two equal to the smaller diameter of one.

Upper Antennæ.—Three joints of peduncle small, successively decreasing much in thickness. Flagellum shorter than peduncle. In the male specimen figured the flagellum on one side had nine joints, that on the other only eight. In the female the flagellum had only six joints.

Lower Antennæ.—Last two joints of peduncle long and stout, the last thinner than the preceding. The tapering flagellum consists of about twenty-eight joints, all except the last one or two distally widened.

Upper Lip with rounded distal border minutely furred, the hairs on either side inclining towards the centre of the margin.

Mandibles.—The cutting edge of each mandible ends in a strong double tooth, preceded in the left-hand mandible by four, in the right-hand by three or four smaller teeth; the secondary plate, on the left mandible, resembles the cutting edge, except that it ends in a single tooth and is less powerful; on the right mandible it has a bidentate termination, the ridges of the double tooth being minutely denticulate, and preceded by three inconspicuous teeth. The spine-row consists of four sinuous plumose bristles, two stout and two thinner ones. The prominent molar tubercle has the oval face set with numerous rows of denticles. There is a long plumose bristle at one corner, and a sort of hairy tuft at the opposite corner. I can find no trace of any rudimentary articulated palp, such as is figured by Savigny for *Orchestia montagui* and Guérin for "*Orchestia gammarella*." There is a prominent lobe rising just above the base of the molar tubercle, obviously connected with the articulation and movement of the mandible, which has perhaps in other species suggested the presence of a palp.

Lower Lip.—The principal lobes very slightly deliseent; the mandibular processes¹ broadly rounded, not projecting far.

First Maxillæ.—The inner plate narrow, tipped with two plumose bristles, its inner edge nearly straight, the other edge sinuous; the broad outer plate is distally edged with nine denticulate teeth in a double row. Just below the broadest part of the plate, within the outer rim, springs a minute palp consisting of one slender joint, at the tip of which a little pimple may be the rudiment of a second joint or of a spine.

¹ See Note on Schiødte, 1875 (p. 449).

Second Maxillæ.—Outer plate longer and slightly broader than the inner one, distally fringed with a mass of slender curved spines, the outer ones the longer; the inner plate has the distal fringe of short spines passing in an even curve some way down the inner margin to a plumose bristle much longer and stouter than the spines; below this there are some hairs, as there are also on the other margins of both plates.

Maxillipeds.—Inner plates rather long, with plumose bristles passing up the inner margin, within the distal, and down part of the outer margin; three short, strong teeth on the distal margin, and one having its insertion just below the inner angle of the plate. Outer plates short, not reaching beyond first joint of palp, short spines within distal margin and upper part of inner margin; other spines, of various sizes, but none large, singly or in groups, on the outer side of this and the preceding joint. First joint of palp with outer border much longer than the inner; second joint distally lobed on the inner side; inner margin of this and the next joint fringed with short spines; all three joints with small rows of spines on the outer sides; the fourth joint rudimentary, a tubercle, tipped with spines.

In the so-called *triturating organ* at the anterior end of the stomach a row of twenty-eight spines is found, becoming longer and thinner at both ends of the row.

First Gnathopods.—The side-plate almost concealed by that of the second segment; spines on its lower border, and on the inner side, and on an inner lobe where the first free joint articulates. In the male, first joint broad except at its origin; fourth joint postero-distally lobed, much longer than fifth; hand with a conspicuous postero-distal lobe; finger short, closing over the slightly concave palm so as to reach the inside of this lobe; distributed over all the joints on margins and surfaces are spines with sub-terminal accessory threads; a row of minute straight hairs on the palm; and a stronger spine where the tip of the finger closes down; some fine spines on the finger at the origin of the nail, where also the inner margin of the finger slightly projects. In the female, the first joint almost parallel-sided, the fourth joint a long narrow triangle, with hinder (especially the distal) spines prominent; hand widening a little distally, the finger projecting beyond the slightly convex palm.

Second Gnathopods.—The side-plate fringed below with spinules; the hinder margin in this and the next two pairs of side-plates having a projecting process for purposes of articulation; branchial vesicle much broader than long, upper border very sinuous; in the male first joint shorter than hand, broadest near its origin, lower edge slightly lobed; second joint antero-distally lobed on the outside and medio-distally on the inside; third joint squared; wrist a small cup, almost lost in the outswelling of the hand beyond it; the immensely powerful hand broadest near its origin; palm sinuous, bordered with spines of various sizes, and forming a groove on the inner side into which the point of the finger closes down; the finger itself strong, inner margin fringed with spinules, and forming a double concavity, that near the tip leaving an open space between finger

and hand, even when the two are tightly closed together. The spines on this limb, except on the palm of the hand, are few and small. In the female, the first joint is more narrowed distally than in the male, the second joint is lobed on the front margin; the third and fourth joints much resemble in form the corresponding joints in the first gnathopod of the male, but the hinder margin of the fourth joint is here thin and without spines; the hand, narrow at its origin, swells out to a postero-distal lobe beyond the palm, without spines on the thin, curved hinder, or nearly straight front, margin; a row of spines along each side, a group close to the hinge of the feeble finger, spinules along the palm, over which the finger closes tightly; fur on the thin lobe which projects beyond the palm. Wrist rather longer than hand and shorter than first joint.

First Peraopods longer than second; spines on both edges of all joints but the second; third joint longer than any but the first, fourth not much, sometimes not at all, longer than fifth, both spinous; finger short, with curved nail; branchial vesicle with a large basal, and a narrow terminal, lobe.

Second Peraopods very similar to first, but dimensions smaller in regard to length, the side-plate somewhat broader, the fourth and fifth joints equal in length; the finger in both sexes differing from that of the first pereopod in having its hinder margin sinuous. There is a corresponding irregularity of outline in this margin in the second pereopods of *Talitrus locusta*, of *Orehestia gammarellus*, and in an exaggerated form in *Talorehestia tumida*, G. M. Thomson; but not, so far as I know, in *Hyale* or *Hyalella*.

Third Peraopods very much shorter than the two following, though more than half the length of the fifth pereopod; front lobe of the side-plate nearly as deep as that of the fourth segment; branchial vesicle with a small basal, and a large oval terminal, lobe; first joint oval, with spines on front, and spinules on hinder, margin; third, fourth, and fifth joints spined on both edges, not differing greatly in length, decreasing successively in breadth; finger small, with curved nail.

Fourth Peraopods.—Hinder lobe of side-plate larger than the front one; branchial vesicle with a short narrow basal and a long narrow terminal lobe, the latter curving first backwards and then downwards; first joint a long oval, third and fourth joints subequal, fifth rather longer and considerably thinner; finger slender, longer than that in the third pereopods.

Fifth Peraopods.—Side-plate not bilobed, deeper behind than in front; first joint broader than that of the fourth pereopods, which in most respects these closely resemble, but with the third, fourth, and fifth joints longer.

Pleopods.—Peduncles long and slender, longer than the rami, wide apart at the base, curving in towards one another, armed with a few small spines; the joints of the rami numbering from seven to eleven; the setæ very finely plumose; I cannot perceive any eleft spines on the long first joint of the inner ramus, such as are commonly found in other families, nor even a single short one, such as occurs in *Talitrus locusta*; the

coupling-spines at the distal end on the inner side of each peduncle are two in number, and something like those of *Talitrus locusta*; the shafts are a little bent and exceedingly short, while the heads by comparison are very broad, showing a retroverted tooth on either side.

Uropods.—The first have the peduncle longer than the subequal rami; both peduncle and rami spined on the edges, a group of spines at the tip of each ramus, one of predominant size. In one of the specimens examined the rami on one side were much shorter than those on the other. The second uropods similar to the first in armature, but shorter, the peduncle subequal in length to the rami. The third uropods with short peduncle and short ramus spined on the outer edges; the peduncle tapering distally, broad below, from above looking as if cylindrically folded over.

Telson.—Broad at origin, tapering to two small distal lobes, these and the lateral margins set with spines; a median suture runs from the base some way towards the meeting point of the distal lobes. The sixth segment of the pleon scarcely visible from above folds beneath the whole length of the telson.

Length about half an inch, sometimes reaching seven-tenths, without counting the antennæ.

Locality.—Fifty-two specimens were taken on the shore at Juan Fernandez. The species is named after Alexander Selkirk, whose romantic story is connected with that island.

Remarks.—*Orchestia serrulata*, Dana, from New Zealand, seems to be its nearest ally, but the two species are separated by numerous differences in detail, among which may be noticed the first gnathopods in the female, the palm of the second gnathopods in the male, the relative lengths of the pereopods.

Family LYSIANASSIDÆ, G. O. Sars, 1882.

For the original definition of the subfamily Lysianassinae, Dana, see Note on Dana, 1849 (p. 229).¹ The subfamily Lysianassinae, Boeck, 1870, is changed by Sars into the family Lysianassidæ, without further definition. Boeck's definition of it in 1872 is as follows:—

“ *Upper Lip* and *Epistome* more or less prominent.

“ *Mandibles* elongate; cutting edge broad, not dentate or only furnished with very few teeth on the inner margin; an inner plate on the left mandible; molar tubercle small, more or less prominent; spine-row furnished with few blunt and often very small teeth; palp elongate, triarticulate.

“ *Lower Lip* elongate; inner plates little, near the apex [? generally absent].

“ *First Maxillæ* with two-jointed palp; rarely without palp.

“ *Second Maxillæ* more or less elongate.

¹ For Schiodte's *Trochalognatha*, see Note on Schiodte, 1875 (p. 449).

“ *Maxillipeds* robust; plates more or less elongate; last joint of the palp unguiform, rarely tubercle-shaped or obsolete.

“ *Body* deep; back thick, generally rounded; very rarely carinate.

“ *Side-plates* deep, narrow.

“ *Upper Antennæ* with the peduncle very short, thick; the second and third joints very small; flagellum more or less elongate; first joint more or less elongate, always longer than the following joints, and on the inner side furnished with two brush-like rows of setæ.

“ *Lower Antennæ* with the flagellum elongate in the male, shorter in the female.

“ *First Gnathopods* more or less elongate, generally with a small subchelate hand; rarely with the hand large or not subchelate.

“ *Second Gnathopods* elongate, filiform, with a small hand; rarely without a nail.

“ *Peræopods* of the last three pairs successively longer; the first joint posteriorly laminar, dilated.”

In the new genus *Sophrosyne* the maxillipeds are rather to be described as slender than robust; the epithet “narrow” is by no means universally applicable to the side-plates in this family, the fourth pair generally, and sometimes others, being of considerable breadth; occasionally the fourth peræopods are longer than the fifth. *Amaryllis*, Haswell, is an aberrant genus in regard to the upper antennæ.

Genus *Anonyx*, Kröyer, 1838.

For the original definition see Note on Kröyer, 1838 (p. 178). Boeck in 1872 defines the genus as follows:—

“ *Epistome* helmet-shaped.

“ *Mandibles* with the palp fixed nearer the apex than the very prominent molar tubercle.

“ *First Maxillæ* with the inner plate ovate, small, furnished with two plumose setæ on the apex.

“ *Second Maxillæ* with the plates broad and short; the inner plate much shorter than the outer.

“ *Maxillipeds* with the outer plate small, not reaching the distal end of the second joint of the palp, nodulous on the inner margin; palp robust; last joint unguiform.

“ *First Gnathopods* more or less elongate, robust; hand quadrangular, obliquely truncate at the apex.

“ *Telson* longer than the peduncle of the last uropods.

“ *Third Uropods* with the branches longer than the peduncles, setose.

“ *Body* not deep. Side-plates not deep; fourth not much excavate, not deeper than broad. Postero-lateral angle of the third pleon-segment produced, upturned, acute.”

Anonyx ampulloides, Spence Bate (Stimpson, MS.) (Pl. III.).

1862. *Anonyx ampulloides*, Spence Bate, Brit. Mus. Catal. Amph. Crust., p. 78, pl. xii. fig. 8.

Rostrum rudimentary; lateral lobes of the head rounded; the head as long as the first pereon-segment; first pereon-segment longer than the second. Peraon dorsally rounded. First four segments of pleon dorsally acute, the third segment deeply excavate above the much upturned, slightly produced postero-lateral angles, the lower margin being as it were bent up so as to form a piece of the hinder margin. The fourth segment with a dorsal depression, the sixth laterally ridged above on each side of the telson.

Eyes reniform, occupying a great part of the surface of the head, and nearly meeting at the top of it, therefore very large. The component ocelli short and small, numbering certainly more than three hundred.

Of the somewhat projecting connate epistome and upper lip a lateral view is given in the Plate.

Upper Antennæ.—First joint large and tumid, second and third very small; flagellum incomplete, eleven joints remaining, of which the first, bearing a brush, equals in length some six or seven together of those which follow; the secondary flagellum, of seven or eight joints, has the first of equal length with the first of the primary and partially sheathed in a fold of that joint; its terminal joints are narrow.

Lower Antennæ.—Gland-cone seemingly very obtuse; third joint narrow proximally, widened distally, with spines on the upper distal margin; fourth joint longer and much stouter than the fifth, furred on the upper margin, carrying a row of feathered cilia on the lower, and on its prominent apex a group of long setæ; the fifth joint furred on its upper margin. Of the flagellum there remained only ten joints, the first of these being equal in length to the two following combined.

Mandibles.—The cutting edge smoothly convex, with a denticle at the top; the lower rim in front is cut into four spine-shaped teeth, the margin of the mandible behind these being straight and smooth; the secondary plate on the left mandible high up on the primary, ligulate or spiniform, very small; the spine-row consists of four spines followed by nine branching spiniform setæ; the molar tubercle long, produced backwards, strongly furred with cilia, but not dentate; the palp set far forward, level with the front of the molar tubercle, the second joint considerably longer than the third, on its outer side a long row of spines or setæ curving round the upper half of inner margin to the outer apex, three on the upper part of the outer margin; third joint widening for rather more than a quarter of its length, and from that point carrying a row of eighteen spines along the inner margin to the apex; this joint has also five setæ in three sets on the inner side near the outer margin.

Lower Lip.—Strongly ciliated on the inner and apical borders; the distal portion of

the front lobes narrow, strongly dehiscent, suddenly widening and therefore coming nearer together about half-way down the long cleft that separates them.

First Maxillæ.—Inner plate small, oval, with two plumose setæ on the apex, the outer the larger; outer plate with the very oblique apical margin densely ciliated, especially on the lower part; its eleven spines strikingly different from one another in their dentation; of the two which stand apart from the rest at the lower end one is slender with many small teeth, the other stout with three large ones; of those set round the upper end some are peculiar by their distal widenings. The large second joint of the palp widens distally, the distal border being cut into six teeth, the tip of each except the minute inner one having a small spine-tooth inserted in it; between the outermost marginal tooth and the next is an additional small prominence, and again between the second and third teeth is a small cilium.

Second Maxillæ.—The plates are similar to one another in general shape, the convex margins meeting in a pointed apex, the outer plate considerably longer than the inner. From the apex down half the inner margin the inner plate has plumose setæ ending in one larger than the rest, and along the same part it has spines shorter than the setæ, the spines being armed midway with straight spine-like cilia. The spines which in like manner arm the outer plate have these cilia, seemingly limited to four in number, except on the lowest spines, which become more seta-like.

Maxillipeds.—Inner plates small, not reaching nearly so far as the distal end of the first joint of the palp, apical margin with three tiny teeth inserted on little prominences, the plumose setæ of the inner margin very long, passing over to quite small ones at the outer angle of the apex; the outer plates large and long, still not reaching the apex of the second joint of the palp, the inner border showing some six and twenty minute prominences as if for teeth, but with no appearance of teeth upon or within them, the same description applying to two on the rounded apical border; the second joint of the palp more slender and somewhat longer than the first; the third joint widening from a narrow neck, with setæ on both borders, distally furred; finger long, with adpressed cilia on the surface, a dorsal cilium nearer to the acute point than to the base.

First Gnathopods.—Side-plates a little excavate in front, much wider below than above, with the usual little cilium-bearing indent at the lower end of the hinder margin. First joint broad, about as long as the third, fourth, and fifth together, with setæ on both margins; third joint with no free front margin, its hinder margin furred, apically carrying geniculate spines and setæ; wrist equal in length to the hand, dilated below, furred on the free part of the hinder margin, with spines round the distal part both before and behind; hand less wide than the wrist, widest at the base, but preserving most of its width all along to the by no means oblique palm, which is bordered with minute cilia, and defined by two spines, between which the finger closes down, the nail overlapping the palm. There are various spines and setæ, singly, in rows, and in groups,

on the two borders and the sides of the hand. The finger has a denticle on the inner margin.

Second Gnathopods.—Side-plates widened below, the front, hind, and lower margins almost straight; the first joint fringed with setæ behind, parallel-sided, distally bending backwards; second joint as long as the wrist, third with the anterior margin short, the posterior much rounded, furred, with several long setæ near the rounded apex; the wrist a good deal longer than the hand, the front margin distally furred, and carrying long setæ near and at the apex; the hinder margin furred nearer to the third joint, and carrying eleven groups of setæ increasing in length successively to the apex; the hand much longer than broad, much furred, armed with the usual spines, narrowing a little distally, the finger comparatively long, occupying almost all the apical margin, its terminal portion not much crooked.

First Peræopods.—Side-plates similar to those of the preceding segment, but larger. First joint strong, carrying setæ on the hind margin; third joint large, nearly as long as the first joint, having groups of setæ, short mixed with long, on the hinder border; fourth joint somewhat shorter, much narrower, armed with spines and setæ, narrowing distally; fifth joint as long as fourth, slender, a little curved, on the hind margin carrying short spines and long ones, and close to the hinge of the finger a minute one with a hook at the tip, bent toward the comparatively short finger.

Second Peræopods.—Side-plates with front and lower margins straight, hinder lunately excavate; a small smooth ovigerous plate. The rest of the limb missing.

Third Peræopods.—First joint much contracted below, at the upper part almost as broad as the side-plate, though not appearing so in the full figure on the Plate, because the side-plate is seen full, while the first joint is not quite full-face to the spectator; its hind margin is nearly straight, shallowly serrated, slightly concave below, while the front margin is convex and spined all round; third joint dilated, a little produced behind, with spines on hinder rim; both second and third joints have spines and setæ on the front rim; fourth joint as long as the two preceding united, broader above than below, the front margin with five pairs of short spines, each of the upper four pairs with a long seta between the two spines, the fifth pair without a seta, a sixth apical pair with a long spine intervening; the fifth joint thinner than the fourth, equal in length, straight, with five pairs of spines on the front margin; finger rather short.

Fourth Peræopods.—First joint oval, contracted below, closely spined on more than half the front margin which is smooth above, the lower margin behind forming a narrow lobe instead of a broad one as in the third peræopods; setæ and spines on the front rim of the short second joint; the remaining joints similar to those of the preceding pair, but each longer than the corresponding one in that pair; the finger missing.

Fifth Peræopods.—First joint of uniform breadth all along, front margin slightly concave, spines increasing in size towards the lower end, and the serrations of the hind margin

doing the same; the third joint not dilated, armed in front with four or five pairs of spines, behind with one at the apex, and another a little way from the apex. The rest of the limb missing on one side, on the other side represented by a somewhat tapering stump as long as the third joint and destitute of armature.

Pleopods.—In the third pair the two blunt-headed coupling spines on the peduncle were observed to have two or more retroverted teeth, and the rami to consist of twenty-one joints, the large first joint of the outer ramus having a fringe of thirteen plumose setæ.

Uropods.—Peduncles of the first pair considerably longer than the rami, carrying numerous spines on both the upper edges, those on the outer edge being smaller than those on the inner; the outer ramus slightly longer than the inner; on its upper edge the outer has eight spines, the three approaching the tip being much stouter than the earlier five; on the inner edge is a row of three very fine spines; the inner ramus also has spines on both edges, and proximally has a little pocket on the under side into which the projecting edge of the other ramus can insert itself. Peduncles of the second pair equal in length to the rami, spined on both the upper edges, the outer edge having twenty-seven nearly uniform spines, the smallest not far from the base, the largest close to the apex, the intermediate not regularly graduated; the outer ramus is bordered with nine spines increasing gradually towards the apex, but stopping far short of it; the last is inserted in a sort of little pocket, as is the case with the last three on the outer ramus of the first uropods. The inner branch is subequal in length to the outer; it has six or seven small spines on the border, followed by a long one inserted in the curved margin which abruptly terminates the broadest part of the branch, the remainder forming a finger-like termination without spines and apparently without any eilium in the angle. The lower border of this branch is much bent. The peduncles of the third pair are shorter than the rami; the rami are subequal, lanceolate, with spines on both borders. That which I take to be the outer ramus is represented in the lateral view of the pleon (fig. *Pl. L.*), without its companion; it terminates in a nail; the other ramus has on its margin a row of setæ. In the other member of the pair, as the figure shows, the ramus with a nail seemed to be the inner one.

Telson.—Its upper lateral margins much overlapped by the folds of the sixth pleon-segment; the sides straight, only in a very slight degree convergent; cleft for three-quarters of its length, the plates becoming gradually dehiscent by the curving away of the inner sides towards the distal end; each outer apical corner a little produced, with a small spine between the angle and the adjoining inner curve.

Length from the front of the head to the back of the second pleon-segment, in the bent position represented, about nine-twentieths of an inch.

Locality.—Station 236, off Japan, June 5, 1875; lat. $34^{\circ} 58' N.$, long. $139^{\circ} 29' E.$; depth, 775 fathoms; bottom, green mud; bottom temperature, $37^{\circ} 6$. One specimen, female. Trawled.

Remarks.—This species bears a close resemblance to that which Krøyer described as *Anonyx lagena*, *Anonyx appendiculosa* and *Anonyx ampulla*, and which Phipps had already described as *Cancer nugax*. Krøyer gave the name *ampulla* under the erroneous impression that his species was identical with Phipps' *Cancer ampulla*, and described it with exact detail in his *Naturhistorisk Tidsskrift*, 2. R. i. 578–599. Though the name *ampulla* is untenable for Krøyer's species, attention is well called to his admirable description of it by the name given to the present kindred species. *Anonyx ampulloides* differs from *Anonyx nugax* in that the eyes are not lageniform, flask-shaped; the apical border of the palp in the first maxillæ is peculiarly divided; the inner ramus of the second uropods is not stiliform, but bent on one side and abruptly narrowed on the other; and in other small details.

In the British Museum Catalogue of Amphipodous Crustacea, it is represented on pl. xii. fig. 8, and the following account is given:—

“*Anonyx ampulloides*, Stimpson, MS.

“In general aspect this species resembles *Anonyx lagena*; but close examination shows the following distinctions:—

“The inferior antennæ are much longer than the superior. The first pair of gnathopoda have the palm fringed with fine hairs, but not a comb-like margin. The second pair of gnathopoda have the carpus slight, and much longer than the propodos; the daetylos quite rudimentary. Telson deeply divided, becoming almost a double appendage.

“Length half an inch.

“I am indebted for this specimen to the kindness of the author, who brought it from Japan.”

As I had myself chosen the name *ampulloides* for this Japanese species, before observing its resemblance to the figures, in Mr. Spence Bate's Catalogue, of the species so called by Stimpson, the identification seems fairly to be depended upon.

Anonyx cicadoides, n. sp. (Pls. IV., V.).

Rostral Margin forming an obtuse but definite angle; the lobe of the head between the upper and lower antennæ rounded above and straight below. The three hinder pereon-segments longer than those which precede, but much shorter than the three segments of the pleon which follow them; the fourth segment of the pleon with a dorsal depression near its origin; the fifth and sixth segments very small, the sixth with a dorsal ridge or fold along either side of the back; the infero-posterior angle of the third pleon-segment much produced upwards.

Eyes not made out; in one of the specimens appearances suggest that they have been present, of a long oval shape, near the front of the head.

Upper Antennæ.—First joint stout, cylindrical, longer than the combined length of the two following joints, which are very short, and the long first joint of the flagellum. Flagellum tapering, in the female consisting of twenty joints, of which the first is longer than the four following united; besides the usual brush it has two large, slightly curved, distal spines; the second joint has two similar spines, and the fourth joint a similar but much smaller spine; the secondary flagellum is of nine joints, the first very long, the last minute. In the male the primary flagellum has calceoli on most of the joints.

Lower Antennæ.—First joint broad; the gland-cone with a conspicuous orifice, not spiniform; third joint with lower and distal margins lobed, fourth and fifth joints furred above, and with various groups of setæ below, one group in the fourth joint being on a little prominence near the base; the fifth joint somewhat longer than the fourth; flagellum in the female of about thirty joints, of which the first is much longer than the second. In the male the flagellum has about fifty joints, and is furnished with calceoli.

Mandibles with the palp far forward, just over the narrow interval between the molar tubercle and the spine-row; cutting edge smoothly convex, but with a small projection at the top, and an emargination in the return of the curve below. The secondary plate in the left mandible is short and narrowly ligulate. The spine-row consists of three curved spines. The molar tubercle is large and prominent, the crown of it minutely dentate and ciliate, pointing away from the cutting edge, the articular condyle pointing towards that edge. The first joint of the palp very short, the second very long, with a row of pectinate spines on the distal part of its margin. The third joint, about half the length of the first and second united, has two long spines near the outer angle of its base, and along almost the whole of its inner margin a row of pectinate spines, of which those at a little distance from the apex are the shortest, those at and close to the apex the longest.

Lower Lip deeply cleft, much ciliated round the margins of the forward lobes, which are rather abruptly contracted near their extremities, thus making the inner margins very sinuous; the ovate mandibular processes almost smooth.

First Maxillæ.—Inner plate small, oval, ciliated along the inner edge, and with two unequal plumose bristles at the apex; outer plate much ciliated on the surface and distal part of inner margin; at its apex five long spines, this row continued inwards on the outer side by two more, while a row of four, rather smaller, descend the sinuous inner margin; all are dentate on their edges some way short of the curved tip, the end one on the outer side having but one tooth, the end one on the inner side having several denticles. The two-jointed palp overtops the spines of the inner plate. The second joint is very much expanded distally, the curve of the outer margin ending in two microscopic teeth at the point of greatest expansion, the margin then running obliquely to meet the great distal curve set with nine teeth and a spine, the spine being outermost, with a short, spiny seta not far off.

Second Maxillæ.—Inner plate much shorter and narrower than outer, fringed from the apex half-way down the inner margin with spines decreasing in size as they recede from the apex, and with plumose setæ the longest of which are beyond the shortest of the spines; outer plate fringed with rows of long and short spines from the apex far down the inner margin, the longer spines curved at the tips. Both plates have their inner edges comparatively straight, the outer much curved, their surfaces and inner edges much ciliated; the outer plate has also a row of small spines from the apex down a small portion of the outer margin.

Maxillipeds narrow. The inner plates not reaching the distal end of the first joint of the palp, widening distally, apical border much excavated and forming a projection at the inner corner, which is set with three broad scarcely prominent teeth, just below which on the outer side of the inner margin are two small spines; long plumose setæ occupy the inner margins, passing over into shorter ones on the distal margins. The outer plates are long, reaching just to the distal end of the second joint of the palp; the lower part of the joint to which they belong is fringed with spines on the inner margin, but this margin of the plate itself is clear of spines, being indented and in each indent carrying an almost rounded tooth, which scarcely projects beyond the margin; some way within the border are small spines, rather less numerous than the teeth. It would not be unnatural to suppose that the marginal teeth had been rounded by wear; but those of the new growth, not yet exposed to wear and tear, exhibit the same shape and position. On the apical portion of the rounded outer margin there is a row of five small spines, almost adpressed to the margin. The second joint of the palp is considerably the longest; like the first and third it is at the outer apex and along the inner edge fringed with long spines or setæ, which, except for the terminal accessory thread, seem to be quite smooth. The fourth joint or finger is not of any unusual length.

First Gnathopods.—Side-plates dilated below and curving forwards, broader though less deep than those of the following segment. First joint not reaching beyond the side-plate, fringed in front and on the lower hinder angle; second joint subequal in length to third, with some fine setæ on the hinder margin; third joint produced to a sharp point below, furred behind, carrying groups of setæ on both sides near the apex; wrist furred behind, scarcely broader distally than the hand at its base, setæ in groups at both the lower angles, and a small group near the middle of the front margin; hand narrowing distally, so as at the extreme apex to be scarcely broader than the finger, furred on upper part of hinder margin, with groups of setæ along both sides of the front, and along the hinder margin and palm; that which may be considered the palm is slightly sinuous, minutely peetinate, a region shorter than the finger, determined by a short blunt spine; finger curved, with inner edge smooth, but for a tooth near the base of the nail; a spiniform eilium arises in the neighbourhood of this tooth.

Second Gnathopods.—First joint long, a little dilated below, much more lightly

fringed than the corresponding joint of the first gnathopods; second joint longer than third, fringed in front and at the lower hinder angle; third joint rather densely furred behind, clasping the next joint closely with its dilated distal part, the hinder angle of which carries numerous long setiform spines, distally pectinate; the wrist elongate, much longer than the hand, densely furred on both sides, carrying spines similar to those of the preceding joint at the front apical angle and along the distal part of the hinder margin; the hand narrow, densely furred, surrounded on both margins with pectinate spines of various lengths, many both long and short at the point where the minute finger hinges.

Second Peraopods.—Side-plates a little deeper than the preceding, as those of the third segment are, compared with those of the second. The branchial vesicles are not pleated. The marsupial plates are long and narrow, with a row of small cilia on one border, the usual long smooth setæ on the other and round the apex. First joint tolerably stout and long, with a bunch of setæ at each apical angle, and very little other furniture; second joint short, with some setæ on the hinder margin, chiefly the group at the lower hinder angle; third joint longer and very much stouter than the following, a little produced downwards in front, fringed behind with several small groups of setæ; fourth and fifth joints narrow, the latter the longer, narrowing a little distally, both bordered behind with numerous setæ, the fourth joint showing also two spines near the base, the fifth joint having twelve or thirteen in a series extending along its whole margin; the finger short and much curved.

Third Peraopods.—Side-plates rather broader below than above, and front margin slightly more convex than the hinder. First joint subequal in extent of surface to the side-plate, narrower below than above, front margin fringed with spines, hind margin serrate, the rounded distal portion overlapping the short second joint; two or three short spines and one long one on the front margin of the second joint; the same number on the hind margin of the third joint, which is short, dilated, slightly produced downwards behind, and has a row of spines and fine setæ on its front margin; fourth joint somewhat dilated, narrower and longer than third; fifth joint much narrower and rather longer than fourth, both with spines on front margin. Finger small, curved.

Fourth Peraopods.—First joint longer and more oval than that of preceding pair, rather narrower below than above; third joint much longer than in preceding pair, broader and shorter than the fourth joint, which in its turn is a little broader and shorter than the narrow fifth joint; armature of the various joints, and the finger, as in the preceding pair.

Fifth Peraopods like the fourth pair, not longer.

Uropods.—Peduncles of the first pair longer than the rami, which are narrow, curving at the tips; the outer a little longer than the inner, with a row of seven spines on the inner margin, ceasing some distance from the apex; the inner with a similar row of ten spines. Peduncles of the second pair (Pl. V. *ur.* 2.) shorter than those of the first pair, subequal in length to the longer ramus; outer ramus considerably longer than inner, a

little curved at the tip, bordered within with eleven spines; inner ramus rather like a tadpole, attached by a narrow neck to the peduncle, a broad oval portion following with a row of six spines on the inner margin, a narrow rather sinuous piece forming the termination, a minute cilium occurring where the ovate portion meets the linear. This peculiar form of ramus has been noticed in *Ichnopus*, Costa, and some other genera. Peduncles of the third pair much shorter than the lanceolate sharply pointed rami, which stretch further back than either of the other pairs; outer ramus having a nail at the tip, spines along the borders, some of them in groups on the outer margin, and plumose setæ on the inner margin; inner ramus shorter than the outer, with spines and plumose setæ on both margins, terminal nail minute.

Telson reaching further back than the peduncles of the third pair of uropods, narrowing a little towards the apex, outer edges straight, cleft for three-fourths of its length, the laminæ not dehiscent except where each curves away from the other to form the apical margin, the outer end of which is produced into a little tooth. At this tooth commences a row of three spines, diminishing in size from the tooth inwards, and followed by two minute cilia. Along the outer edges there is a row of three spines on each side, the largest a little lower down than the top of the cleft, the middle one the smallest.

Length.—The pair of specimens, male and female, to which the above description and the figures of Pl. V. refer, measured each three-quarters of an inch, exclusive of the antennæ.

Locality.—Station 149D, Royal Sound, Kerguelen Island, January 20, 1874; depth, 28 fathoms; bottom, volcanic mud. Three specimens, which were especially noticeable as being of a deep brown colour in spirits. Dredged.

Station 149, Accessible Bay, Kerguelen Island, January 9, 1874; depth, 20 fathoms; bottom, volcanic mud. Several specimens. Dredged.

Station 149H, off Cumberland Bay, Kerguelen Island, January 29, 1874; depth, 127 fathoms; bottom, volcanic mud.

Remarks.—The specimens from Stations 149 and 149H were of various sizes, one reaching as much as nine-tenths of an inch; they showed the light creamy colour so common in spirit-specimens, and this difference in colouring, combined with other variations, made me long hesitate as to whether the species of Pl. IV. was the same as that of Pl. V. There were differences in the relative proportions of the joints of the antennæ, in the shapes of the spines on the outer plate of the first maxillæ, in the proportions of the second gnathopods, in the armature of the uropods, and especially the inner ramus of the second pair of uropods, though exhibiting the sudden contraction above described, was otherwise more regularly stiliform. I have, however, convinced myself that none of these differences are of specific value. Among the light-coloured specimens the relative proportions of the antennary joints are not constant; for example, in the upper antennæ the first joint varies much in the peduncle, the primary flagellum and the secondary

flagellum; in the lower antennæ the fifth joint of the peduncle may be a little longer or a little shorter than the fourth; the spines of the first maxillæ vary much in general appearance, in this as in other species, according as they are fresh or worn with long use. To the ramus of the second uropods I should have attached more importance had I not found in a small light-coloured specimen the ramus shaped just as in the large dark-coloured specimens.

This species, in respect of the antennæ, mouth-organs, second gnathopods, peræopods, and general structure of the pleon, closely resembles *Anonyx gulosus*, Krøyer, the *Anonyx cicada* (O. Fabricius) of this Report (see pp. 46, 47). It differs from it in respect of the first gnathopods and the second uropods, in these two respects agreeing with *Ichnopus*, Costa, as defined by Boeck, but from that genus it differs in regard to the maxillipeds and the branchial vesicles, which are pointed below, but without the pectinate folds considered characteristic in *Ichnopus*. Since, by the omission of the epithet "quadrangulari," as applied to the hand of the first gnathopod, in Boeck's definition of *Anonyx*, that definition will include the present species, it seems advisable by that expedient to save the creation of a new genus. To point to its agreement with the older species, I have therefore named the new one *Anonyx cicadooides*. *Anonyx pumilus*, Lilljeborg, is retained by Boeck himself in the genus *Anonyx*, although the hand of the first gnathopods is not quadrangular.

Genus *Tryphosa*, Boeck, 1870.

For the original definition, see Note on Boeck, 1870 (p. 399). The genus is so near to *Anonyx*, Krøyer, as defined by Boeck himself, that they ought perhaps to be reunited, as suggested both by G. O. Sars and Gerstaecker.

Tryphosa antennipotens, n. sp. (Pl. VI.).

Rostrum obsolete, lateral angles of the head acutely produced; back well-rounded, most dilated at the fifth segment of the peræon; postero-lateral angles of the third pleon-segment not acute or upturned; fourth pleon-segment with a dorsal depression, distally carinate, tip-tilted, the lateral margin continuous with the curve of the lower margin of the third segment; the sixth segment ridged on each side of the telson.

Eyes indistinct, but apparently large, set back from the front margin, reniform, meeting at the top of the head.

Upper Antennæ.—First joint long and tumid, second and third joints short, narrowing distally, the distal borders sinuous; first joint of the flagellum short, equal to the four following, caleoli large and crowded, there being one on each of the fifty-two joints of the flagellum, with the exception of the first and two or three at the end. The

flagellum is long and thick, and seemingly little flexible. The secondary flagellum of four joints together is shorter than the first of the primary.

Lower Antennæ.—Gland-cone very prominent, third joint short, fourth and fifth subequal in length, with some cilia on the upper and setæ on the lower margins; flagellum of fifty-three joints, rather thinner and longer than that of the upper antennæ, the calceoli equally numerous, placed on the upper margin confronting those of the upper antennæ, but in both pairs so placed that, while the calceoli of alternate joints are seen full face, those of the other alternate joints will be seen in profile.

Epistome a little prominent.

Mandibles.—Cutting edge evenly convex, with a tooth at the top, the lower apex scarcely indented; secondary plate of the left mandible small, curved; spine-row of three small spines, behind these a long tract of fur leads to and partially lines the molar tubercle, the crown of which is minutely denticulate, strongly directed backwards, and carrying a fuzzy tuft above; the palp is set forward, over the front of the molar tubercle, its first joint short, the second rather stout, with some five small spines on the inner margin near the apex, and three or four along the upper half of the outer margin; the third joint much curved, a short piece of its inner margin clear, the remainder fringed with eight and twenty spines, the first twenty-one pectinate on the upper border, the other seven longer, near and at the apex, pectinate below; a single long spine or seta near the outer margin close to the base.

Lower Lip.—Apical margins of the forward lobes broad, somewhat squared, much ciliated, little dehiscent.

First Maxillæ.—Inner plate small, with two unequal plumose setæ on the apex; outer plate with very oblique apical margin; of the eleven spines that stand inmost has seven marginal teeth, the next above it four; these are somewhat isolated; of the rest the outer are the stoutest, with one, two, or three marginal teeth; one about central has seven; the second joint of the palp has six or seven small teeth on the apex and one spine or short seta; below the palp the shaft has on its outer border some groups of long setæ.

Second Maxillæ.—Outer plate decidedly longer than the inner; the long curved spines on its apical border are followed by a row of small ones continued some little way down the outer border; on the inner plate the spines and setæ of the very oblique apical border are terminated by a long plumose seta.

Maxillipeds.—Inner prismatic¹ plates broad, reaching nearly to the apex of the first joint of the palp, the plumose setæ in the usual position, the apical border almost squared, with three close-set teeth, followed by four curved spines decreasing in size as

¹ The epithet *prismatic* was applied to these plates first, I believe, by Krøyer; it refers to that which an unshaded diagrammatic drawing cannot show, namely, that to a spectator looking upon the inner surface of the maxillipeds the inner edges of these plates are almost invariably nearer, sometimes much nearer, to the eye than their outer edges.

they pass round to the outer margin, on which lower down there is a fifth; below the corner tooth on the outer side of the plate are two strong spines; the broad outer plates, reaching nearly to the apex of the second joint of the palp, have on the inner margin a score of small teeth set close together, followed by a separate single tooth on the apical margin, which in turn is followed by eight spines passing round the apical and some way down the outer margin; the second joint of the palp is a little longer than the first and much longer than the third; the finger is not very long.

First Gnathopods.—Side-plates very broad, broader above than below; first joint extending beyond the side-plate, broad, with setæ extending down about two-thirds of the front margin; the third joint with a short front margin and a long hinder one, which is furred, and near the produced pointed apex carries a row of spines; the wrist rather shorter than the hand, has the long front margin clear, except for the row of long spines about the apex; the hinder margin is furred and also has spines about the apex; there is a ridge or pocket on the inner side parallel with the furred part of the margin; the hand is broad and long, at the base nearly as broad as the wrist distally, furred on the hinder margin near the base, and here having on the side a ridge or fold of the skin parallel with the margin; there are various groups of spines or setæ on the hind margin and surface of the hand and at the front apex; the finger closes down between the two spines, which define the sloping apical palm.

Second Gnathopods.—Side-plates widening downwards, at the top much less wide than those of the first pair. Branchial vesicles expanding greatly from a narrow neck, narrowed below; marsupial plates moderately broad. First joint extending much beyond the side-plate, equal in length to the third, fourth and fifth joints together, with a few setæ on the front margin; second joint as long as the wrist; third joint shorter, front margin free for some distance, hind margin furred below, and with a large group of long, thin spines on the rounded apex; wrist very lightly furred anteriorly, but strongly behind, also towards the distal end carrying numerous groups of slender spines of various lengths; one such group at the apex in front; the hand shorter than the wrist, but elongate, the sides but little curved, much furred all along, while the centre of the surface on both sides of the hand is naked or nearly so; in addition to the furring, both edges and adjacent parts of the hand are crowded with groups of spines, those in front when they reach the apex standing out far beyond the finger; they are pectinate, very slightly curved; the finger is very small, closing down on a palm, the outer part of which is nearly straight, at right angles to the hinder margin of the hand.

First Peraopods.—Side-plates with the hind margin straight; marsupial plates expanded a little below till near the apex, having on the lower half and apex numerous very long setæ in front and a few short ones behind. First joint of the limb not reaching the lower rim of the side-plate; third joint longer and stouter than either the fourth or fifth, slightly decurrent in front, with groups of long, slender spines or setæ on the hinder margin,

and the apex in front; the fourth joint similarly armed, stouter than the fifth, in length subequal to it; the fifth with numerous short as well as long setiform spines on the hinder margin; two very short ones at the junction with the slightly curved finger.

Second Peræopods.—Side-plates excavate far down, the lower margin curving up to the excavation so as to form a rounded point. Branchial vesicles broad except at the neck. Joints of the limb similar to those of the preceding pair.

Third Peræopods.—Side-plates rather wider than deep, front margin very convex, hind margin nearly straight. First joint a round oval, broader above than below, the rounded lower margin behind reaching as far down as the second joint, front margin with numerous spines fringing it entirely, hind margin serrate; third joint much longer than broad, somewhat decurrent behind, with spines at the back, spines and setæ in front, and apical groups of spines; fourth joint scarcely so long as third, similarly armed; fifth joint much narrower but longer than fourth, with eight sets of spines on the front margins, some spinules on the back border; finger about half the length of the fifth joint, slightly curved.

Fourth Peræopods.—First joint a long oval, narrower below than above, spines on the front margin few and small on the upper part, numerous and longer below, hind margin serrate; third joint as in the preceding pair, but somewhat longer; fourth joint longer than third, with nine groups of spines on the front border; fifth joint scarcely shorter than the fourth, with ten groups of spines on the front border; small spines on the hind margins of third, fourth and fifth joints; finger not nearly half as long as the fifth joint.

Fifth Peræopods.—Branchial vesicles a broad oval, with the hind margin drawn out into somewhat pointed processes. First joint broadly oblong with rounded corners, the front margin as in the preceding pair, the hind margin serrate, rather deeply at the lower part; the third joint shorter and narrower than in the two preceding pairs, with four groups of spines in front, and four behind; fourth joint longer than third, with eight groups of spines in front, three behind; fifth joint longer than fourth, with nine groups of spines in front, five behind, these latter being all very small, except the apical; finger not half the length of the fifth joint.

Uropods.—Peduncles of the first pair longer than the rami, rami subequal, stiliform, spines numerous on the peduncles and also on the rami. Peduncles of the second pair a little longer than the rami; the rami stout, the outer somewhat longer than the inner; marginal spines numerous. Peduncles of the third pair shorter than the rami, the rami broadly lanceolate, almost equal, extending much further back than the second pair; spines on both edges; plumose setæ also on one.

Telson long, extending far beyond the peduncles of the third uropods, cleft for more than four-fifths of its length, narrowing distally, a series of five spines along each side; in each apical cleft two spines, of which the outer is the larger.

Length.—The specimen, in the position figured, measured, without the antennæ, three-quarters of an inch; with the outstretched antennæ, an inch.

Locality.—Station 150, off Heard Island, February 2, 1874; lat. $52^{\circ} 4'$ S., long. $71^{\circ} 22'$ E.; depth, 150 fathoms; bottom, coarse gravel; bottom temperature, $35^{\circ}\cdot2$. One specimen, female. Dredged.

Remarks.—The specific name refers to the singularly stout and stiff antennæ.

This species agrees well with Boeck's definition of his genus *Tryphosa*, except that the outer plate of the maxillipeds does not reach beyond the second joint of the palp, in which respect it agrees better with his definition of the genus *Anonyx*; on the apex the plate in question is armed with the requisite two spines, but it has more than two. In *Anonyx* the inner plate of the second maxillæ is much shorter than the outer plate, which is not the case in *Tryphosa*, but beyond this it is not easy to find any character on which absolute reliance can be placed for distinguishing the two genera. Boeck, in his account of *Tryphosa*, compares it only with *Orchomene*, but when discussing the genus *Anonyx*, he says,¹ "the mouth-organs in this genus show a certain agreement with those in some of the following genera, especially in *Orchomene*, *Tryphana* [? *Onesimus*], and *Tryphosa*; the upper lip in them all is helmet-shaped and covers the tips of the mandibles with its thickened end. These genera differ, however, from one another in the form of the other mouth-organs, the antennæ, the two pairs of gnathopods, and the telson. Thus, the mandibles in *Anonyx* are very strong but not especially elongate, with a long but narrow molar tubercle, and the palp is fixed nearer the end than the molar tubercle. The first maxillæ are also very broad, but the inner plate is very short, only a little longer than broad, with two strong plumose setæ on the apex. The plates of the second maxillæ are also short but broad; the outer plates of the maxillipeds are very large, and have on the rims a close row of small nodules. The third joint of the lower antennæ is short, and the first gnathopods are more or less elongate. The telson is also elongate, longer than the peduncle of the last uropods, and deeply cleft. The body is also on the whole tolerably elongate, and the fifth side-plate accordingly longer than deep."

Tryphosa barbatipes, n. sp. (Pl. VII.).

The lateral lobes of the head much produced and sharply angled.

Postero-lateral angles of the third pleon-segment not acute and yet scarcely rounded.

Fourth pleon-segment with a dorsal depression.

Eyes not discerned.

Upper Antennæ.—First joint tumid, second and third short, the third, as is often the case in the Lysianassidæ, excavate below; flagellum of eight joints, the first large, slightly

¹ De Skand. og Arkt. Amph., p. 151.

tapering, considerably longer than the other seven together, having the cylindrical hairs of the brush not very long, and carrying two spines at, and one spine near, the apex; the other joints diminishing successively in breadth, and towards the end in length also; the secondary flagellum of four joints together equal in length to the first of the primary.

Lower Antennæ.—Gland-eone prominent, third joint somewhat inflated, in length equal to the composite first and second joints, fourth and fifth subequal, both with small cilia above and setæ below; the flagellum tapering, probably consisting of seven or eight joints; in the specimen (female) examined there were five left on one member of the pair and six on the other.

Mandibles.—The cutting edge smoothly convex, bounded by a very small tooth above, pointed downwards, and an equally small one below pointing forwards; above this in the left mandible is a minute tubercle breaking the evenness of the convex edge, but this is probably only an individual peculiarity; the top border over the upper tooth is minutely serrate; the secondary plate of the left mandible is short and small, dilated forwards and apically cut into five or six minute denticles; the spine-row consists of three slender spines; the molar tubercle is prominent, the dentate crown pointing backwards, oval, with three central teeth apart from the lines of denticles; the region between the spine-row and the crown furred with cilia, a long group of these also above the crown; the palp not far back, over the molar tubercle's front part, the first joint short, the second with nine spines near the apex; the third joint with the first subequal in length to the second; more than the first third of its inner margin smooth, the remainder fringed with fifteen spines; one spine near the base on the outer side. Behind the palp and molar tubercle the shaft of the mandible is broad.

First Maxillæ.—Inner plate short and narrow, with two unequal plumose setæ on the apex; outer plate long, two of the spines a little below the apical margin, the inner of the two with fifteen rather elongate teeth, the other spines much crowded together, nine in number, strong, the outer less dentate than the inner, the longest of all in company with a short one standing nearest to the two first mentioned; the second joint of the palp narrower proximally and distally than in the middle, its apical border set with seven spine-teeth serrate on the outer border, a single seta near the outer apex.

Second Maxillæ.—Outer plate longer and broader than the inner, apical margin oblique, with pectinate spines increasing in length to the apex on the outer side, a few shorter ones following down the outer border; apical border of the inner plate likewise oblique, armed with spines, a plumose seta on the inner margin just below the spine-row longer than any of the spines.

Maxillipeds.—Inner plates not reaching the apex of the first joint of the palp, with plumose setæ planted in the ordinary manner on the inner margin and passing across to the outer corner of the apical; apical border with three strong teeth, the innermost the most prominent, beyond these a plumose spine or seta distinct from the series just mentioned;

outer plates reaching as far as the second joint of the palp or a little beyond, with ten strong teeth on the inner margin set close together, an eleventh on the apical margin separated by a short interval from the rest, and beyond this two spiniform teeth; second joint of the palp not longer than the first, the third joint shorter; the finger short, with a rather long nail accompanied by three cilia, the usual dorsal cilium rather nearer the origin of the finger than that of the nail.

First Gnathopods.—Side-plates broader above than below, very convex behind, with a slight concavity in front. First joint extending much beyond the side-plate, fringed with long setæ in front; third joint with no free front margin, some groups of setæ on the hind margin; wrist subtriangular, much shorter than the hand, and scarcely broader distally than the base of the hand, very setose on the free hinder margin and the contiguous portion of the inner side; hand oblong, longer than the three preceding joints combined, a little broader at the base than at the palm, front margin continuous with that of the wrist, having few setæ except at the apex, while the hinder margin and contiguous inner side are densely setose with plumose setæ; palm a little concave, bounded by two stout spines with fine curved tips; along the palm are close-set straight cilia, and a row of longer cilia not close set; the finger just the length of the apical margin of the hand, with one tooth on its inner edge, and a dorsal cilium near the base.

Second Gnathopods.—Side-plates of very even width throughout. Branchial vesicles large and broad except at the neck. First joint a very little wider below than above, scarcely curved, the setæ on the front margin fewer and much shorter than in the preceding pair; the second joint nearly as long as the wrist; third much shorter, a little furred behind, with spines on the rounded apex; the wrist furred on the hinder margin, with little fan-shaped scales on the breast, and long pectinate spines near the apex; the hand furred but not densely, somewhat narrowed proximally and distally, the hinder margin a little outdrawn, the overarching spines of the front and apical margins and those of the hinder margin having their pectinations confronting in each set those of the other set; the palm sloping inwards, microscopically pectinate, the minute finger neatly fitting it with its inner edge also for the distal half microscopically pectinate, and carrying a dorsal cilium on the thick portion near the hinge. The tip of the finger closes down against spines at the outer end of the palm; it is probable that this is the case in all species of this family, but in regard to many the fact is not mentioned from the difficulty of observing such spines with certainty in the midst of the dense fur sometimes present.

First Peræopods.—Side-plates long, slightly widening downwards. Branchial vesicles broad, seemingly without folds. Marsupial plates, in this specimen, narrow, with few setæ. First joint reaching about as far as the side-plate; third joint much longer than fourth or fifth; fourth scarcely so long as fifth; the third and fourth bordered behind with groups of setæ of various lengths; in the fifth the groups consist of a spine with a

long accessory thread and a seta, two short straight spines adjoining the hinge of the finger on the inner side; the finger short, little curved, with a small nail, the dorsal feathered cilium near the hinge.

Second Peræopods.—Side-plates of considerable breadth below. The joints of the limb scarcely distinguishable from those of the preceding pair.

Third Peræopods.—Side-plates a little outdrawn below in front, length and breadth subequal; first joint elongate but not narrow, broader above than below, the rounded lower margin behind descending below the second joint, front margin spined, with a few setæ, the hinder margin not strongly serrate; the third joint expanded, hinder angle outdrawn downwards; fourth joint narrower, perhaps a little longer; fifth joint narrower and a little longer than the fourth; finger short, curved.

Fourth Peræopods.—First joint similar to that of the preceding pair but larger, not drawn out below the second joint; the third joint much longer than in the preceding pair, and less expanded in proportion to its breadth; the fourth joint longer than the third or the fifth, which are subequal; finger short, but longer than that of the preceding pair; the whole limb considerably longer than the pair preceding or the pair following.

Fifth Peræopods.—The first joint longer and much broader than in the preceding pairs, the third joint shorter and less expanded, the fourth equal in length to that in the third pair, but narrower; the fifth joint and the finger rather longer than those in the third pair. In these three pairs of limbs the armature is similar; on the hind borders of the third, fourth and fifth joints some small spines, with larger ones apically; setæ and spines on the front margins of all the earlier joints, spines only on the fifth; a rather large group of spines on the front apex of the fourth joint.

Pleopods.—The coupling spines on the peduncles exhibit a row of three marginal retroverted teeth; the joints of the rami number from fifteen to seventeen; the cleft spines form a series of four in the first pair and the second, of three in the third pair.

Uropods.—Peduncles of the first pair longer than the rami, rami stiliform, a little curved at the tips, with four or five marginal spines; peduncles of the second pair equal in length to the rami, the rami equal; the peduncles of the third pair subequal in length to the inner ramus; the rami short, broadly lanceolate, the outer exceeding the length of the inner by nearly the length of its nail, the inner having no nail or only a rudiment.

Telson extending beyond the peduncles of the third uropods, eleft for more than two-thirds of its length, widening from the base to a level with the top of the cleft, then narrowing with convex outer margin to the apiees, which are more outdrawn on the outer than the inner edges, between the two angles each containing a strong spine with accessory thread; on each side is a small spine nearly on a level with the top of the eleft, and lower down a larger one.

Length of the specimen, in the position figured, about seven-twentieths of an inch.

Locality.—Station 149H, off Cumberland Bay, Kerguelen, January 29, 1874; depth, 127 fathoms; bottom, volcanic mud. Dredged.

A minute specimen, not a tenth of an inch long, from the same locality, is probably the young of this species. Two other specimens were taken at Kerguelen, at a depth not mentioned.

Remarks.—The specific name alludes to the bearded appearance of the wrist and hand in the first gnathopods.

In the young specimen there are clear traces of eyes, the mandibles are well developed, but with few spines on the palp; on the palp of the first maxillæ there are only four teeth; on the inner plate of the maxillipeds the three apical teeth are well developed, but the outer plate has on the inner margin but one tooth, which is that near the apex, and two on the apical margin; the branchial vesicles are narrow; the fingers of the peræopods comparatively more developed than in the adult.

Genus *Hippomedon*, A. Boeck, 1870.

For Boeck's definition of this genus, see Note on Boeck, 1870 (p. 397). To embrace the new species here assigned to the genus, the first maxillæ should be described as having two *or more* setæ on the inner plate, and the epithet *broad* should be omitted from the account of the maxillipeds. The description of the lower antennæ as having the fifth joint much longer than the fourth must be cancelled, being in fact contrary to the descriptions which Boeck himself gives of the only two species which he assigns to the genus.

Hippomedon kergueleni (Miers) (Pl. VIII.).

1875. *Lysianassa kergueleni*, Miers, Ann. and Mag. Nat. Hist., vol. xvi. p. 74.

1879. *Anonyx kergueleni*, Miers, Transit of Venus Exped., Zoology of Kerguelen Island, Crustacea, pp. 8, 9, pl. xi. fig. 4.

Lateral lobe of the head acute, produced some distance along the first joint of the upper antennæ. Third segment of the pleon with the postero-lateral angles much prolonged and curved upwards as narrow pointed lobes. Fourth pleon-segment with a dorsal depression. There are some small scattered hairs upon the back.

Eyes not discerned.

Upper Antennæ.—The first joint long, stout, cylindrical, with a row of minute cilia near the base, and some larger feathered ones on the opposite margin, distally, such being scattered also on the two following joints, which are very short, narrowing distally; flagellum of fourteen joints, the first as long as the four following combined, carrying the usual

brush of filamentary cylinders¹ beneath ; the other joints furnished with cilia, and some of them with cylinders ; the accessory flagellum of five joints, of which the first is the longest.

Lower Antennæ.—Third joint as long as first and second united, and but little shorter than the fifth ; fifth a little shorter and narrower than the fourth ; gland-zone prominent, as can be seen when the antennæ are disengaged from the head ; flagellum of sixteen articulations. Feathered cilia on the fourth and fifth joints of the peduncle, besides smooth setæ of various sizes.

Mandibles.—The palp set very far forward ; the cutting edge evenly convex, with a small projection at the top ; secondary plate of left mandible narrow, seemingly a little dentate at its slightly dilated apex ; spine-row of three small spines or stiff curved setæ ; molar tubercle with the dentate crown oval, not strongly outdrawn backwards as in *Anonyx cicadooides* ; palp with first joint very short, second joint very long, with slight bend or constriction below the centre, and a row of seven spines near the apex ; the third much shorter joint has twelve short spines along the margin, followed by six more successively increasing in length to the apex ; not far from the base, at and near the convex margin, there are two or three long setiform spines ; the surface of this joint is as usual striated with closely appressed cilia.

Lower Lip ciliated as usual on the forward apices ; the outer margins and mandibular processes in the specimen figured quite smooth.

First Maxillæ.—Inner plate slender, ovate, apically furnished with two plumose setæ, the inner much the smaller ; outer plate broad, carrying on the obliquely truncate apex six dentate spines, and others, probably five, in a second row below these ; the second joint of the palp is laminar, much curved, overarching the outer plate, having its slightly narrowed apical margin fringed with twelve to thirteen teeth pectinate on the outer edge, and one cilium or small seta near the margin. In describing these maxillæ, Mr. E. J. Miers² uses the following words, “the outer lobe strong, truncate, armed at the apex with three or four spines.” When the part in question is examined with a low power, this would be the natural way to describe it, but under a high power of the microscope it can be seen that the spines are much more numerous, those actually at the apex numbering six very much crowded together, and in the specimen here described very blunt at the tips. That this bluntness is only the effect of wear is clear from the sharply-pointed new spines which can be discerned within the plate.

Second Maxillæ.—The plates rather narrow, the outer a little longer than the inner, the apices with the usual fringes of pectinate spines, which pass rather further down the inner margin in the inner plate than in the outer ; on the inner plate the row terminates with a plumose seta.

The Maxillipeds narrow, not broad at the base as might be inferred from the figure,

¹ By the expression *filamentary cylinders* or *cylindrical setæ* I mean the organs now generally regarded as olfactory.

² *Loc. cit.*, p. 8.

which represents the two halves much flattened out; inner plate reaching a little beyond the first joint of the palp, having three teeth on the apical margin, the plumose setæ commencing near the middle of the inner margin, and passing round to the outer corner of the apical margin, but not continued down the outer edge; none of them large; the outer plate reaching much beyond the second joint of the palp, its inner border (beginning from the base) carrying a cilium, then a setiform spine, then a spine, then two microscopic teeth, then a close row of thirteen small teeth, those at the curve of the apex being the largest, beyond these the curved outer margin apparently quite naked; there is a row of five little spines on the side of the plate, a little removed from the inner margin; of the palp-joints the first is longer than the third, the second longer than the first, the fourth or finger provided with a sharp nail.

First Gnathopods.—Side-plates very little dilated below; first joint almost straight, sparingly setiferous in front; third joint with the emarginate front border much shorter than the hind border, which has a group of setæ near the apex; the wrist rather longer than the hand, nearly half of its hinder margin coinciding with the distal margin of the preceding joint, the remainder parallel with the front margin, slightly furred and carrying two groups of setæ; the hand almost parallel-sided, like the wrist having some groups of setæ near the front border, and a conspicuous group at its apex, on the hinder border having four groups; the sloping, rather convex palm, microscopically pectinate, defined by a spine, bordered with spiniform cilia, in addition to two linear groups of setæ, and close to the hinge of the finger two minute spines; the finger, besides the usual cilium on the back near the hinge, has one about the middle of its inner margin; this margin develops a small tooth near the origin of the nail, two cilia taking rise at this point.

Second Gnathopods.—Side-plates and the first joint of the leg a little longer and narrower than those of the preceding segment; branchial vesicle with a broadly rounded upper lobe rising above the neck, the central part of the vesicle having the twist of a screw, the lower part narrowing rather abruptly;¹ marsupial plate narrow; second joint as long as the wrist; third joint short, furred behind, apically somewhat rounded, and carrying a group of pectinate spines; wrist much longer than hand, densely furred behind, less so in front; pectinate spines near the lower end of the hinder margin; hand long-ovate, densely furred, numerous pectinate spines of very various sizes arrayed on both borders, especially in front apically, the pectination and curvature in both sets being directed towards the finger; the finger itself, as so commonly in this family of the Amphipoda, minute, almost lost in the surrounding forest of spines, broad at the base, then narrowing suddenly, the inner edge of the narrowed part microscopically pectinate and produced into a tooth, over which the nail bends, with cilia at its base; there is also a cilium on the back of the finger.

¹ The figure, Pl. VIII. *gn. 2.*, unfortunately does not show or even suggest the details above described, but only gives the shape of the vesicle flattened out and mounted on a slide for the microscope.

First Peræopods.—Side-plates a little broader and longer than those of the preceding pair; branchial vesicle from a small neck swelling out into a broad sac with a narrow terminal lobe; first joint of the leg with the front margin straight; third joint stouter and much longer than the fourth, but little produced downwards; fourth joint stouter than fifth, subequal to it in length; fifth joint naked, like the two preceding, on the forward margin except at the apex; on the hinder margin all three have groups of spiniform setæ, one long one at the apex of the fourth joint and some shorter ones on the border of the fifth seeming to be truly spines; the finger long, narrow, slightly curved, with edges bare except for the feathered cilium on its back near the base.

Second Peræopods.—Side-plates broad below, excavated above; the marsupial plates in this and in the preceding segment long and very narrow (in the specimen figured); the joints of the leg like those of the preceding pair.

Third Peræopods.—The branchial vesicle broad and squared above, curling round in a narrow lobe below, with a long thin accessory vesicle starting from the base. First joint very broad, slightly broader above than below, lower margin behind with a deep rounded lobe overlapping the next joint, the lateral margins very little curved; the third joint short, broad, somewhat decurrent behind, with spines on the hinder margin, spines and fine setæ on the front margin; fourth joint ovate, somewhat shorter and much narrower than the preceding, garnished in like manner; fifth joint slender, longer than the fourth, with few spines; finger long, thin, little curved, seemingly quite naked.

Fourth and Fifth Peræopods similar in general structure to the third, but with the first joints longer and about the same breadth, the third joint in the fifth pair less dilated, the fifth joint longer in proportion to the finger. As the dorsal cilium of the finger is here present, it may be only accidentally missing from the third pair. Branchial vesicle of the fourth pair was on one side of the specimen not unlike the accessory vesicle of the third, but curved instead of straight, and at the top broader, as also in the somewhat narrowed middle part, while the terminal part is thinner; on the other side the lower part of the branchia was expanded. The branchial vesicle of the fifth pair is quite small, irregularly shaped both as regards the neck lobe and the larger terminal one, which has the appearance of being attached to the other by one corner.

Pleopods.—In the coupling spines the apex is rounded, undilated; the lateral retroverted teeth are two in number; on the large basal joint of the inner ramus there are three cleft spines of the usual form, as described in the account of *Cyphocaris micronyx* (p. 660); the joints of the rami are from sixteen to twenty in number, the outer ramus apparently as a rule having one or two more joints than the inner.

Uropods.—The first pair have the peduncles somewhat longer than the rami; the outer ramus rather longer than the inner; both stiliform, slightly curved at the tips; in the second pair the peduncle is rather shorter than the rami; these are subequal, each, as

in the preceding pair, armed with three spines along the proximal part of the upper border; in the third pair the peduncle is short, the rami slenderly lanceolate, the outer and longer branch terminating with a nail, having five spines along one of its margins, on the other two spines and one or two setæ near the nail; the inner branch with spines and setæ along one margin, and some spines near to the other margin.

Telson.—Cleft nearly to the base, evenly narrowing to the apex, each half of which is emarginate, the inner part more produced than the outer, and carrying a spine and a feathered cilium in the hollow; three spines are placed at intervals on the surface of the telson near each outer margin.

Length.—The specimen figured measured, without the antennæ, about two-fifths of an inch.

Locality.—Station 149, Accessible Bay, Kerguelen Island, January 9, 1874; depth, 20 fathoms; bottom, volcanic mud. Dredged.

Station 149H, off Cumberland Bay, Kerguelen Island, January 29, 1874; depth, 127 fathoms; bottom, volcanic mud. Several specimens. Dredged.

Remarks.—Mr. Miers, in the Zoology of Kerguelen Island, p. 9, says:—

"In the form of the antero-lateral angles of the cephalon, and of the postero-lateral angles of the third segment of the pleon, this species to some extent resembles (1) *Hippomedon holbölli*, Kröyer, as described by Boeck, as well as (2) *H. abyssi* [*abyssi*], Goës, and (3) *Anonyx pumilus*, Lilljeborg,—all from the Northern Seas. But it differs from these species in having the inner lobes of the maxillipeds proportionately much longer; and in this respect it approaches more nearly to the type of structure exhibited in *Orchomene*, Boeck. The eyes also, which are well marked in the species just referred to, are not visible in any of the specimens of *A. kergueleni*.

"On account of the subcheliform character of the first pair of the gnathopoda, and the divided telson, I refer this species to the genus *Anonyx*, as defined by Mr. C. Spence Bate, instead of retaining it in *Lysianassa*, where I placed it at first. I cannot refer it with certainty to any one of the numerous genera recently established by Boeck in his systematic arrangement of the Scandinavian and Arctic *Amphipoda*; I believe, indeed, that it will be found necessary to introduce important modifications of the systematic arrangement and generic characters proposed by this author into any general revision of this difficult order, which may hereafter be undertaken, based upon the comparison of species from foreign as well as the European and Arctic Seas."

A specimen, however, of *Hippomedon abyssi* (Goës), from the "Valorous" Expedition, lent me by Canon Norman, shows both the inner and outer lobes of the maxillipeds corresponding in their proportions with those of the present species, which I have therefore transferred to the genus *Hippomedon*, where Mr. Miers himself seems to have had some disposition to place it.

Hippomedon trigonicus, n. sp. (Pl. IX.).

In many respects this species shows a very close resemblance to *Hippomedon kergueleni* (Miers), although there are peculiarities which have induced me, after some wavering, to keep it distinct. In the present form the postero-lateral angle of the third pleon-segment is but little, instead of greatly, curved upwards. Of the fourth pleon-segment the proximal portion is very convex, the depression being distal, so that the end of the segment forms a raised angular apex rising above, instead of forming a continuous curve with, the following segment.

It originally appeared to me that the dorsal depression in *Hippomedon kergueleni* was in a marked manner proximal, and in the form now under consideration conspicuously distal, but I find in this and many other species of Amphipods that the dorsal appearance of the fourth pleon-segment is very essentially altered according as the pleon happens to be more or less extended or flexed. In the state of extension the proximal portion of this segment often telescopes far into the third segment, sometimes completely hiding a dorsal depression, and at others making such a depression appear proximal, when in regard to the whole dorsal length of the segment it is in fact distal or central.

The other differences between the two forms may be judged of from the following account.

Upper Antennæ.—The peduncles comparatively slender, the first joint longer in proportion to its breadth than in the form already described; the flagellum consisting of eleven joints, the first equal in length to between two and three of those succeeding it; the secondary flagellum of three joints, of which the first is not quite so long as the first of the primary.

Lower Antennæ.—Gland-cone prominent, third joint equal in length to the fifth; fourth joint decidedly longer than either; flagellum nine-jointed.

*The Mouth-Organ*s appear to be in close agreement with those previously described. In the specimen examined there were fewer teeth on the apex of the palp of the first maxilla.

First Gnathopods.—There seems to be no difference of importance except in the shape of the side-plates, which are here of less regular form, shorter and stouter, outdrawn in front below. At the beginning of the palm of the hand there are two spines.

Second Gnathopods.—In this species the wrist is a little plumper distally, hand and wrist both densely furred, but the distal spine-armature of the hand both at front and back less important than in the other species.

Second Peræopods.—What may be called the shank of the side-plate is here somewhat longer in proportion to the broad lower portion.

Third Peræopods.—First joint more contracted below, and with margins more curved, so as to have an oval rather than the square appearance presented in the other species; the third and fourth joints longer compared with their breadth.

Fifth Peraopods.—The front margin of the first joint is here almost absolutely smooth for the upper two-thirds of its length, while in the other species it is spined almost through its whole length; on the other hand the cilia on the postero-distal curve are here more numerous. The fingers in this species are less slender than in the other.

Pleopods.—Two very small coupling spines, with a row of three back-turned teeth along the margin; the inner ramus with twelve, the outer with fourteen joints, the first of the outer fringed as in the companion species with numerous plumose setæ, the first of the inner with the eleft spines three in number.

Uropods.—In the first pair there are four spines on the margin of the outer ramus, and five on that of the inner, leaving a comparatively small terminal portion free from spines; in the second pair the outer branch has four, the inner three, spines; in the third pair the outer branch has three spines on one margin, and on the other one at the base of the nail; this branch is not longer than the peduncle, the other, which is much shorter, has but one spine.

Telson.—This, though similar in the details of its structure to that of *Hippomedon kergueleni*, is extremely different in its proportions, being in fact but little longer than its greatest breadth.

It is not very safe to establish new species upon small differences in the relative lengths of joints of the antennæ and limbs, or upon variations in the number of spines that form a marginal row, since these discrepancies and such as these may be due to age or sex or individuality, but in the present instance it must be noticed that in regard to the two forms named *Hippomedon kergueleni* and *Hippomedon trigonicus*, specimens of the same sex have been compared, and that the more striking form of the fourth pleon-segment, and the larger number of spines on the first and second uropods, belong to the smaller, not to the larger species.

Length, one-quarter of an inch without the antennæ.

Locality.—Kerguelen Island; depth not specified.

Remark.—The specific name *trigonicus*, triangular, refers to the shape of the hump on the fourth segment of the pleon.

Hippomedon miersi, n. sp. (Pl. X.).

Lateral lobe of the head produced into a rounded angle. Postero-lateral angle of the second segment of the pleon slightly acute, of the third segment rounded. The fourth segment with a dorsal depression, the sixth segment with dorsal ridges on either side of the telson.

There seemed to be a faint indication of eyes.

Upper Antennæ.—First joint short, tumid; second and third joints very short, the third a little outdrawn above; flagellum of eleven joints, the first subequal to the remainder united, and longer than the four-jointed secondary flagellum; on the first joint of the peduncle a spine-like feathered cilium on the central bulge below, longer feathered cilia on its distal border, and on the next joint; the usual brush on the first joint of the flagellum, this joint being distally drawn out into a little sharp tooth; calceoli on several of the small joints.

Lower Antennæ.—First three joints short, gland-cone twisted round towards the first joint; third joint shorter on the inner than the outer side; fourth and fifth joints furred above, fifth longer and thinner than the fourth; flagellum of some thirty-eight joints, with small calceoli seemingly only on every alternate joint.

Mandibles.—Cutting edge as usual convex, with a small projection above, the rounded part below perhaps a little indented behind; the secondary plate on the left mandible a little curved, bluntly pointed, too broad to be called spine-like, probably in a worn condition; spine-row seemingly of three small spines; molar tubercle prominent, the crown rather elongate; the palp long, set as far forward as the front of the molar tubercle, the second joint but little longer than the third, thirteen spines at the distal part of the second joint, in the third joint one spine at the back close to the base, on the opposite border nearly a third part free, the row of spines consisting of twelve decreasing, followed by six or seven increasing, in length successively towards the apex.

Lower Lip as in the next species, *Hippomedon geelongi*.

First Maxillæ.—Inner plate not very large, with two plumose setæ on the rather broad apex, the inner one much smaller than the outer; outer plate with eleven dentate spines crowded on and about the apical margin, the inner margin furred distally, the spines near to the inner margin slender, with numerous teeth, the outer more stout with few teeth; the palp over-arching the outer plate, with nine teeth round its apical margin, increasing successively towards the centre, pectinate on their concave outer edges; one seta projects near the outer apical angle.

Second Maxillæ.—The outer plate longer than the inner, the sloping apical margins of both fringed with rows of pectinate spines; on the inner plate there are stiff plumose setæ as well as spines, and a little below the apex a larger and proportionately less stiff plumose seta on the inner margin.

Maxillipeds.—The inner plates reach about to the apex of the first joint of the palp, with three teeth followed by two curved eliated spines on the apical margin, and one tooth on the inner margin just below the apex; the outer plates reach as far forward as the second joint of the palp or a little further, the ten teeth of the inner and apical margins increasing in size towards the apex, at which the ninth is the longest, though thinner than the eighth, while the tenth is both shorter and thinner than the ninth; the second joint of the palp is but little longer than the first; the third joint is much shorter

than either; the finger with its sharp curved nail is as long as the third joint; it has some cilia near the nail, and a dorsal cilium much nearer the nail than the base.

First Gnathopods.—Side-plates small, long-oval, narrowst at the lower end. First joint strong, projecting much beyond the side-plate; third joint very short in front, much longer behind; the wrist not so long as the hand, and scarcely broader, widened beyond the triangular portion which adjoins the third joint, and furred on the hind margin of the widened part; the hand long, nearly parallel-sided, with a slight curve, hinder border scarcely furred, some setæ on both margins and on the side; palm sloping, a little convex, defined by two spines with stout accessory threads; between these spines the finger closes down neatly fitting the palm, and having a tooth on the inside just before the nail is reached.

Second Gnathopods.—Side-plates deeper than those of the preceding segment, much wider below than above; first joint long, widening a little and curving backwards as it approaches the long second joint; third joint shorter than second, furred about the middle of the hinder margin, which carries near the apex long slender spines or setæ of geniculate appearance; the wrist but little longer than the second joint, furred both before and behind, and with long slender spines near the apex on both sides; the hand much shorter than the wrist, oval, densely furred, with the usual armature of spines; the finger very small, set pretty well clear of the anterior group of spines, lying close to the produced hinder portion of the hand which provides the palm.

First and Second Peraeopods.—Side-plates of the first similar to the preceding pair, but larger, side-plates of the second much wider below than above; first joint just reaching the lower rim of the side-plate; third joint nearly parallel-sided, scarcely produced downwards, considerably longer than the fourth joint, both fringed posteriorly with setæ, which increase successively in length towards the distal end of the margin; the fifth joint as long as the third, but much thinner, gently curved, posteriorly armed with spines and setæ, and carrying close to the hinge joint of the finger a pair of spines shorter than those above, blunter, and seemingly with fine backward serratures. Finger about half the length of the hand in the first peraeopod. In the second peraeopod the third joint and the hand are rather shorter than in the first.

Third Peraeopods.—Side-plates rather broader than deep. First joint as broad as side-plate, length and breadth about equal, narrowed below, the distal curve behind produced nearly to the end of the second joint, convex front border set with spines and setæ; third joint dilated, not longer than the fourth, except for the produced infero-posterior angle; fourth joint more dilated above than below; fifth joint longer than fourth, much narrower, a little curved, with five pairs of spines on the anterior margin; finger rather long and slender.

Fourth Peraeopods.—First joint a long oval, most of the front border spined; the third joint shorter than either of the next; fourth a little wider but shorter than the

fifth, a row of four rather long spines on its front margin, each between two short ones; the fifth with five sets of spines on the front, each consisting of a long and a short spine, except the lowest set, in which the spines are equal. The finger is long and slender, curved near to the small nail.

Fifth Peraopods.—First joint broader and longer than that of the preceding pair, widest above; third joint not dilated; rest of limb missing. The branchial vesicles were not in a good state for observation; they presented many irregular folds, and the usual gradations of size.

Pleopods.—So far as examined these correspond very nearly with those described for *Hippomedon geelongi*. Six cleft spines were observed on one of the rami.

Uropods.—Peduncles of the first pair longer than the rami, outer ramus rather longer than the inner, small spines on the upper margins, four on the outer ramus, three on the inner, a short bright nail at the tip; in the new rami in a state of preparation within the old this bright nail makes itself conspicuous, as though it were already a part of the outward armature (see fig. *nr. 2.*). Peduncles of the second pair shorter than the rami, which are similar to those of the first pair, except that they are shorter without being less broad; peduncles and rami of the third pair shorter than those of the second pair, though not greatly so; outer ramus longer than inner, with some small spines along the side; each ramus ends in a small nail to which it rather abruptly narrows, and each has the border fringed with very long plumose setæ.

Telson.—Much longer than broad, cleft about four-fifths of its length, distally narrowing a little, but so as to leave both divisions broad-ended. In a small emargination at the outer part of each apical border is a stout spine with a cilium close on each side of it. The inner part of the apical border is rounded. On each side nearly on a level with the top of the cleft is a feathered cilium, and two spines on the margin lower down.

Length.—The specimen, without the antennæ, was nearly half an inch long.

Locality.—Station 162, off East Monœœur Island, April 2, 1874; lat. $39^{\circ} 10' 30''$ S., long. $146^{\circ} 37' 0''$ E.; depth, 38 fathoms; bottom, sand and shells. One specimen. Dredged.

Remarks.—There is much agreement between this species and *Hippomedon ker-gueleni*, Miers. To call attention to this, and at the same time to show respect to the clever naturalist who first described the species just mentioned, I have named the present species *Hippomedon miersi*. It possesses that character of the antennæ which Boeck makes generic, but which is perhaps peculiar to the male. It has many sufficiently distinct features, in the first joint of the flagellum of the upper antennæ, the long third joint of the mandible palp, the first side-plate of the peræon, the third pleon-segment, the tips of the uropods, the broad termination of the telson, and other details.

Hippomedon geelongi, n. sp. (Pl. XI.).

The head narrow, much longer than the very short first peraeon-segment, produced into pointed lateral lobes between the upper and lower antennæ. First segment of the pleon with the postero-lateral angles much, second with the same little, rounded; third with the same acute and bent upwards; the third segment the longest; the fourth segment with a dorsal depression.

No eyes were perceived.

Upper Antennæ.—First joint large and tumid, upper margin distally produced; the second joint almost embedded in the first; the second and third both short, narrowing as they approach the flagellum, of which the first joint is large and long, adorned with the usual brush; of the other joints only two remained, the second bearing a large caleolus, and a row of five cilia near it. The secondary flagellum consists of five joints, furnished with setæ.

Lower Antennæ.—Gland-cone rather prominent, third joint not long, still equalling in length the composite first and second; fourth joint thicker, but scarcely longer than fifth, both furred on the upper margin and carrying feathered cilia on the lower. Flagellum of thirty joints, each apparently except the last furnished with a caleolus and a row of cilia behind it. The caleoli seemed to be rather short-stalked and with the outer rims firmer than usual.

Mandibles.—The cutting edge not well observed, but probably in near agreement with that of *Hippomedon kergueleni*; the spine-row of three curved, rather short spines; the molar tubercle with the dentate crown oval; the palp set just over the front part of the molar tubercle, its second joint considerably longer than the third, slightly constricted below the middle, this being the place where the muscles in connection with the first joint end, and where those in connection with the third joint begin; nearer to the apex begins a row of fourteen spines, which increase successively in length as they approach the outer angle of the apex; the third joint is long, slightly curved, narrowing distally, with two long setæ near the beginning of the outer border, and twenty-two pectinate spines along the concave edge; these slightly diminish in size as they approach the apex, till, close upon it, they rapidly increase.

Lower Lip.—The front lobes ciliated all round, apically as usual with more fulness; the mandibular processes narrow and not produced far back.

First Maxillæ.—The inner plate not very long, on the distal portion of its inner margin and the apex carrying a row of seven plumose setæ, graduated in size, the first of the row being very slight and the apical one very large; the proximal part of the margin is furred by the projection of the fine cilia on the surface of the plate; the outer plate carries distally eleven spines all strongly dentate, the six round the apical border very stout, the five below them on the surface of the plate more slender, not

in a parallel row; the second joint of the over-arching palp distally furnished with twelve teeth and a seta, in the maxilla examined.

Second Maxillæ.—The inner plate with almost its whole inner margin fringed with plumose setiform spines; the outer plate over-topping the inner, its apical border fringed with peetinate spines; both plates furred with cilia.

Maxillipeds.—The inner plates scarcely reaching as far as the apex of the first joint of the palp, furnished with the usual setæ on the inner margin passing round to the outer apical corner, and three teeth on the apical margin; the outer plates reaching some way beyond the second joint of the palp, carrying ten teeth on the inner margin, slightly increasing in length to the apex; a few small spines within the border; the curved outer and apical margin clean. The first two joints of the palp equal; the third joint shorter; the finger much shorter than the third joint, with some cilia on the inner side near the nail.

First Gnathopods.—These approach closely to the form described for *Hippomedon kergueleni*. The hand and wrist are equal in length; the hand widens a little distally, and the finger closes very exactly over the sloping convex palm, which the tip of the finger conspicuously overlaps, without any distinct tooth on its inner side; the palm being defined by some slender spines. There is no sign here of any furring of the hinder border of the third and fourth joints as in the species just mentioned, and in some other respects, as the figures show, they are somewhat differently furnished. The margins only must be compared in the figures, as of the present species it is the inside, not, as usually, the outside of the hand that has been represented.

Second Gnathopods.—In general appearance these are scarcely distinguishable from those of *Hippomedon kergueleni*; distally the wrist is a little fulled out, with short, bent spines or scales on the breast, that is, the postero-distal portion.

First and Second Peræopods as in *Hippomedon kergueleni*, with the upper part of the side-plate of the second pair somewhat broader and less elongate.

Third Peræopods.—Branchial vesicle much folded. First joint narrowed distally, much more prominently spined on the front border than in the species above mentioned; fourth joint widest proximally, not ovate; fifth joint much longer than fourth, both armed with rows of long and short spines. Finger long and slender, a little curved at the tip, naked except for the dorsal cilium near the base.

Fourth Peræopods.—Branchial vesicle as usual much smaller than in the preceding pair, on one side of the specimen ending in a narrow sinuous sac, but on the other side more dilated. First joint a long oval, most of the upper half of the front margin free from spines; third joint but little dilated; rest of the limb missing.

Fifth Peræopods.—First joint longer and broader than in the preceding pair, front margin rather sinuous, the concavity about the middle, upper half with only two

or three very small spines, hind margin very, but not evenly eonvex, rather deeply serrate; third joint not dilated; rest of the limb missing.

Pleopods.—The round-headed coupling spines have from three to four retroverted teeth; the rami have each from nineteen to twenty joints carrying densely plumose setæ; the first joints vary in the different pairs, being longer in the first pair than in the seeond, and in the seeond than in the third; the first joint has in the first pair thirteen or fourteen plumose setæ on one margin and four on the other, but fewer in the following pairs; the first joint of the inner ramus in the first pair has six eleft spines, in the seeond pair, I believe, only five, and in the third pair only three. The number of these spines, therefore, will not be of service as a specific character, unless all three pairs of pleopods are earefully scrutinized.

Uropods.—The pedunule in the first pair longer than the slender rami, of which the outer is but slightly longer than the inner; pedunule in the seeond pair equal in length to the rami, whieh are equal to one another, shorter than those of the preeeding pair; peduncle in the third pair much shorter than rami; outer ramus with a nail, spines on or near the outer border, plumose setæ on more than half the inner border as far as the nail; inner ramus slightly shorter than outer, with spines on both borders, and plumose setæ all along the inner border.

Telson reaehing beyond the pedunule of the third uropods; eleft for two-thirds or more of its length, the plates a little dehiseent distally, the apex of eah rather more produced on the outer than the inner side of the terminal spine eavity; on each border two spines and between them a small feathered spiny seta.

Length.—The speeimen measured, without the antennæ, nearly half an inch.

Locality.—Station 161, off Melbourne, April 1, 1874; depth, 33 fathoms; bottom, sand. One specimen. Trawled.

Remarks.—The speefie name refers to Geelong, near the Station at whieh this species was captured.

I was tempted, ehiely on aeeount of the mouth-organs, to refer this speeies to a new genus intermediate between *Callisoma* and *Hippomedon*. The mandibular palp agrees with that of *Callisoma crenatum*, Spenee Bate, in its shape, but in its position with that in the speeies of *Hippomedon*. The inner plates of the second pair of maxillæ agree in their armature with *Callisoma* and not with *Hippomedon*, those of the first pair also disagreeing with *Hippomedon* as deseribed by Boek. The palps of the maxillipeds, the antennæ, the third uropods and telson nearly resemble the corre-sponding parts of *Callisoma crenatum*, while the gnathopods and other features are in closer agreement with *Hippomedon kergueleni*. However, on examining disseetions of a speeimen of *Hippomedon abyssi* (Goës), kindly lent me by Canon Norman, I found that the inner plate of the first maxilla had, like the present speeies, more than two

setæ, in agreement with the figure given by Goës himself. It seemed on the whole, therefore, better to widen Boeek's definition of *Hippomedon* than to add to genera already, as many authors think, too numerous.

Genus *Cheirimedon*, n. gen.

Epistome with an ascending lobe.

Mandibles with the palp set far forward, just over the molar tubercle, the third joint a little shorter than the second; molar tubercle prominent.

First Maxillæ with the inner plate carrying two plumose setæ; the palp not dilated, with several teeth on the apical border.

Second Maxillæ with the outer plate rather longer than the inner, neither of the plates armed far down the inner margin.

Maxillipeds with the palp having none of its joints elongate, fourth joint unguiform; inner plate reaching as far as the apex of the first, outer as far as the apex of the second, joint of the palp; outer plate with well-developed teeth, two at the apex spiniform.

Lower Antennæ with the peduncle elongate, fourth and fifth joints subequal.

First Gnathopods with the wrist very short, hand large, distally dilated, subcheliform.

Body with the postero-lateral angles of third pleon-segment sharply upturned.

Telson cleft.

The generic name *Cheirimedon*, χείρ, the hand, and μέδων, a lord, alludes to the importance in this genus of the hand of the first gnathopods. As usual, when a genus is founded for a single species, the characters should be regarded as preliminary and liable to modification, should other closely related species be subsequently found which could be included by small changes in the original definition of the genus.

Cheirimedon crenatipalmatus, n. sp. (Pl. XII.).

Head with a small rostrum and sharply produced lateral lobes; first two segments of the pereon short, third pleon-segment longer than any other of the segments, its postero-lateral angles sharp, greatly upturned towards the downward bending dorsal margin, the hind margin thus forming a deep cavity; the fourth pleon-segment with a deep dorsal depression, the dorsal margin acutely prolonged backwards.

Eyes not perceived, yet not certainly altogether absent.

Upper Antennæ.—First joint long, cylindric; second and third short, narrowing distally; flagellum of twelve joints, of which the first is very long, equalling seven or eight of the following joints combined, cylindric, slightly tapering, with only one or two filamentary cylinders in our specimen, but an appearance as if a narrow brush of them

might have been present originally; the remaining joints short, successively diminishing in length and thickness, many of them carrying long filamentary cylinders; the secondary flagellum of three slender joints, two long and one very short, the three together not equal in length to the first of the primary.

Lower Antennæ.—The gland-cone prominent, the third joint not much shorter than the composite first and second, the fourth and fifth long, straight, parallel-sided, the fourth rather wider than the fifth, equal to it in length, and also equal in length to the first four joints of the seven-jointed flagellum.

Triturating Organ.—In the Lysianassidæ this organ differs much from the form presented in the Orchestidæ. In the present species the oval organ exhibits round one margin a row of some two dozen spines, of which the basal half is thick, the other half becoming abruptly thinner and curved; round the opposite margin is a still more closely set row of some twenty-eight longer spines, nearly straight, pretty evenly thick all along to the end, which is cut into a short fork; where the two rows meet at the outer extremity of the organ there are some ciliated spines.

Mandibles.—Cutting edge smoothly convex, with an upper tooth turned a little downwards and a lower one turned a little upwards;¹ secondary plate on the left mandible small, strap-shaped, its edge cut into four or five teeth; spine-row consisting of three slightly curved spines (only two present on the right mandible); molar tubercle prominent, its oval crown somewhat ciliated on the edges, carrying four or five teeth down the centre, the remainder divided into rows of very minute denticles; the palp set far forward just over the molar tubercle, the first joint short, the next rather long, with eight or nine spines near the apex; the third joint shorter than the second by about the length of the first. The pectinate spines on the inner margin of the third joint, beginning below the middle, increase in length to the apex; they numbered seventeen on the left, fourteen on the right mandible.

Lower Lip.—With the forward lobes broad, pretty strongly ciliated.

First Maxillæ.—Inner plate small, oval, with two plumose setæ at the apex, the inner being the smaller; outer plate large, the apical margin with six strong dentate spines, below which are five others, the outermost strong, little dentate, the others a little more slender, not much curved, each with four or five lateral teeth; the palp reaching beyond the outer plate, its second joint nearly parallel-sided, the apical margin carrying from nine (on the right maxilla) to twelve teeth (on the left maxilla), the outermost longest, and one pectinate seta on the surface not far from the outer tooth.

Second Maxillæ.—The outer plate broader than the inner and prolonged a little beyond it; on the apex and a short way down the inner margin of the inner plate

¹ The true shape of this part of the mandibles was not clearly made out till after the figures, Pl. XII. *m. m.*, had been lithographed.

are about a dozen spines, followed below by half-a-dozen plumose setæ; the apical border of the outer plate set with spines curved at the tips, the longest at the outer apex, followed by two or three short ones down the outer margin.

Maxillipeds.—The inner plates reaching about as far as the apex of the first joint of the palp, with three teeth on the apical margin, of which the outer is much the smallest, and plumose setæ on the inner margin passing over to the outer apex; outer plates reaching slightly beyond the second joint of the palp, the inner margin set with teeth numbering from nine to ten, followed by two longer ones on the apical margin; eight or nine small spines may be seen on the outer surface of the plate, at a little distance from the inner margin; the palp compact, the second joint but little longer than the first; the third joint not longer than the finger, which is robust, ending in a long, thin, sharp nail; it has two cilia on the inner margin near the nail, and the dorsal cilium not far from the base.

First Gnathopods.—Side-plates a little widened and much rounded below; first joint projecting a little beyond the side-plate, of even width, with setæ on the front margin; second, third and fourth joints differing but little in length, together scarcely as long as the hand, the third oblong, the fourth triangular; the hand large, increasing in width distally, the palm a little sloping, defined by two spines, between which the finger-nail closes down, the palm-margin crenate, with cilia just within the border and setæ a little deeper within it; the finger has a dorsal cilium near the hinge, and one at the base of the nail, which in our specimen was broken.

Second Gnathopods.—The side-plates narrow, slightly rounded below and scarcely at all dilated; the branchial vesicles broad except at the base, without folds. First joint a little dilated and bent below, nearly equal in length to the third, fourth and fifth united; the second joint nearly as long as the wrist; the third joint much shorter, equal in length to the hand, furred behind, with some small setæ near the apex; the wrist lightly furred on the distal half of the front and the proximal half of the hind margin, below this on the dilated breast having tooth-like cilia or little incurved spinules, and, in addition, numerous scale-like ornaments, not, I believe, uncommon in this family, minute in size, fan-like in appearance; the hand is furred, a quadrangular oval, the lower part of the front and forepart of the apical margin occupied with the usual rows of pectinate spines, the small finger being set on beyond these, and antagonizing with the well-advanced point of the hinder margin of the hand, which is thickly set with pectinate, geniculate spines. The dorsal cilium of the finger fixed about centrally, projects over the tip of the finger.

First Peræopods.—Side-plates a little dilated below, scarcely rounded; first joint just reaching the lower rim of the side-plate; third joint much longer than fourth, rather broader, scarcely produced; fourth joint broader than fifth, but a little shorter; fifth joint with the hinder margin straight, with some spines; the hind margins of the

second, third, fourth and fifth joints all carrying setæ; the finger long and slender, almost straight.

Second Peraopods.—The side-plates with the excavation of the hind border unusually shallow, the lower part of the border showing a serration of three or four teeth; the branchial vesicle contracted a little below, very broad centrally. The joints of the limb almost precisely as in the preceding pair, the fifth joint a little shorter.

Third Peraopods.—Breadth and greatest depth of the side-plates about equal, the anterior lobe produced a little lower than the posterior; the first joint much longer than broad, its length surpassing that of the next four joints combined, broader above than below, spined along the front margin, the hinder serrate; the second joint has setæ on the front margin and some minute apical spines; the third joint dilated and out-drawn behind, has setæ and small spines on the front, spine-like setæ on the hind margin; the fourth joint scarcely equal in length to the third or the fifth joint and intermediate in thickness, has on its front margin long, single spines set between pairs of very small ones; the fifth joint narrows distally, its spine-groups, except the lowest, consisting of a long and a short spine side by side; the finger is much shorter than in the preceding pair.

Fourth Peraopods.—First joint longer and broader than in the preceding pair, but not as long as the four next joints of the limb, very slightly narrowed below; front margin spined and ciliate, hind margin serrate; the third joint little expanded or produced, about equal in length to the fifth; the fourth a little shorter than the third; the fifth narrow, narrowest distally; small spines on the front margins of all these joints, long ones also on the fourth and fifth, and setæ on the second and third; the finger thin and short.

Fifth Peraopods.—First joint longer and broader than in the preceding pair; hind border much more convex than in the two preceding pairs, but, as in them, deeply serrate, the upper part of the front border free from spines; the third joint shorter than the fourth, and the fourth than the fifth; the finger small; the armature of the joints similar in character to that of the preceding pair.

Pleopods.—The pair of coupling spines on each peduncle have two backward-directed hooks on each spine; the joints of the rami appear to vary in number from ten to twelve for the inner branch, and from twelve to thirteen for the outer; the cleft spines form a row of five on the first pair, of three on the second and third pairs.

Uropods.—The peduncles of the first pair are longer than the slender, almost straight rami; the outer ramus longer than the inner, the margin spines few, none of them near the sharp apex, which is formed by a minute nail with a cilium at its base on the lower margin; peduncles of the second pair subequal to the rami, which are more stoutly spined than those of the preceding pair, the outer ramus but little longer than the inner; peduncles of the third pair short, shorter than the outer, longer than the inner,

ramus; the outer ramus broadly lanceolate, with spines on one margin, and ending with a decided nail; the small branch ending acutely, without a nail, a slender spine on one margin near the apex, and some way above it a cilium; higher upon the other margin another cilium.

Telson projecting beyond the peduncles of the third uropods, cleft for more than three-quarters of its length, narrowing distally, where it becomes slightly dehiscent by the curving round of the margins of the cleft; the inner part of each apex a little more produced than the outer, and in the hollow a stout spine inserted with a cilium by its side. Near each outer margin, a little below the top of the cleft, the telson has a spine on the surface, and below this one or two feathered cilia, and here and there a simple cilium.

Length.—The specimen, in the position figured, measured three-tenths of an inch.

Locality.—Station 149H, off Cumberland Bay, Kerguelen, January 29, 1874; depth, 127 fathoms; bottom, volcanic mud. One specimen, female.

Remarks.—The specific name, *crenatipalmatus*, refers to the palm of the first gnathopods.

The only other species in this group which has a form of hand similar to that of our species is, so far as I know, *Normania latimana*, G. O. Sars, but that species has been only provisionally assigned to Boeck's genus *Normania*, with which, as defined by its author, neither that species nor this agrees. The mouth-organs of *Normania latimana* have not yet been described, so that I cannot say whether it belongs or not to the genus now instituted.

Genus *Platamon*, n. gen.

Mandibles with the palp set forward over the dentate crown of the molar tuberele.

First Maxillæ with the inner plate oval, carrying two plumose setæ, the second joint of the palp greatly expanded, with numerous teeth on the apical border.

Second Maxillæ with the inner plate broader than the outer, its inner border fringed as well as the apical.

Maxillipeds with the inner plates remarkably broad, the outer plates with numerous teeth on the inner border, and two closely adjacent to the rest on the apex.

Both pairs of *Gnathopods* long and slender, with the fingers well-developed, the hand in the first gnathopods shorter than the wrist, oval, subchelate.

Third Uropods with the rami as long as those of the second.

Telson divided beyond the centre, extending beyond the peduncles of the third uropods.

The generic name is derived from the Greek word *πλαταμών*, a broad space, in allusion to the great breadth of the parts of the maxillæ and maxillipeds above described.

Remarks.—There seem to be many points of affinity between this genus and the genus *Glycerina* of Haswell. Of the type species, *Glycerina tenuicornis*, Mr. Haswell very kindly sent me a specimen, but the bottle containing it being broken in transit, the specimen was dry when it came to hand, and therefore not well fitted for the observance of minute details. Mr. Haswell states that there is no accessory plate to the mandibles. On this I cannot pronounce any opinion from my own observation. I observed three strong spines in the spine-row, and on the long molar tubercles several (nine or ten) little bright spines of cylindrical appearance standing out, not closely set, surrounded by a fur of elia; the spines of the first maxillæ run some distance down below the apical margin; the teeth on the apex of the palp are only seven or eight in number; the outer plates of the maxillipeds are feebly toothed; nor are other differences wanting.

Platamon longimanus, n. sp. (Pl. XIII.).

A small rostrum; lateral lobes of the head produced to a point, forming an equilateral triangle, dorsal line of the head longer than that of the first pereon-segment; postero-lateral angles in the first segment of the pleon rounded, in the second rectangular, in the third acute and upturned; fourth segment with a dorsal depression, slightly carinate, pointed behind; the sixth segment with lateral ridges on the back, which converge towards the telson and diverge when they reach its base.

Eyes not observed.

Upper Antennæ.—First joint very broad, distally projecting over the two next joints, which are very short, the projection being (like the rest of the joint) dorsally sharp, apically rounded; the flagellum of seven joints, the first tapering, equaling in length the other six united, the cylindrical setæ short, in some thirty rows; a long spine is placed at the distal end of the first joint, a shorter one on the second; the secondary flagellum slender, of three joints, together nearly equal in length to the first of the primary flagellum, the first a little curved, longer than the other two combined.

Lower Antennæ.—First joint not greatly dilated, gland-one of the second joint long and narrow, third joint short, fourth and fifth joints long, subequal, the fifth the narrower and rather the longer; flagellum (on one of the antennæ) of thirty-five joints.

Triturating Organs of the stomach present a double very sinuous row of short, somewhat curved spines on one edge, on the other a projecting row of seta-like spines, set as the ornamental pipes of an organ-front often are, with the longest in the middle, those on either side gradually decreasing in size.

Mandibles.—Cutting edge convex, bent out of shape in the specimen examined, but seemingly with the usual denticle-like prominence above, and the lower apex not divided; secondary plate of left mandible strap-shaped, rather long, ending acutely, with two teeth above the apex; spine-row not made out; dentate crown of molar tubercle very

prominent ; palp long, set just over the molar tubercle, both being far forward, first joint of palp short, second with a row of eighteen spines on the upper part ; the third joint widening a little from the base, then narrowing almost to a point, carrying a row of thirty spines on the inner border; none were present on the outer border.

Lower Lip with the distal part of the forward lobes strongly furred, the lobes seemingly dehiscent.

First Maxillæ.—Inner plate oval, rather broad, with two unequal plumose setæ on the rounded apex ; outer plate broad, not greatly elongated beyond the inner, apical margin not confluent with the inner margin ; all the spines and their denticles of stout structures, but especially the five or six of the upper row ; the palp with its second joint remarkably dilated, both lateral margins convex but the outer much more than the inner, the very broad apical margin set with nineteen spine-teeth, of which the outer two are excavate on the outer side ; they are followed by a straight pectinate spine at the outer corner, and a similar one is found at about the centre of the row of teeth but a little below it.

Second Maxillæ.—Inner plate shorter than outer, the lower part very broad, distally narrowing, its sinuous inner margin set with fifteen plumose setæ, the apical margin set with rows of spines of different sizes, the smaller seemingly smooth, the larger pectinate, the stoutest of these being at the inner angle near to the setæ ; the outer plate less broad than inner, the outer margin so much folded over that it cannot be flattened out in mounting for the microscope without separating it from its shaft, the apex rather more oblique than that of the inner plate, set closely with rows of pectinate spines.

Maxillipeds.—The inner plates of very unusual breadth, projecting rather in advance of the first joint of the palp, the plumose setæ of the inner border being comparatively short, numbering fourteen actually on the margin, the row being continued by shorter ones passing over towards the outer apex ; the apical margin carrying three pointed teeth followed by a row of several pectinate spines ; the outer plates long, reaching beyond the second joint of the palp, the straight inner margin smooth for some distance from its base, then presenting a spine, at a short interval from which begins a close-set series of eighteen sharp teeth, succeeded at the apex by a nineteenth tooth and a curved spine ; on the surface within the margin are eight small slender spines ; the second joint of the palp is longer than the first ; the finger is as long as the third joint ; its inner margin is pectinate, the short sharp nail accompanied by some short eilia ; the dorsal cilium much nearer to the base of the finger than to the nail. In position these maxillipeds are by no means broadly flattened out, as represented in the Plate for the sake of showing the details;¹ the two halves fold boatwise upwards, when *in situ* ; in the

¹ In regard to all the Plates it will be understood that figures intended to give the minute details are drawn from dissections laid out as flat as possible with a view to examination under the microscope ; in regard to the figures of this species that circumstance requires more than usually to be borne in mind.

figure it should be noticed that the inner plates are not flattened out to their full extent, the outer part being folded back against the outer plate; similarly it should be noticed that there is a folding over of the outer edges of the second and third joints of the palp. The dilated palp of the first maxillæ, likewise, when *in situ*, was far from being in the same plane with the rest of the maxilla.

First Gnathopods.—Side-plates more than twice as long as broad, with a convex front margin projecting over the base of the lower antennæ, hind margin nearly straight. First joint equal in length to the three following united, projecting considerably beyond the side-plate, a little expanded below, with some seven setæ on the front margin; second joint shorter than third; third nearly equal in length to the hand; wrist longer than the hand, like the third joint having setæ on the hind margin; hand long-oval, with setæ in various parts, especially several groups on the hind margin, the lower half of which is marked off as a palm rather by its pair of spines than by any break in the convexity; the spines are of unequal length, the palm-margin is ornamented by being cut into a series of sharp straight denticles, below which are small cilia; the finger is curved to fit the palm; it has a dorsal cilium near the base, and the tip of the finger appears as if formed of two plates laid one upon the other, as though the finger itself ran out to a point, and had a small triangular process (the nail) laid within the point.

Second Gnathopods.—Side-plates similar to those of the preceding pair, the hind margin rather less, and the front rather more, convex; first joint as long as the three following united, a little expanded and bent below, numerous setæ on the front margin; second joint much longer than third, smooth; third joint furred behind, with a few spines on the squared apex; the wrist longer than the second joint, very much furred behind and before, with spines on both the somewhat sloping sides of its apex; hand subequal in length to the third joint, narrow at base, but immediately expanding, widest at the palm, hind margin straight, front very convex, much furred on both sides, pectinate spines near the outer angle of the palm and round the hinge of the finger, the palm concave, not a thin edge but broad and set through most of its course with several rows of short sharp teeth, its sides also fringed with cilia and rows of pectinate spines, the pectinate spines having a short terminal piece abruptly narrower than the shaft, with a shorter accessory thread by its side; the finger is sickle-shaped, the much-curved inner margin being hairy, with cilia near the origin of the finger. The finger here is as strong as that in *Euonyx chelatus*, Norman.

First Peræopods.—Side-plates larger than those of the preceding segment, hind margin straight, front but little curved. Marsupial plates long, slender, the setæ extending along most of the front border. Branchial vesicles without folds, from a narrow neck expanding at once greatly for some distance, and then very much more to the long almost straight distal margin. The first joint of the limb broad, extending a little beyond the side-plate, with some setæ on the front margin; second joint short,

third broad, rather longer than either of the next following, with setiform spines on the front apex and the hind margin; fourth joint similarly armed, much broader than the fifth joint, which is subequal in length to it and similarly armed, gently curved, attached to the fourth joint at the anterior part of the distal margin; finger as long as the fifth joint, slender, curved slightly, and unarmed except for a minute dorsal cilium near the hinge, and a cap to the nail, the cap being a little broader than the nail and projecting slightly beyond it. In the figures *gn.1.* and *prp.1.* the nail is not shown.

Second Peræopods.—Side-plates not of any unusual breadth below, the greatest breadth being where the excavation ends about the middle of the plate, giving the appearance of an upturned point; the limb closely resembles that of the first peræopods.

Third Peræopods.—Side-plates rather small, broader than deep, neither lobe produced noticeably below the other. Branchial vesicles not reaching the dimensions of those of the first peræopods, broad above, narrow below, with a long and very narrow accessory lobe and a short one. First joint ovoid, much broader above than below, front margin with small spines, hinder with slight serrations, a lobe ascending at the top in front, another descending behind; third joint broader but considerably shorter than fourth, little decurrent, with spines on the front margin, and three on the hind margin, two high up and one apical; fourth joint broader than fifth but scarcely so long, with five groups of spines on the front margin, the apical group containing five spines of different lengths; on the front margin of the fifth joint there are six or seven groups of spines; the finger is long, very slender, shorter than the hand; the nail minute.

Fourth Peræopods.—Side-plates not much smaller than the preceding pair. Branchial vesicle with what appears to be an irregularly branched accessory lobe. First joint narrower than in the preceding pair, scarcely wider above than below; all the joints except the finger longer than in the preceding pair, but otherwise very similar.

Fifth Peræopods.—First joint large and long, of even breadth for some way down, the hind margin then rather abruptly sloping forward, little serrate, the front margin sinuous, little spined except at the lower part; the third joint narrower than in the two preceding pairs, the three spines on its hind margin much stronger; the fourth and fifth joints shorter and narrower than in the preceding pair, each with a spine at the middle of the hind margin, which is not found in either of the preceding pairs; the armature otherwise similar; finger very slender.

Pleopods.—The two coupling spines on the peduncles have three retroverted teeth; the cleft spines on the inner ramus numbering seven in the first pair, six in the other two pairs; joints of the rami twenty-eight to thirty, the first joint of the inner ramus longer than that of the outer.

Uropods.—Peduncles of the first pair subequal in length to the rami, a little longer than the inner, a little shorter than the outer, strongly spined on the upper margin;

rami long and slender, slightly spined, and only on the proximal part; peduncles of the second pair shorter than the rami; outer ramus longer than the inner, both shorter than those of the preceding pair; peduncles of the third pair much shorter than the rami, with groups of spines at the apical points, the rami about equal in length to one another, and to the longer of the second pair, the outer and under one forming a kind of neck at the base, with its sides unarmed to below the centre, then with five small spines on the inner, and four on the outer convex margin, ending with a decided nail; the upper and inner ramus broadest close to its base, and here on the inner margin with three spines, then a long interval followed by three more leading to the apex; on the outer margin five unevenly spaced, three small ones at intervals on the surface.

Telson reaching beyond the peduncles of the third uropods, much wider at the base than below, cleft for two-fifths of its length, the whole cleft more or less dehiscent, a spine in the notch of each narrow apex; several marginal spines, seemingly not quite symmetrically placed.

Length of the specimen from the rostrum to the back of the second pleon-segment, in the position figured, three-fifths of an inch.

Locality.—Station I., off Cape Finisterre, December 30, 1872; lat. $41^{\circ} 58'$ N., long. $9^{\circ} 42'$ W.; depth, 1125 fathoms; bottom, blue mud. Dredged. The specimen when it came into my hands was already broken into two portions. There was also the front portion of a second specimen.

Remark.—The specific name *longimanus*, long in the arm, refers to the unusual length of the first gnathopods. In view of the peculiarities of the species, it is of interest to note the great depth recorded for its habitat.

Genus *Onesimoides*, n. gen.

Mandibles with the palp set just over the dentate crown of the molar tubercle.

First Maxillæ with the inner plate carrying two unequal plumose setæ; the second joint of the palp not dilated, with more than six spine-teeth on the apical margin.

Second Maxillæ with the plates of nearly equal length, the outer rather the broader; the oblique apical margins, but not the inner ones, fringed.

Maxillipeds with the outer plates reaching about as far as the apex of the second joint of the palp, nodulous teeth numerous on the inner margin, one spine-tooth on the apex.

Upper Antennæ with the first joint of the primary flagellum long, that of the secondary equally long, spreading its wing (a thin laminar dilatation) over the other.

Lower Antennæ with the third joint short, the fourth and fifth subequal in length.

The side-plates of the pereion not projecting over the mouth-organs and base of lower antennæ.

First Gnathopods with a short triangular wrist, a very robust oblong hand, with the palm at right angles; subchelate.

Second Gnathopods weak, feebly chelate.

Peræopods all with the nail very short; peræopods of the last three pairs short, the first joint of the last pair greatly dilated.

Uropods short, successively decreasing, inner ramus of the last pair almost rudimentary.

Telson short, broad, entire.

Remarks.—The generic name is chosen to call attention to the relationship between this genus and *Onesimus*, Boeck. In assigning only "5-6" spines to the apex of the palp of the first maxillæ Boeck unduly limits the number, as there are more in *Onesimus edwardsii* (Krøyer).

Onesimoides carinatus, n. sp. (Pl. XIV.).

Rostrum rudimentary, lateral lobes of the head produced not far in a rounded angle; a carina scarcely perceptible on the first five peræon-segments, well-marked on the sixth and seventh of the peræon and the first four of the pleon; the fourth segment of the pleon with a dorsal depression, the sixth outlined on either side of the telson; all parts furred with short hairs; a slight dorsal depression on the segments from the fourth of the peræon to the third of the pleon gives a crenate appearance to the dorsal outline; the postero-lateral angles of the third pleon-segment are right angles.

Eyes not made out.

Upper Antennæ.—First joint of the peduncle much longer than broad, with a dorsal depression near the base, and many minute feathered cilia along the upper margin; second and third joints short; flagellum of twelve joints, the first nearly as long as the first of the peduncle or as five of the following joints of the flagellum; this joint tapers distally, and so does the flagellum as a whole, although all its joints except the first and last widen a little distally; the secondary flagellum of four joints, of which the last minute, the first as long as the first of the primary, close to which it lies, spreading out a broad thin membrane over the numerous rows of slender cylinders which form the brush; on the under side of this shield are five or six sets of cilia singly or in groups.

Lower Antennæ quite free from the side-plates of the peræon; rather shorter than the upper antennæ; the first joint not greatly expanded, partly covered by the projecting lobe at the lower front angle of the head; gland-cone very prominent; third joint short; fourth joint a little expanded distally, rather longer than the fifth, nearly as long as the first joint of the upper flagellum; flagellum of nine joints.

Lower lobe of the epistome projecting a little in front of the upper lip.

Mandibles.—Cutting edge folded back in the specimen so that its contour could not

be exactly made out, seemingly of the usual form; secondary plate of left mandible very small, strap-shaped, curved, microscopically dentate at the apex; spine-row of three very small curved spines close together; molar tubercle prominent, the dentate crown showing some fourteen or fifteen transverse blades, and set round the edge with prominent teeth pointing in towards the blades; articular condyle large; the palp set just over the molar tubercle; some eighteen spines form a row on the upper part of the second joint; there are twenty-two spines on the inner border of the third joint, beginning below the middle, and one spine near the outer border and the base; the third and first joints together about equal the length of the second.

Lower Lip.—Forward lobes but little dehiscent distally, overlapping below when flattened, inner and apical margins ciliated, but not the outer margins; margins of the mandibular processes ciliated.

First Maxillæ.—Inner plate narrow at the apex, tipped with two plumose setæ; outer plate long, apical margin fringed with six strong dentate spines, with four, more slender, below them, and the eleventh, a strong one, standing a little apart from the rest on the inner margin; those in the left maxilla (figured on the right-hand side of the Plate), seem to have been much more worn than those in the companion maxilla, a rather odd circumstance; the first joint of the palp very short, the second long, of almost uniform width, in the left maxilla showing twelve spiniform teeth on the apex, while on the other maxilla there are only nine; in each there is also a plumose seta.

Second Maxillæ.—The plates slender, the outer broader, very little longer than the inner; the apical margins of both very oblique, the fringe of the inner plate being bounded by a plumose seta much longer than the adjacent spines.

Maxillipeds.—Inner plates with plumose setæ on the inner margin, nine in number, diminishing in size towards the apex, which they reach before the series is continued towards the outer corner by one or two additions; the apical margin has three teeth, the innermost the largest, below which is a smaller spine-tooth; on the outer side of the three is a curved spine; the plates themselves, though flat on the inner surface, on the outer are so strongly ridged as to be in fact longitudinally three-edged rather than laminar, answering to the epithet "prismatic" applied by Krøyer to the corresponding plates in his *Anonyx edwardsii*; they reach beyond the first joint of the palp; the outer plates reach as far as the apex of the second joint of the palp; on the inner margin are four long setæ among cilia followed by a long spine, and this by thirteen close-set nodulous teeth, the two uppermost and largest of which may be reckoned as apical; these are followed by a pectinate spine-tooth; on the outer surface away from the margin are seven spines of some length; of the palp the first joint is short, the second not very greatly longer; the finger is short, with a narrow nail set among cilia; the dorsal cilium is midway between the base of the finger and the base of the nail.

First Gnathopods.—Side-plates leaving the head and mouth-organs almost entirely
(ZOOL. CHALL. EXP.—PART LXVII.—1887.)

unecovered, broader above than below, the front margin concave, the lower part of the plate squared, with rounded angles. First joint of the limb extending much beyond the side-plate, narrowest near the base, then expanding to its greatest width and narrowing slightly to the end; second joint as long as the third, with some long setæ chiefly at the hinder distal end; the third joint distally rounded, its whole hinder margin densely clothed with long setæ; the wrist triangular, cup-shaped, scarcely longer than the preceding joint, broad distally, the free hind margin setose; the hand rather broader than the wrist and much longer, of equal width throughout, bearded on the hinder margin with setæ, which become shorter in proximity to the palm; the front margin with only a distal tuft; the palm at right angles to the hind margin, defined by two spines socketed deeply in the surface of the hand; a row of cilia on either side of the palm margin; the finger much curved, the tip of the nail fitting exactly to the end of the palm.

Second Gnathopods.—Side-plates oblong. Branchial vesicles elongate, the part that rises above the neck rounded, the central part the widest, the end narrowing almost to a point. The first joint of the limb extending beyond the side-plate, not so long as the branchial vesicle, straight, only slightly expanded below; second joint longer than third; third rounded below, minutely furred on the breast or hind margin, which also carries a few spines or setæ; the wrist at first a little narrowed, then gradually widening a little, longer than the hand, furred on the hind margin, carrying very few setæ; the hand oval, minutely furred and covered with small scales, carrying on the hind margin four groups of spines short but strongly pectinate on two edges, a larger group in several rows and of varied sizes on and near the front apex over-arching the minute finger, which is set in the middle of the apical margin and closes pretty tightly over the inward curving ciliated palm. In the figure, as in the specimen, the hand and wrist of this delicate and not very elongate limb are twisted round, and of the wrist it is not a lateral surface that is shown but rather the region of the anterior margin.

First Peraopods.—Side-plates similar to the preceding pair, rather broader. Branchial vesicles long, of nearly uniform breadth except at the neck. First joint of the limb scarcely reaching beyond the side-plate; third joint longer than fourth or fifth, scarcely decurrent, of almost uniform breadth, this and the other joints having setæ on the hinder margin; fourth joint rather thicker, barely shorter, than the fifth; fifth joint with six sets of spines as well as setæ on the hinder margin; finger very short and stumpy, inner margin furred like the preceding joints; a minute nail, abruptly narrower, set among cilia.

Second Peraopods.—Side-plates broadly oblong, excavate behind, the hinder margin forming a slightly outdrawn angle at the bottom of the excavation, lower margin ciliated; the joints of the limb in close agreement with those of the preceding pair.

Third Peraopods.—Side-plates rather broader than deep, front lobe descending a

little below the hinder. Branchial vesicle expanding greatly from a narrow neck, then with a broad triangle ending in a rounded point; close to the neck a small, narrow, accessory vesicle; first joint of the limb not so broad as the side-plate and not much longer, broader above than below, with setæ on the front margin, serrate on the hinder, with fine hairs on both; third joint short, expanded below, slightly decurrent behind, setæ on the front margin of this and the preceding joint, this with slender spines on the hind margin; fourth joint a little longer than the third, rather broader above than below, where it is twice the breadth of the fifth joint, the spines on both borders slender; fifth joint slightly longer than the fourth, the stoutest of its spines close to the hinge of the short, stumpy, curved finger; all the joints more or less furred.

Fourth Peraopods.—Side-plates produced downwards in a rounded lobe behind. Branchial vesicle oval, pointed below, shorter than the first joint. First joint a long squarish oval, with a few scattered spines above and setæ below on the front margin, serrate on the hind margin; third joint as in the preceding pair; the rest of the limb missing.

Fifth Peraopods.—Side-plates small; first joint greatly dilated, narrower above than below, front margin nearly straight, equalling the length of the third, fourth and fifth joints united, the serration on the lower margin behind directed to face the serration of the hinder margin; the third joint very short, scarcely either dilated or decurrent, with two spines on the lower part of the hinder margin; fourth joint longer as well as broader than the fifth, of almost even thickness throughout; fifth joint longer than the third; finger as in the preceding limbs.

Pleopods.—The coupling spines on the peduncles very small; the cleft spines on the inner ramus numbered five in the first and second pairs, four in the third pair, the spoon-shaped branch being nearly as long as the other; the joints of the rami numbered from eighteen to twenty-two; on the large first joint of the outer ramus of the first pair there were eighteen plumose setæ.

Uropods.—Peduncles of the first pair not much longer than the outer ramus; inner ramus with three spines on its upper margin, much shorter than the unspined outer ramus; second pair short and stout, peduncles longer than the subequal rami, which are slightly curved, sharply tipped, and carry some spines on their edges; peduncles of the third pair very short, a little longer than the outer ramus, which has a spine on the surface and one on either side of the nail; the inner branch very short and narrow, with a spine on the middle of its inner margin and one or two cilia near the apex, which descends but little below the spined apex of the peduncle.

Telson not extending beyond the peduncles of the third uropods, undivided, its breadth and length equal, narrowing but little distally, with eight cilia on the more or less rounded or squared distal border.

Length of the specimen, in the position figured, from the rostrum to the back of the second pleon-segment, two-fifths of an inch.

Locality.—Station 184, off the north-east coast of Australia, August 29, 1874; lat. $12^{\circ} 8' S.$, long. $145^{\circ} 10' E.$; depth, 1400 fathoms; bottom, Globigerina ooze; bottom temperature, 36° . One specimen. Trawled.

Remarks.—By its carina, mouth-organs, short hinder peraeopods and short uropods, this species seems connected with the *Lysianassa umbo* of Goës, but the antennæ, first gnathopods, and undivided telson again remove it from that connection. It also bears much resemblance to the genus *Onesimus* of Boeck, and in particular to *Anonyx edwardsii*, Krøyer, which Boeck assigns to *Onesimus*, but the differences are too numerous to admit of the present species being brought under the generic definition given by Boeck. For the definition of *Onesimus* or *Onisimus*, Boeck, see Note on Boeck, 1870 (p. 398).

The specific name speaks for itself.

Genus *Sophrosyne*, n. gen.

Mandibles with the palp set far forward, molar tubercle small or obsolete.

First Maxillæ with the inner plate small, the outer plate and the palp with the apical teeth few.

Maxillipeds with the inner and outer plates very small and the palp long.

First Gnathopods strong, especially the chelate hand.

The Uropods small, successively decreasing in size.

The Telson not projecting beyond the peduncles of the third uropods, more or less cleft.

The genus is strikingly distinguished by the feeble structure of the mouth-organs and of the after-part of the pleon in contrast with the powerful structure of much of the rest of the animal and of the first gnathopods in particular. In Boeck's definition of the Lysianassinae it will be necessary to qualify the epithet "robusti" applied to the "Pedes maxillares" by the adverb plerumque, to enable the definition to include the present genus.

The generic name is derived from $\sigma\omega\phi\rho\sigma\sigma\nu\eta$, temperance, voracity being probably precluded where the mouth-organs are so slightly framed.

Sophrosyne murrayi, n. sp. (Pl. XV.).

Head slightly produced in an obtuse angle between the upper antennæ; the lateral angles between the upper and lower antennæ rounded. Back rounded, third segment of the pleon with two latero-dorsal humps near the extremity, its postero-lateral angles produced into a sharp upward-turned process, so as to form part rather of the hinder than of the lower margin; fourth pleon-segment with a dorsal depression, abruptly

narrower across the back than the wide distally squared dorsum of the third segment; the first three segments of the pleon large, the remainder small, the contrast between the two portions when viewed from above being especially conspicuous.

Eyes not observed.

Upper Antennæ.—First joint of the peduncle shorter than the head, much longer than thick, upper margin convex, with a slight depression near the base; second joint longer than third, and longer than the first joint of the flagellum; flagellum of seven joints, the first equal in length to the two following, all the joints carrying filamentary cylinders; secondary flagellum of four joints, the first as long as the first of the primary, the other three shorter than the next three of the primary.

Lower Antennæ.—Gland-cone prominent; third joint not very short, fourth longer than fifth, widening distally, both fourth and fifth with some slender lateral spines; flagellum of eight articulations, of which the first is the longest, each with a distal tuft of cilia.

Mandibles.—The cutting edge very slightly convex, with the upper tooth sharply produced downwards and the lower tooth bifid, produced upwards and outwards, the secondary plate of the left mandible small, spiniform, placed low down; both spine-row and molar tubercle seemed to be wanting; the palp set far forward, the first joint short, the second with six or eight spines at the upper end, the third joint little shorter than the second, with six or seven spines at and near the upper end, and numerous adpressed cilia on the surface projecting beyond the inner margin. The figures in the Plate show the mandibles as they appear with their edges somewhat bent in; the enlarged figure of the left mandible shows the true outline of its cutting edge; that of the right mandible is probably similar, but it could not be made out with certainty.

First Maxillæ.—Inner plate very short, rounded at the top, carrying a single seta; outer plate showing a minute serration with four minute spine-teeth at the upper part of the inner margin, and apically two powerful bent teeth, the outer much the larger and over-arching the inner, but whether these two teeth consist of prominences surmounted by spines or constitute simple processes of the margin, could not be definitely made out; the second joint of the palp widens greatly from the base, and on the broad truncate apex carries four or five little spine-teeth, the outermost larger than the others; on the inner border it has four or five slender spines.

Second Maxillæ.—The outer plate seemingly much longer than the inner, with seven spines dispersed along the upper part of the inner margin and the apex; the inner plate, so far as made out, with few spines.

Maxillipeds extremely slender; inner plates minute, slender, not reaching even to the base of the first joint of the palp; the apical margin produced into a tooth-like point on the inner side, near the much lower outer side carrying a long spine, the only armature of the plate; the outer plates slender, reaching but little beyond the first joint

of the palp; on the inner and apical margin twelve spines may be counted, those lowest down being small, the four at the apex the largest, the outermost conspicuously exceeding all the rest; the first joint of the palp short, with one long pectinate spine on the inner, and one spine or seta on the outer, apex; the second joint larger than the outer plates, with several spines on the inner and apical margins; third joint longer than first; finger long, with a short nail, dorsum cilium near the base of the finger.

First Gnathopods.—Side-plates narrow at the base, very greatly dilated below, projecting over the base of the lower antennæ. First joint of the limb projecting little beyond the side-plate, very broad, dilating downwards, with setæ along the front margin; the second joint with several tufts of setæ or rather long pectinate spines on the hind margin; third joint a long triangle with the point downwards, with no free anterior margin; the wrist triangular, cup-shaped, behind carried out into a lobe flanked by the apical margin of the third joint and the hind margin of the hand, but with a narrow interval on each side; the hind margin of the third joint and of the lobe of the wrist just mentioned are armed with long geniculate pectinate spines, and also with rows of shorter, but strong and strongly pectinate spines, increasing in length distally; the powerful hand is longer than broad, widest at the palm, with convex front and concave hind margin, the latter set with six strong spines, increasing in length towards the palm, and with pectinate spines or setæ, such as occur also on various parts of the surface of the hand; the hind margin runs out into a long sharp tooth, the point of which contains at the back a small spine with accessory thread, just showing its tip beyond the point; the inward sloping palm is convex beyond the triangular apex, and is set with spinules, one stronger and blunter than the rest being close to the hinge of the finger; the finger itself overlaps the tip of the palm with its sharp nail, and seems to be without other armature than the minute dorsal cilium, and a sharp but short projection of its inner margin one-third of the distance between the hinge and the tip; on either side of this process is a cilia-like spine. The hand may be described as chelate.

Second Gnathopods.—Side-plates oblong in general character, less wide than the preceding pair. Branchial vesicles large, narrowed below. The limb weak, first joint slender, not projecting beyond the side-plate; second joint much longer than third, equal in length to the wrist, furred on the lower part of the hinder margin; third joint short, equal in length to the hand, furred on the hinder margin; the wrist strongly furred almost all over, carrying a few long spines distally; the hand expanding distally, widest at the palm, strongly furred, also with scales over the breast; the front margin further produced than the hinder, and occupied at the apex with the usual pectinate spines over-arching the small much-curved finger which is set close to this point; the concave palm is bordered with rather long cilia, and such also are found on the finger at some little distance from the nail; the palm being concave and the finger much bent; the latter will not be likely to close on the other without leaving a considerable cavity.

First Peræopods.—Side-plates similar to the preceding pair. Branchial vesicles very large. Marsupial plates narrow. First joint of the limb not reaching the lower rim of the side-plate, with some setæ on the hind margin, very long ones at the apex; third joint much longer and broader than the fourth, with long setiform spines at the decurrent apex in front, and, like the preceding and following joints, with many groups of them on the hinder margin; the fifth joint longer than the fourth, with a few groups of slender spines on the hinder margin, and some spinules on either side of the hinge joint of the long, slender finger.

Second Peræopods.—The side-plates very broad below, a little tooth at the hinder extremity of the lower margin, and one facing it not far from the front extremity of the same. The limb similar to that of the preceding pair.

Third Peræopods.—Side-plates with the front lobe descending below the hinder one. First joint broadly oval, strongly spined on the very convex front margin, the hind margin serrate, the lower margin smooth, rounded, descending below the back of the second joint; the third joint longer than the fourth, spined on both margins, inflated, decurrent; the fourth joint broader than the fifth, but scarcely so long, its lower margin on the outside flatly rounded, broad; all the five joints carrying spines and setiform spines on the front margin; the sixth joint or finger slender, unarmed.

Fourth Peræopods.—Branchial vesicles throwing out a narrow, accessory, sac-like process from the upper part of the hinder margin. The joints similar to those of the preceding pair, but broader and longer.

Fifth Peræopods.—The first joint longer and very much broader than in the preceding pair, very strongly spined on the front margin, more deeply serrate on the hinder, and with the lower margin behind somewhat squared, not reaching below the second joint; the third joint scarcely dilated, spined at the decurrent apex behind and just above the apex; the fourth joint narrower than the third, shorter than the fifth, the spines in front of these joints shorter and stronger than those of the preceding limbs.

Pleopods.—Coupling spines minute, with two retroverted teeth just below the apex on one edge and a backward serrature along the other edge; four eleft spines on the inner ramus of the first and second pairs; the joints of the rami from fourteen to sixteen in number.

Uropods.—Peduncles of the first pair strongly spined, considerably longer than the rami; outer ramus longer than inner, with five spines along the border, stopping some way short of the apex; inner ramus with three spines; peduncles of the second pair not reaching so far back as those of the first, a little longer than the rami; the rami subequal, short, with few spines remote from the apex; peduncles of the third pair shorter than the short stiliform rami; outer ramus rather longer than inner, both almost entirely unarmed.

Telson as broad as long, not reaching to the end of the peduncles of the third uropods, cleft for less than two-thirds of its length; a small lateral spine on each side level with the top of the somewhat dehiscent cleft, the apices rounded not quite smoothly, less produced on the outer than the inner side, and on the outer side showing a cavity as if for a spine, above which is a small cilium.

Length of the specimen from the forehead to the back of the third pleon-segment, in the position figured, just under half an inch.

Locality.—Off Christmas Harbour, Kerguelen. One specimen, female.

Remark.—This being one of the most interesting forms among the Amphipods brought home by the Challenger, I do myself the pleasure of naming it after Mr. John Murray, under whose skilful and energetic administration the scientific results of the expedition are being worked out.

Genus *Cyphocaris*, Lütken and Boeck.

From the account of this genus given by Boeck in 1870 (see Note on Boeck, 1870, p. 398) must be excluded the statements that the second gnathopods are destitute of a nail, and that the third and fourth side-plates are coalesced. They may or may not be characters of the type-species, but the two species here described are without these characters and yet beyond all question belong to the genus.

Cyphocaris micronyx, n. sp. (Pl. XVI.).

Head almost concealed in the over-arching first peræon-segment, the summit of the head when withdrawn from its shelter taking a frontal position, while the lateral margin excavated for the antennæ faces downwards; first peræon-segment rather sharply outdrawn in front, in one of the specimens, fig. A, forming a peak, and in this exceeding in length the three following segments combined, in the other specimen, fig. B, not quite equaling them; the fifth, sixth and seventh segments successively increasing in length; the first three segments of the pleon each subequal to the first of the peræon, exceeding it in fig. B, falling short of it in fig. A; the fourth segment with a deep dorsal depression near its origin; the fifth and sixth as long as the fourth and fifth of the peræon. The first three pleon-segments posteriorly squared below, with the angles of the second and third a little rounded, those of the first segment more decidedly.

Eyes doubtful.

Upper Antennæ.—First joint stout, longer than the two following together; second and third joints short, rather stout and tapering; flagellum of twenty-one joints, the first very long, tapering, with a large brush of long and broad filamentary cylinders in

numerous rows on the inner or under side, second joint with three terminal spines, one slight, another longer with an accessory thread, third very long, sharply pointed, the remaining joints small, with distal rows of small cilia, the joints becoming longer and more slender towards the end of the flagellum; secondary flagellum slender, scarcely exceeding in length the first joint of the primary, its first joint far the longest of the five which compose it; some small cilia and filamentary cylinders at the apices of the three terminal joints.

Lower Antennæ.—First, second and third joints very short, closely united; first rather prominently lobed, cone of second prominent, blunt, third triangular; fourth joint the longest, a little dilated proximally; fifth joint shorter and much thinner; flagellum of seventy-five articulations, becoming longer and very slender throughout the distal portion of the antennæ; like the last two joints of the peduncle they are slightly ciliated. As in *Onesimoides* and *Eurytenes*, the base of the antenna is uncovered.

Upper Lip with front edge a little in advance of that of the epistome, apex furred.

Mandibles.—Cutting edge smoothly convex, with a small tooth above and another below, which on the right mandible is so little prominent as to form rather a notch than a tooth; secondary plate on the left mandible small, distally widened, with dentate edge of six teeth; spine-row of five or six setæ; molar tubercle prominent, crown with numerous rows of denticles; palp very large, set just above the articular condyle that rises over the molar tubercle; first joint small, second of great size, central part protruding where the muscles from the first joint end, the muscles which run to the third joint being inserted very near the first joint and therefore overlapping the others; near the distal end of the second joint there is a close-set row of pectinate spines with curved tips, twelve in number; third joint powerful, subequal in length to the second, ciliated on the surface, spine-border nearly straight, having some thirty-five spines pectinate on two edges, and at its curved apex two setules; the opposite convex border naked; the pectination of the spines seems to take a new departure at about one-third of their length from the base, giving the spines a jointed or geniculate appearance.

Lower Lip ciliated round the edges of the front lobes, the cilia on the apex and inner border being stouter than the others.

First Maxillæ.—Inner plate bordered distally with seven plumose setæ; outer plate much ciliated, apical border with its eleven spines in two rows, one set slender, flexuous, multidentate, the other set straight, stouter, with fewer teeth; palp with second joint very broad, six spine-teeth on the apical margin minutely serrate on their outer edges, a row of cilia near the spines, a long plumose one and a longer smooth one at the outer corner.

Second Maxillæ.—Inner plate broader than outer, and much broader at base than apex. Plates subequal in length, much ciliated on the surface and edges; inner plate with seven plumose setæ along the inner margin, and a double row of pectinate spines about

the apex ; outer plate with a double row of longer pectinate spines about its apieal border, with some short setæ on the outer margin.

Maxillipeds.—Inner plates not extending equally far with the first joint of palp, bordered with long plumose setæ on the inner margin, these passing over into plumose spines on the squared apieal margin which carries three broad teeth ; outer plate with ten teeth along the serrate inner margin, a row of flexuous spines behind them on the outer surface, plumose setæ on the apieal outer border, eilia round the remainder of the curved outer border and on the surfacee of the plate. The first joint of the palp the longest, reaehing almost as far as the apex of the outer plate, so that the three remaining joints, whieh successively decrease a little in length, project very prominently. All the joints of the palp except the last are bordered on the inner side with plumose setæ ; those whieh they carry on the outer distal corners seem to be smooth ; the third and fourth joints are ciliated on the surfacees ; the last has a single apieal plumose seta and a smooth one on the eonvex outer border.

First Gnathopods.—Side-plate very small, rounded below ; first joint longer than all the rest of the limb, hinder margin sinuous ; third joint furred on the hinder margin, a group of slightly crooked spines near the apex ; wrist furred behind, subequal in length to the hand, having on the hinder margin a row of spines peetinate on two edges ; hand narrowed distally, the palm not very clearly defined, microseopically peetinate, set with various spines and setæ, a few of the latter ocurring on the anterior borders and apiees of both wrist and hand ; finger miero scopically peetinate on the inner margin, with a stumpy spine and some eilia near to the nail. Of the spines on the palm some are strong, smooth, curved at the tip, with the aecessory thread near the end, others are slender and peetinate.

Second Gnathopods.—Side-plates small, oval, rather larger than those of the first segment ; brachial vesicle at its base narrow, main lobe large, longer than the first joint of the leg ; first joint as long as that of the first gnathopods, but much shorter than the rest of the leg ; seeond joint much longer than the third, subequal in length to the wrist ; wrist longer than hand, furred on both margins, on the hinder margin adorned in a remarkable manner with several rows of peculiar curved spines or setæ, of very various lengths, which thicken apically, there presenting something the appearance of the under side of a horse's hoof, a thin striated wing on each side leading up to this termination, the two transparent slightly overlapping ends produueing the appearance mentioned ; on the sides there are some peetinate pointed setæ ; the oval hand is much furred behind and distally in front, the armature consisting of remarkable spines as on the wrist, and in addition rows of shorter spines bending in the opposite direection, that is, towards the finger, distally peetinate, an aecessory thread extending beyond the apex ; on both hand and wrist the spines are graduated in length, increasing as they advance distally, so that the tips form a regular curve ; the setiform spines on the side and infero-anterior corner

of the hand have flexible ends. The minute finger ends in a kind of double nail, some minute teeth occupying the inner margin of the outer and longer division, the nail proper, which curves over towards the palm in the usual manner, while the smaller division, perhaps only a projection of the finger-margin, curves away from the palm ; at the origin of the two is a long cilium.

First Peraopods.—Side-plates scarcely as large as those of preceding segment ; branchial vesicle like that of the preceding limb, and both there and here attended by a very small oval plate, quite smooth, which seems to be an accessory vesicle ; first joint of leg much shorter than in the two preceding pairs ; third joint longer than fourth, subequal to fifth, bowed forwards ; fourth joint slender, parallel-sided, four small spines on the back rim, the two longer ones faintly geniculate ; the fifth joint much dilated distally, presenting a sort of palm with two strong teeth pointing towards the finger-hinge and beset with strong spines, a single and two pairs ; these spines are straight, with tiny curved tips pointing in the same direction as the teeth on the palm, and with accessory threads springing from about the centre. The finger is powerful, about as long as the fourth joint, much curved, smooth edged, sharply pointed.

Second Peraopods.—Side-plates larger than the preceding three combined, narrow at the base, projecting far forward so as to cover a considerable piece of both the preceding side-plates, largely excavated behind for the great side-plate of the fifth segment ; branchial vesicles like those already described ; first joint of leg considerably longer than in the preceding pair, to which this pair is in other respects similar, except that the third, fourth and fifth joints, and especially the fourth, are more elongate.

Third Peraopods.—Side-plates very large, as broad as those of the fourth segment, and at the base very much broader, front lobe incised below, not much deeper than the hinder part, which has its lower margin straight ; branchial vesicle with small accessory plate as in preceding segments ; first joint inserted by a bent neck within the incised lobe of the side-plate, seven short spines along the front margin, the hinder part produced almost as far as the three following joints, the hind margin divided into eight very pronounced, sharp, downward-pointed teeth, and the inner margin of the process divided into seven of similar character, the apex of the process forming a sharp terminal tooth considerably larger than any of the lateral dentations. The second joint is small ; the third, spined on both edges, longer than the fourth, but shorter than the fifth ; the fourth spined in front, and slightly behind ; the fifth similar in structure to the corresponding somewhat smaller joint of the preceding pair, with three pairs of spines at the palm ; finger as in the preceding pair, not larger. The remarkable decurrent processes of the first joint do not show an absolute uniformity in the marginal incisures between the two members of the pair of limbs, a point deserving of attention in view of the manufacture of species based upon minute differences.

Fourth Peraopods.—Side-plates rather large, a little deeper behind than in front ;

branchial vesicle more dilated above than below; first joint spined on front margin, hinder margin not much produced downwards, but cut like that of the preceding limb, forming eleven teeth, of which the first and last are the smallest, the last not reaching so far down as the last but one; the second joint and the finger as in the preceding limb; the third, fourth and fifth joints more elongate, spined on both margins; the fifth joint less expanded near the palm.

Fifth Peraopods.—Side-plates less deep than the preceding, but of equal breadth; branchial vesicles less elongated; first joint much more elongate, scarcely spined on front margin, narrowing below, not produced far downwards, but overlapping the very short second joint, the hind margin cut into fourteen teeth, the last two as in the preceding peraeopods; the third joint stouter but shorter than the corresponding joint of the preceding pair and than the fourth joint of its own pair; the fourth joint long, a little shorter than the fifth; the whole limb very straight, ending in a long, slender, very slightly curved finger, sharply pointed, without any trace of nail, fringed on the anterior margin with a close-set row of microscopic spines bending downwards. On the third, fourth and fifth joints there are various groups of spines on both margins and at the lower angles, the hand and wrist being sharply indented on the front margin, the hand not having a palm as in the preceding peraeopods, though its distal edge is cut into teeth, apparently all round, certainly behind.

Pleopods.—The peduncles of the three pairs, as is usually the case, decrease a little in length successively backwards; on the inside of the peduncle near the infero-anterior angle are three spines, one small and simple, the other two (the coupling spines) stout and large, having from four to six teeth on the distal half of the front margin pointed back towards the base of the spine, and about the middle of the other margin a single tooth directed forwards; the rami have the first joints not very elongate, followed by sixteen to eighteen short joints, all with the usual long plumose setæ; the first of the outer ramus has at its origin an irregularly shaped process seeming to serve the double object of interlocking it with the peduncle and with the other ramus, on the first joint of which there is a small corresponding process. On the inner side of the first joint of this inner ramus there is also a row of five cleft spines; they are thick at the base, plumose throughout their slightly sinuous length as far as the split termination, the inner portion of which is of a pointed spoon-shape, the outer and longer spiniform, with the inner edge denticulate. The cleft spines in most species are very similar to those here described, but the details are seldom so easily observed as in this species.

Uropods.—Peduncle of first pair longer than rami, some spines on the upper edges; rami slender, spined on the upper edges, outer ramus shorter than inner, both curving inwards at the tips, both with microscopic pectination on the upper border, the pectination being much stronger in the outer ramus; peduncle of second pair shorter and less stout than in the preceding pair, equal in length to the inner ramus; rami similar to those of the

preeeding pair, a little less curved at the tips; third pair with short peduncles, rami long, broadly lanceolate; the outer with plumose setæ on the inner margin, a spine at each side of the base of the nail, which is pectinate on the inner side; the inner branch rather the longer, with spines and feathered setæ on both sides, inner margin pectinate, no nail.

Telson elongate, narrow, reaching far beyond the peduncles of the third uropods, slit nearly three-quarters of its length, not dehiseent except apically, the two halves in the specimen A not quite symmetrical, with three spines on one margin and only two on the other; each half is apically divided, the shorter tooth being on the outside; a spine is inserted in each cleft.

Length of specimen A, in curved position, half an inch; specimen B, in the same position, a little shorter. The details were figured from specimen A.

Locality.—Station 295, off the west coast of South America, November 5, 1875; lat. $38^{\circ} 7'$ S., long. $94^{\circ} 4'$ W.; depth, 1500 fathoms; bottom, Globigerina ooze; bottom temperature, $35^{\circ} 3$. Specimen A; taken in the tow-net at the trawl.

Station 335, near Tristan da Cunha, March 6, 1876; lat. $32^{\circ} 24'$ S., long. $13^{\circ} 5'$ W.; depth, 1425 fathoms; bottom, Pteropod ooze; bottom temperature, 37° . Specimen B; taken with the deep trawl. The specimen as mounted contains several Globigerinæ.

Remarks.—Between this species and the type species of the genus, *Cyphocaris anonyx*, Lütken, as described and figured by Boeck, there are numerous points of close resemblance. Lütken's species was named *anonyx* obviously on the ground that the second gnathopods were devoid of an unguis or finger. The present species is named *mieronyx*, to point to the fact of the second gnathopods possessing a finger, though a minute one. At the same time it is possible that there is one also in the earlier species, which has been overlooked. Boeck, who gives as part of the generic character, "pedes 2di paris elongati, ungue destituti," only says in the specific account that the finger seems to be absent. In *Cyphocaris anonyx*, from Greenland, the third and fourth side-plates are said to be coalesced, which is not the case in our species, and the remark that, in the first and second peræopods, "the fifth joint is somewhat thicker towards the end, and is on the inner margin armed with some small spines," is all the notice taken of what, if the species be identical with ours, are the rather remarkable palms on these two and on the two following pairs of peræopods.

Cyphocaris challengerii, n. sp. (Pl. XVII.).

Head having a certain amount of play within the first peræon-segment, the top of the head directed forwards, its anterior margin a little sinuous; the first peræon-segment about equal to the third and fourth united, the second shortest of all; the first three of the pleon each longer than first of peræon; the fourth with a dorsal depression near the

origin, the fifth and sixth equal to the fifth and fourth of the peraeon; the lower hinder angle rounded in the first segment, squared and minutely produced in the second and third segments, of the pleon.

Eyes, apparently none. Some pigment-flecks in the ocular region, probably having nothing to do with vision.

Upper Antennæ.—First joint short, tumid; second and third together subequal to first; flagellum of fifteen joints, first tapering, as long as the first of the peduncle, with a not very dense brush of cylinders, the second short, with a long, straight spine at its end, the following joints quite small, longer and very slender towards the end of the flagellum; secondary flagellum of three slender joints, together equaling the first four of the primary.

Lower Antennæ.—First three joints very small, the gland-cone not very prominent, third joint triangular, fourth joint the longest, but not long, dilated near the middle; fifth joint shorter and thinner, dilated distally; flagellum of about forty joints, the later ones becoming long and thin, the earlier being very short, except the first, which has the appearance of containing some ten or a dozen rings in preparation to become joints.

Mandibles almost exactly as in *Cyphocaris micronyx*, the trunk massive, the great palp fixed far forward over the prominent molar tubercle, the secondary plate on the left mandible having six teeth. The palps were destitute of spines, but probably only by accident, as the inner new growth showed traces of them.

Lower Lip, forward lobes rather broad.

First Maxillæ, not conspicuously different from those of *Cyphocaris micronyx*. The same remark applies to the *second maxillæ* and to the *maxillipeds*.

First Gnathopods.—Side-plates very small, rounded below; first joint longer than the rest of the leg, lower half a little dilated; second joint very small; third short, triangular; wrist a little furred behind, scarcely as long as the hand, but thicker where distally dilated; on the lower hinder angle three spines pectinate on two edges of the distal half; hand narrowing distally, almost all the hinder margin, including the palm, microscopically pectinate, most of the palm more finely than the rest of the margin; besides cilia and pectinate setules, there are on the palm margin three spines, one very slender marking the beginning of the palm, a second rather stouter, with an accessory thread, a third shorter, with the hind margin minutely pectinate; finger with inner edge denticulate, having a larger tooth and cilia some way short of the nail.

Second Gnathopods.—Side-plates very small, narrowed below; first joint shorter than that of first gnathopods, a little bent; second joint as long as the wrist; third joint short; wrist longer than hand, with some setiform spines near the lower hinder angle; hand narrowed distally, furred, set with some spines and eilia; finger small, with a process antagonistic to the over-arching nail, eilia being set in the cleft between the nail and the process.

First Peræopods.—Side-plates very small; first joint about as long as in the preceding pair; third and fourth joints subequal in length, third rather the stouter, with the front margin curved; fifth joint longer, but more slender than fourth, spines on these joints few and small; no dilated palm on the fifth joint, a pair of spines at its junetion with the curved, pointed finger.

Second Peræopods.—Side-plates very narrow at base, curving forwards so as to hide much of the three preceding side-plates, almost the whole of that of the third segment, deeply excavated behind so as on the whole to have the shape of an irregular collar; the leg similar to the preceding.

Third Peræopods.—Side-plates large, broad at base, widened below; the first joint projecting from the anterior part of the side-plate and tending to bend back underneath it, its front margin then forming a great forward-projecting knee, while the hind margin is cut into seven sharp, decurrent teeth, and below these produced into an enormous process, sharply pointed, extending down almost to the base of the finger; the second joint is as usual very small, the third and fourth subequal in length; the fifth much longer than either, though shorter than the two combined; finger curved, equal in length to the third joint.

Fourth Peræopods.—Side-plates rather large, though much smaller than the preceding pair; the first joint with front margin almost smooth, and, except at the top, straight; the joint, wide at the base, narrows so much below as to become almost triangular; it is produced halfway down the third joint by the hinder margin, which is cut into fourteen teeth; the third joint stouter and a little shorter than the fourth, which bears similar relations to the fifth; spines on both margins of these joints; the finger somewhat longer than in the preceding pair.

Fifth Peræopods.—Side-plates rather smaller than the preceding pair, rather deeper behind than in front; first joint long, front margin straight, hind margin cut into twelve or thirteen teeth, which form a gentle curve overlapping the third joint, but not so far down as the middle of it; second joint very short; third a little dilated above, longer than the fourth, shorter than the fifth; spines on the borders of all three; finger short, but straight, sharply pointed.

Pleopods.—The stout coupling spines near the infero-anterior angle of the peduncle were seen, but whether their strueture was precisely as in *Cyphocaris micronyx* could not be determined; the rami consist of some eight to ten joints; the cleft spines on the first joint of the inner ramus are three in number, inereasing in size successively downwards.

Uropods similar to those of *Cyphocaris micronyx*, but the rami with fewer spines, the outer and inner of each pair nearly equal in length.

Telson similar to that of the preceding species, except that no spines were discerned upon it except one in each apical cleft.

Length of the specimen in its bent position about one-fifth of an inch.

Locality.—The label on the mounted specimen states that it was taken 400 miles north of the Sandwich Islands; probably near Station 256. One specimen.

Remarks.—The differences between this species taken in the North Pacific and its congener from the South Pacific and South Atlantic are obvious; the shape of the first segment of the pereon and its size in comparison with the head, the armature of the second gnathopods, the form of the fourth pair of side-plates, and, above all, the first joint in the third pereopods, afford clearly distinguishing marks. It will be noticed that it is in the smaller species that the third pereopod has its most striking development, precluding any probability that this species might be a younger stage of the other.

Genus *Cyclocaris*, n. gen.

Mandibles broad in front, molar tubercle not dentate, palp central.

First Maxillæ with the inner plate bearing more than two plumose setæ, spines of the outer plate slender, teeth of the palp few.

Second Maxillæ with the inner plate much shorter than outer, a large part of its inner margin fringed with setæ.

Maxillipeds with the inner and outer plates very broad, the outer with spaced denticles on the inner margin, spine-teeth and setæ round the apex and part of outer margin; these plates reaching as far as the apex of the second joint of the palp.

Upper Antennæ with the peduncle very short.

Lower Antennæ with the base not covered by the side-plates of the pereon.

Gnathopods very slender and very long.

Side-plates of the first two pereon-segments very small.

Third Uropods with long rami extending much beyond the other pairs.

Telson long, extending much beyond the peduncles of the third uropods, deeply cleft.

The generic name is derived from *κύκλος*, a circle, and *κάρα*, head, it seeming probable, from the structure of the side-plates, that the animal naturally coils itself into a circle, bending its head round to the protection of the side-plates of the third and fourth pereon-segments. The form of the name also points to the affinity between this genus and *Cyphocaris* of Lütken and Böck.

Cyclocaris tahitensis, n. sp. (Pl. XVIII.).

Head short, lateral margin sinuous, bowed out between the upper and lower antennæ; the side-plates of the pereon not extended forward over the head or base of the lower antennæ; the last four segments of the pereon rather long; of the pleon-segments the postero-lateral angles of the first rounded, of the second acute, of the third blunt, lower

margins of second and third ciliated; the fourth segment with a dorsal depression, the sixth with lateral ridges on the back curving outwards at the telson. The specimen was coiled almost into a circle.

Eyes not made out with any certainty.

Upper Antennæ.—First joint tumid, very little longer than the second and third united, these being short and thick; flagellum of ten joints rapidly tapering, the first stout and large, subequal in length to the following nine together, the brush formed by some twenty-four rows of setæ; apically the first joint has a long slender spine, the following joint having two such, the third joint two and a smaller one, the fifth joint two of the smaller size, all the joints having spiniform cilia; the secondary flagellum of six joints, the first long, the six together as long as the first five of the primary; some spines at their distal ends.

Lower Antennæ.—First joint a little dilated below, the gland-cone small and little prominent, third joint quite short, fifth joint thinner and rather longer than fourth, neither very long, both ciliated on the upper margin; flagellum of twenty-five joints.

Upper Lip projecting a little in a convex lobe between the mandibles.

Mandibles broad in front, the cutting edge long, very convex in the right mandible, much less so in the left, having a prominent tooth at the top, angled below, with two teeth or serrations on the lower margin behind the angle; the secondary plate of the left mandible placed high up, very small, strap-shaped; spine-row of nine spines, below and behind which a space on the outer surface of the mandible is armed with prickles; molar tubercle seemingly weak, tongue-shaped, produced far backwards, slightly ciliated, not at all dentate (not shown in the figure); palp set some way back behind the spine-row; between the palp and the cutting edge the top border runs up into a great triangular lobe, with the small articular condyle rising just over its apex; the first joint of the palp very short; there are nine spines in the row at the upper part of the second joint; the third joint with the first equalling the length of the second, carrying fifteen spines on the inner border.

Lower Lip, the mandibular processes long and smooth, apically rounded.

First Maxillæ.—Inner plate bordered above with nine long plumose setæ; the outer plate much longer than the inner, with its eleven spines all slender and long, among cilia, two of them some way below the apex, those actually on the apex very elongate; the denticles of the spines not numerous, and not placed near the apices of the spines; the first joint of the palp very short, the second long, of tolerably even width, its apex cut into five teeth, of which the three central very prominent, surmounted by little spine-teeth, a little spine also in the cavity formed by the small inner tooth and a longer spine at the outer almost obsolete tooth; on the outer margin, some way below the apex, a long seta is inserted, and a shorter one near the tooth next but one to the outer margin.

Second Maxillæ.—Inner plate much shorter than the outer, bordered on the inner
(Zool. Chall. Exp.—PART LXVII.—1887.)

margin with about a dozen long plumose setæ, and also with spines not reaching quite so far down the margin as the setæ; the outer plate bordered with spines on the upper half of its inner margin and on the apex.

Maxillipeds.—The inner plates not reaching as far as the apex of the first joint of the palp, widening distally, the outer margin very convex, the apical border very large, concave, produced at the outer corners; ten plumose setæ passing from the inner margin at once obliquely across to the outer apex; in the concavity of the apical border three little nodulous teeth at intervals, at the outer extremity three setæ, the longer innermost; just below the innermost nodule a longer spine-tooth is placed, as it were crossing swords with the corresponding tooth of the opposite plate; outer plates very broad and long, reaching as far forward as the second joint of the palp; on the inner border some thirteen denticles are spaced, on the apex three or four spines successively increase in size, and pass over into long feathered setæ which fringe the outer margin more than half-way down; near the inner border is a row of some nine or ten spinules on the surface of the plate; the second joint of the palp is considerably longer than the first, which is nearly equal in length to the third; all the three joints have setiform spines on the inner margins and outer apices, the third joint having also three groups, and the second joint one group, on the outer margin below the apex; the finger is rather slender, with a line of pectination near the inner margin, a very small nail and some cilia near it, and a dorsal cilium midway between the nail and the hinge.

First Gnathopods.—The side-plates very small, narrowed below. The first joint much longer than the side-plate, narrow, of even width throughout, smooth; second joint very long, though shorter than the first joint or the wrist, with one or two cilia-like spines upon it; third joint much shorter than the second, with scarcely any free front margin, having a group of setiform spines on the hind border near the produced acute apex; the wrist long and narrow, a little shorter than the first joint, a little longer than the hand, with a few setiform spines about the centre and at the apex; the hand long and narrow, tapering, with setæ on both edges, these edges, however, representing those of the hinder surface of the hand rather than those of the hand as usually viewed laterally; the finger slender, with some cilia near the nail.

Second Gnathopods.—Side-plates quite small, rounded in front, with two or three cilia-like spines on the lower margin. Branchial vesicle long, simple. First joint of limb long, slender, smooth, scarcely dilated below and a little curved; second joint much longer than the third but shorter than the wrist; third joint with but little free margin in front, behind furred, having one small spine high up, three longer near the pointed apex; the wrist very long and narrow, not dilated, furred on both sides, with five groups of setiform spines on the hinder margin; hand much shorter than wrist, but still comparatively long and narrow, furred both back and front, with numerous groups of spines on both borders as well as some on the surface; the spines show but little curve, the pectination, as

usual, of those in front faees backwards, of those behind forwards; the palm is defined by two stout spines, beyond which it forms a peetinate eonvexity, over which the small finger closes; the finger thick at the base, has a long inner tooth, near to which the margin is peetinate, and two or three cilia are placed; the dorsal cilium is nearer the base than the nail.

First Peræopods.—The side-plates are abruptly larger both in length and breadth, exceeding in size those of the two preceding segments united; they are much dilated below and rounded, with some small spines where the lower curves round to the hinder margin; the first joint massive, projecting beyond the side-plate, its hinder margin convex, with spines on the lower half; third joint broad, a little decurrent in front, much longer and larger than the fourth joint; there are some long and short spines on the hind border of both the third and fourth joints, as well as on the apex in front; the fifth joint equal in length to the third, somewhat curved and tapering, its distal rim microscopically pectinate; six groups of spines on the hinder margin, the pair at the finger-hinge showing oblique striæ; some spinules on the convex front margin; the finger small, unarmed, except for a small dorsal cilium.

Second Peræopods.—Side-plates very broad, little excavate, nearly as broad as deep. The joints of the limb closely resembling those of the preceding pair.

Third Peræopods.—Side-plates much broader than deep, fully as broad as those of the preceding pair. First joint about as broad as long, with a rounded lobe in front raised upwards, and the hinder lobe drawn downwards beyond the second joint; the front margin much spined, the hinder serrate; the third joint not much dilated, a little decurrent behind, subequal in length to the fourth and shorter than the fifth joint, like those two in having spines on both margins, and several groups of them on the front margin; finger slender, not half the length of the fifth joint.

Fourth Peræopods.—The first joint with its front margin sinuous, a little contracted before reaching the lower hinder lobe; the last four joints similar to those of the preceding pair, but rather longer. The inner margin of the finger was observed in this pair to be finely pectinate.

Fifth Peræopods.—The first joint considerably longer and a little broader than that of the preceding pair, the other joints very similar to those of the pair just mentioned.

Pleopods.—Peduncles broad and long; the two coupling spines long, having from four to five retroverted teeth; by the side of these coupling spines are three pointed spines, two of them feathered; the cleft spines are six in number in the first pair, five in the second and third pairs, as usual increasing in size successively downwards, the spoon-shaped part running out nearly as far as the serrate part, the shafts thickly plumose. The joints of the rami number from twenty-one to twenty-three.

Uropods.—The first pair not reaching so far back as the second, the peduncles longer than the rami, the rami subequal, rather deeply notched for the few lateral spines;

peduncles of second pair equal in length to the shorter of the two rami; third pair reaching much further back than the second, peduncles much shorter than the rami; rami lanceolate, spined on both sides, setose on the inner, the outer and under longer than the sharply pointed inner ramus, and ending in a long nail. Some or all of the borders of the rami are minutely peetinate; some of the lateral spines show an oblique striation, and are finely dentieulate.

Telson very long, narrow, tapering, produced far beyond the peduncles of the third uropods, cleft for nearly five-sixths of its length, the inner part of each apex produced to a fine point beyond the outer part of the apex, and having in the cavity a spine with accessory thread and a cilium; there are five spines along each lateral margin. The telson, like many other parts of this species, is exceedingly thin and transparent.

Length.—The specimen in its coiled position was seven-twentieths of an inch long. The smoothness of the side-plates of the first two peræon-segments suggests that the much larger side-plates which follow are in their natural position in relation to the head and front legs, and from this it may be inferred that the coiled position of the dead specimen would not be unnatural for the living animal.

Locality.—It was labelled as taken in the tow-net, off Tahiti, the 2nd of October, 1875. This corresponds with Station 279; lat. $17^{\circ} 30' 26''$ S., long. $149^{\circ} 33' 45''$ W.; depth, 420 fathoms; bottom, volcanic mud. One specimen.

Remarks.—The specific name refers to the place near which it was taken.

In regard to the antennæ, side-plates and pleon, and in some other points, this species shows some affinity with the species of *Cyphocaris*; in regard to the side-plates and slenderness of the gnathopods it agrees with *Lysianassa* (?) *cymba* of Goës, but differs from that species in not having a rostrum and in having a long, narrow, much-divided telson instead of one broadly oval with the apex whole.

Genus *Euonyx*, Norman, 1867.

The original definition of the genus is:—

“Differing from *Anonyx* in having the first gnathopods chelate, and the second stronger than the first, subchelate, nail large and strong. Posterior uropods two-branched. Telson cleft.”

For the inclusion of the present species, the words “nail large and strong” must be excised; on the other hand it might be well to include in the definition the statement that the side-plates of the first peræon-segment are short and small.

Euonyx normani, n. sp. (Pl. XIX.).

Rostrum rudimentary, lateral lobes of the head rounded between the upper and lower antennæ; back rounded; postero-lateral angles of the first pleon-segment rounded, of the second acute, of the third blunt, fourth pleon-segment with a dorsal depression, sixth with lateral ridges on the back curving a little outwards as they reach the telson, this segment on the under side being produced into a point between the peduncles of the third uropods.

Eyes not very distinct, apparently forming a narrow oval on the sides of the head, midway between the front and back.

Upper Antennæ.—First joint stout, subcylindrical, somewhat longer than its thickness at the base; two following joints very short, the third being deeply excavate for the brush-surface of the flagellum; the flagellum of twenty-nine joints, the first with a thick brush of cylinders in some sixteen rows, the joint equalling in length the five following united; stout spines on some of the earlier joints, stiff little cilia on all, the twenty-eight joints varying irregularly in length. Secondary flagellum of nine or ten joints, of which the first three equal the first of the primary.

Lower Antennæ.—First joint dilated below, gland-eone long, projecting nearly as far forwards as the distal end of the short third joint; fourth joint longer and thicker than fifth, with one or two terminal spines; fifth joint long, almost unarmed; flagellum of thirty-five joints, with very short, stout, distal cilia.

Epistome.—The front edge presents two curved lobes with an emargination between them, the lower lobe being much the more curved and prominent, the edge becoming straight lower down to the junetion with the upper lip, the frontal portion of which is less prominent than the epistome.

Mandibles.—Cutting edge convex, with a small tooth above, and two small teeth behind the lower angle; secondary plate of left mandible small, strap-shaped, probably dentate at the tip; spine-row of three rather stout, curved spines, followed by small feathered setæ or cilia; the molar tuberele projecting far back, ciliated, not dentate; the articular condyle projecting far forward; the palp set well back, but not very far back as in *Orchomene* and *Lepidepecreum*, its first joint not extremely short, the second long, narrowest at the base, without constriction, since the muscles of the upper and lower portions overlap considerably; the row of spines of the upper portion begins some way from the inner margin and apically does not reach the outer margin; it is, as usual, on the outer surface of the palp; the third joint is short, narrow at base and apex, with both margins convex, on the inner one carrying twenty pectinate spines, and two near the base and outer margin. In the Plate, the outer surface of the right mandible is figured so that the spine-row and molar tuberele are not visible, and the upper tooth of the cutting edge is turned inward out of view; the spines of the second joint of the palp

are more numerous than shown in either of the figures *m.m.*, numbering about eighteen on each mandible.

Lower Lip.—Triangular, the forward lobes being distally narrowed; the mandibular processes straight and narrow.

First Maxillæ.—The inner plate short, apically tipped with three strongly plumose setæ, of which the outermost is a little the longest; the outer plate long; of its eleven spines three stand at intervals on the inner margin, the lowest with five, the next with six, the following with seven lateral teeth; the next spine is subapical, with six lateral teeth; in the six apical spines the number of lateral teeth varies from six to three, the subapical tooth on the outer side has four; the long and narrow second joint of the palp has four slightly curved spine-teeth and a cilium or short seta. On the left maxilla some of the spines of the outer plate had one more lateral denticle than the number counted above from the right maxilla.

Second Maxillæ.—Inner plate considerably shorter than the outer, a double row of spines and plumose setæ from the apex about half-way down the inner margin, ending as usual with a plumose seta longer than the rest; the outer plate with the usual pectinate spines on the apical part.

Maxillipeds.—Inner plates not reaching as far as the apex of the first joint of the palp, the apical margin sloping outwards, with three little pointed teeth, the two innermost close together, the third standing a little apart, followed by seven or eight feathered setæ which occupy the remainder of the margin; besides the usual long setæ which pass from the inner margin to the outer apex, the plates have on their outer surface two marginal spines below the apex and a cross-row of three small setæ; outer plates large, but not reaching so far as the apex of the long second joint of the palp, teeth of the inner margin minute and numerous, separated by more than their own width; far back on the apical margin are three spine-teeth, the largest and most-curved outermost, followed by plumose setæ down part of the outer margin; low down on the outer surface of the plate are four groups of setiform spines near the inner margin, and parallel with the marginal teeth a row of fifteen spinules, with one long spine beneath; the second joint of the palp much longer than the first, the third a little longer than the first; the finger small, its surface striated with cilia, the dorsal cilium small, centrally placed; the nail small, spiniform, with short cilia at the base.¹

First Gnathopods.—Side-plates very small, almost concealed by those of the next segment, front margin convex; first joint subequal in length to the elongate hand; second joint much longer than either the third or fourth; the third and fourth subtriangular, so placed that the third is almost without free front, the fourth almost without free hind

¹ Besides the slender spines with which many parts of the palp are furnished, the third joint has at its apex one spine stouter than the rest, pectinate on both edges, and such a spine is, I believe, by no means unfrequent in this position.

margin ; the hand drawn out into a thumb of the same length as the finger, with which it forms a complete chela ; its front margin gently convex, the hind margin straight till it curves backward at the thumb, which is ciliate on the inner or palm margin with one or two spines at the tip, against which the curved and ciliated tip of the finger closes tightly ; the hand tapers gently from the base, and has a few small groups of cilia ; the finger is quite small, and so also the dorsal cilium near its base.

Second Gnathopods.—Side-plates of normal size, excavate in front, dilated below, the rounded lower part projecting over the base of the lower antennæ. The marsupial plate narrow. The whole of the limb slender, the first joint long, extending beyond the side-plate; the second joint longer than the third or fifth, but shorter than the wrist; the third joint furred behind, with some spines centrally and near the rounded apex; the wrist long and slender, furred, with many groups of spines on the hinder border and the surface, as also very long ones at the apex both behind and in front; the hand long and slender, somewhat oval, much furred, and beset with fine pectinate spines, some of great length ; the small finger closing down among some very short stumpy spines, the outward sloping palm and inner margin of the finger wearing a pectinate appearance.

First Peræopods.—Side-plates longer, first joint shorter than in the preceding pair ; third joint much longer than fourth, scarcely decurrent ; armature insignificant ; fourth joint somewhat shorter than fifth, with thirteen spines on the hinder margin, the first two and last two minute, the others small and short but thick ; fourteen of these stumpy spines fringe the hind margin of the hand, followed by a much larger one at the hinge of the finger; on the convex front margin are five spinules ; the finger is more than half the length of the hand ; in this and other limbs the nail is purplish, suggesting that the animal when alive may have been of that colour or something akin to it. The bluntness of the marginal spines is probably in part due to use.

Second Peræopods.—The side-plates very broad, much broader below than at the base, the excavation carried only a short way down ; the limb as in the preceding pair, but the fifth joint a little longer, and with one more marginal spine.

Third Peræopods.—The side-plates wider than deep, the hinder lobe descending below the front one. The marsupial plate short, expanded to some extent in the lower half, with its front border and apex notched, but without setæ present. The branchial vesicles in this and most of the branchial segments massive, the main sac rather placed parallel with the neck than pendant from it ; a small accessory vesicle in one or more of the centre pairs. The first joint of the limb roundly quadrangular, the lower part descending behind the second joint with a width nearly equal to the basal portion ; the front margin with small spines, the hinder not deeply serrate ; the third joint very much longer and broader than the fourth, sharply decurrent behind, spined on both edges ; the fourth joint much shorter than the fifth, with three groups of spines in front ; the fifth joint not so long as the third, with seven groups of spines along the front, followed by a

larger spine at the hinge of the finger, four spinules on the hind margin; finger together with its purple nail half the length of the fifth joint.

Fourth Peræopods.—First joint much longer than in the preceding pair, and more narrowed below; the fourth joint also much longer, the limbs in other respects being very similar.

Fifth Peræopods.—First joint wider and longer than in the preceding pair, its hind border more convex, but the distal breadth equal to that at the base; the rest of the limb closely similar.

Pleopods.—The two coupling spines on the peduncles with, in some cases, as many as five retroverted teeth on one margin, the opposite margin being serrate; along with the blunt-headed spines there are three or more sharp feathered ones; the cleft spines of the rami numbering from seven to five in a series, preceded by two slender plumose setæ placed above them, both divisions of the cleft part very long and slender, the spoon-shaped part much exceeded by the other; the joints of the rami numbering from seventeen to twenty-one.

Uropods.—Peduncles of the first pair somewhat longer than the longer ramus, with numerous spines along the upper margins; eight spines along the margin of the longer ramus, six (or seven) along that of the shorter, both rami stiliform; peduncles of the second pair scarcely as long as the longer ramus, which has ten spines on one margin, five on the other; peduncles of the third pair shorter than the rami, with a group of short spines at the outer corner; the rami short, broad; the upper lying flatly over the lower and reaching almost to its nail, with five little spines on each border, the apical portion forming an equilateral triangle, of which the tip is sharp but not in any way outdrawn; the lower ramus with seven little spines on the inner, and five on the outer side, the apex being formed by a broad nail, which at its base is observably less broad than the part of the blade from which it issues.

Telson reaching beyond the peduncles of the third uropods, almost oblong but a little narrowed distally, cleft three-fourths of its length, the cleft a little dehiscent, three spinules on each lateral margin, and a fourth in the apex close to the lateral margin; beyond this the apex is slightly and squarely prolonged with a small cavity as if for a spine.

Length.—The specimen, in the position figured, measured half an inch from the forehead to the back of the third pleon-segment.

Locality.—Station 170A, near the Kermadec Islands, July 14, 1874; lat. $29^{\circ} 45' S.$, long. $178^{\circ} 11' W.$; depth, 630 fathoms; bottom, volcanic mud; bottom temperature, $39^{\circ}.5$. One specimen, a female. Trawled.

Remarks.—The specific name is given out of respect to my friend, A. M. Norman, who is highly distinguished in so many branches of marine zoology, and by whom the genus *Euonyx*, to which I have referred this species, was originally instituted.

The present species resembles the type of the genus in the shape of the hand of the first gnathopods, but it has the wrist of that hand short instead of long, nor in the second gnathopods has it a strong nail like that in the type species. It agrees with the type in the lower antennæ, the side-plates of the first and second pereon-segments, and in the pleon. The mouth-organs of *Euonyx chelatus*, Norman, so far as I can judge from mounted dissections of the type specimen lent me by Canon Norman, show a general agreement with those of the present species, but the palp of the first maxilla has seven spine-teeth on the apex of the second joint, and what appears to be the outer plate of the maxillipeds has the inner margin and apex fringed with nine plumose setæ, being at the same time quite devoid of teeth.

Genus *Orchomene*, Boeck, 1870.

For the original definition of the genus, see Note on Boeck, 1870, p. 399.

Orchomene musculosus, n. sp. (Pl. XX.).

Head short, lateral lobes protruding, rounded; back rounded; lower and hind margins of the first three pleon-segments connected by curves in no way angular, fourth segment with a deep transverse dorsal depression between two humps, sixth segment dorsally ridged or folded on either side of the telson; small hairs on various parts of the integument.

Eyes not perceived.

Upper Antennæ.—First joint very tumid, scarcely longer than broad, second and third very short, the third excavate on the under side; flagellum of eleven joints, the first as long as the first of the peduncle, rapidly tapering, the brush formed of very slender cylinders, the remaining joints small, successively narrowing; some calceoli present; the secondary flagellum of four joints, the first longer than the other three united.

Lower Antennæ.—Gland-cone prominent, not acute; third joint as long as the first two united, fourth and fifth joints subequal, furred on the upper margin, with some setæ on the lower; flagellum of thirteen joints, the first six or seven together equalling in length the fifth joint of the peduncle; some calceoli present.

Mandibles.—Cutting edge convex, with a small downward-directed tooth at the top, and a small tooth behind the rounded lower angle; the secondary plate of the left mandible is a narrow, slightly curved strap, with the end divided into four small teeth; the spine-row of three short curved spines, broad at the bases; behind these the margin is furred for some distance back to the backward-pointing, narrow, dentate crown of the molar tubercle, above the hinder portion of which is a bush of fur; the articular condyle is directed far forward; the palp is set far back, behind the molar tubercle, its

first joint short, the second slightly constricted below the centre, with eleven or twelve spines near the upper end passing round to the outer apex; the third joint with the first about equalling the length of the second, widening from the base for the first third of its length, from that point narrowing to the apex, and fringed on the inner margin with nineteen or twenty spines; one spine or seta on the back near the base.

Lower Lip.—The front lobes strongly ciliated; the mandibular processes rounded, a little ciliated.

First Maxillæ.—Inner plate small and narrow, carrying on the apex two unequal plumose setæ of no great length; outer plate large, apical margin very oblique, furred, the two lowest spines broad, multidentate, standing rather apart from the rest, the other nine all powerful, the outermost with three lateral teeth, none of the others with less than four; the palp with the inner margin straight, the outer curving as the second joint expands from a narrow base almost to the apex, which in our specimen in one of the pair had eleven serrate spine-teeth and a spine, in the other eight spine-teeth and a spine.¹

Second Maxillæ.—The plates strongly ciliated, rather long and narrow, the outer overtopping the inner; the inner plate on the very sloping apical portion carrying a row of spinules and a row of pectinate spines, ending below in a spiniform plumose seta; the pectinate spines of the outer plate not confined to the apex, but appearing some little way down the inner margin.

Maxillipeds.—Inner plates short, rather rectangular, not reaching so far as the apex of the first joint of the palp, the apical margin excavate, produced on the inner side, the process carrying at its tip a minute tooth, two others equally minute being set at intervals in the excavation; the series of plumose setæ of the inner margin is continued round to the outer apex by cilia and spiniform setæ; the outer plates large, extending beyond the second joint of the palp, the inner margin carrying fourteen little nodulous teeth, while the apical border has two much larger teeth, the inner short and broad, the outer somewhat longer and thinner; the plates carry also a row of spinules on the outer surface near the inner margins; the first joint of the palp is large, distally rounded, very little shorter than the second joint; the fourth joint ends in a very minute sharp nail, and has on its inner border near the nail a row of five cilia.

First Gnathopods.—Side-plates nearly as broad as deep, lower part of the plate produced forwards, hind and lower margins nearly straight; first joint short and massive, subequal in length to the wrist and hand combined; second, third and fourth joints all short, compact, subequal in length; the third and the wrist lightly furred behind, the third having scarcely any free front margin, and the triangular, cup-shaped wrist a very small free hind margin; the hand oblong, thickest near the base, the front margin slightly convex, the hinder margin a little angularly concave, micro-

¹ In *Onesimoides carinatus* in like manner the palp of the left maxilla showed twelve spine-teeth, that of the right maxilla only nine; see p. 649.

scopically furred as far as the angle; the palm at right angles to the hind margin, convex, cut into irregular microscopic teeth, defined by two strong spines, between which the finger closes down; the finger, which neatly fits the palm, has, besides the dorsal cilium, one on the inner margin near the hinge, and two on the side near the tooth of the inner margin. There is a row of cilia on the hand on either side of the palm.

Second Gnathopods.—Side-plates oblong, little rounded, much narrower than the preceding pair. First joint elongate, narrow; second joint a little shorter than the wrist; third joint shorter than the second, furred behind, apically rounded and armed with long pectinate spines; the wrist furred almost all over, having the not unusual scale-like ornaments on the breast; from a narrow neck near the base the joint expands evenly to its junction with the hand, here carrying on either side long pectinate spines; the hand a little shorter than the third joint, narrow at the base, front margin convex, carrying several rows of curved spines pectinate on two edges, and occupying much of the apical margin, this part carrying also a row of setules; the very small finger set far back closes tightly down upon the small, convex, inward-sloping, pectinate palm; near the nail the finger has a denticle on its inner margin; the dorsal cilium is placed rather nearer to the nail than to the hinge.

First Peræopods.—Side-plates similar to those of the preceding pair, but larger. Branchial vesicles broad, without folds. First joint shorter than the second and third united; third joint scarcely produced downwards, much longer than fourth, subequal in length to the fifth joint; third, fourth and fifth joints with some very slender spines on the hinder margin; fifth joint narrow, with some short spines on the hinder margin; finger short, curved, with a very small dorsal cilium.

Second Peræopods.—Side-plates very broad below, much excavated behind, the joints similar to those of the preceding pair, the third, fourth and fifth rather smaller.

Third Peræopods.—Side-plates as broad as long, hinder lobe more outdrawn downwards than the front; first joint broad, a little narrowed below, scarcely longer than its breadth, attached to the middle of the lower margin of the side-plate by a sort of pocket or fold of its front margin, front margin with half-a-dozen small spines, hinder with six or seven minute notches; the third joint broad, produced downwards behind, some short spines and spine-like setæ or scale-like spines on the margins; the fourth joint a little shorter than the third, with spines on the front margin; the fifth joint much longer than the fourth, with very small spines on the front margin; finger short, curved.

Fourth Peræopods.—First joint longer than broad, attached as in the preceding pair, its nearly straight front margin with few spines, the hind margin with distant notches; the third joint longer, less expanded in proportion to its length than in the preceding pair, with two spines on its hind margin; the fourth and fifth joints likewise longer; the finger short.

Fifth Peræopods.—These are similar to the fourth pair, except that the first joint is

much larger and much more expanded above and behind; the third joint has three spines on the hind margin. The last five joints in this, as in the two preceding pairs, are much smaller than the last five of the first peræopods.

Pleopods.—The coupling spines on the peduncle are slender, with three or four retroverted teeth. The cleft spines are six in a series in the first and second pairs, five in the third pair. The outer ramus has seventeen or eighteen joints, the inner from fourteen to sixteen.

Uropods.—The first pair with peduncles longer than the slender, pointed rami; in the figure, *ur. 1.*, the flat instead of the side view of these is given; the edges of the subequal rami are almost devoid of spines, but microscopically pectinate; the peduncles of the second pair scarcely as long as the rami, which are equal in length, with spines on the borders as well as pectination; the third pair have the peduncles shorter than the rami; the outer ramus with a nail, somewhat longer than the inner, both pectinate on both edges, with few spines and some plumose setæ; though shorter than the other two pairs, they project further back.

Telson elongate, distally narrowing, projecting beyond the peduncles of the last uropods; cleft not extending to the middle, more or less dchiscent for its whole length; the apices somewhat pointed, each containing a spine and a cilium; on each side near the outer margin there is a feathered cilium above, and a small spine below, the top of the cleft. In the figure, *Pl.*, the base of the telson is concealed by the peduncle of the third uropods.

Length.—The specimen, in the position figured, measured from the front of the head to the back of the second pleon-segment nearly two-fifths of an inch.

Locality.—Station 230, south of Japan, April 5, 1875; lat. $26^{\circ} 29' N.$, long. $137^{\circ} 57' E.$; depth, 2425 fathoms; bottom, red clay; bottom temperature, $35^{\circ} 5$. One specimen; surface.

Remarks.—The powerful muscles exhibited by the compact first gnathopods suggested the specific name *musculosus*.

For the union of this species with Bocck's *Orchomene*, it is necessary in some respects to curtail his definition of that genus, omitting the epithet *prælongata*, which he applies to the inner plate of the first maxillæ, and the epithet *brevissima*, which he applies to the telson, as well as the statement that the telson does not reach the end of the peduncle of the third uropods. His own figure of *Orchomene pinguis* disagrees with this part of his definition, which may therefore well be dispensed with.

Orchomene abyssorum, n. sp. (*Pl. XXI.*).

Head apparently without any rostral prominence, lateral lobes largely developed, rounded; back rounded; pleon-segments as in *Orchomene musculosus*, except that the

convexities of the lower and hind margins of the third segment meet in a less-rounded angle.

Eyes not clearly perceived, but probably large.

Upper Antennæ as in *Orchomene musculosus*.

Lower Antennæ similar to those in the species just named, but the third joint as long as the fifth, the fourth longer than either; the flagellum of fifteen joints.

Upper Lip.—Front margin rounded in lateral view, apex strongly furred below.

Mandibles as in *Orchomene musculosus*, but having the trunk narrower behind the palp; the second joint of the palp more elongate, with eighteen to twenty spines on the upper part; and on the third joint three and twenty spines on the front margin.

Lower Lip and *Maxillæ* as in the kindred species. In the first pair of maxillæ the spines on one maxilla do not appear to agree exactly in dentation with those on the other, and in the two species some variation would probably be found upon a comparison of spine with spine.

Maxillipeds differing but slightly from those of *Orchomene musculosus*, the little marginal teeth of the outer plates being only eleven in number, the first joint of the palp rather less developed; the slender terminal joint has two cilia beside the slender spine-like nail, one on the pectinate inner margin not far from the nail, and a longer one on the outer margin also not far from the nail; near the base is a small depression on the outer margin, but without a cilium present in our specimen.

First Gnathopods.—Side-plates longer than broad, a little widened below, scarcely produced forwards, front margin nearly straight. First joint reaching beyond the side-plate, as long as the rest of the limb, not broad or expanded at any part; the remainder of the limb not massive as in *Orchomene musculosus*, but otherwise showing a remarkable similarity in detail; the pectination of the palm differs a little in the two species, but this minute character might vary in different specimens of the same species.

Second Gnathopods with the hand rather longer than the third joint, its hinder margin eoneave, strongly produced to antagonize with the minute finger, the very oblique lower margin being set with eight or nine curved spines, so graduated that in one of the gnathopods their tips presented an even line in continuation of the hinder margin of the hand. These spines are partially serrate on the inner side, and have an accessory thread at the tip, giving the tip a rather ragged appearance. The limb in general resembles that in *Orchomene musculosus*, and has the same delicate furring of the wrist, but the hand is considerably more produced, so as to be on a minute scale chelate rather than subchelate.

First Peræopods.—Side-plates long and narrow, of almost even width throughout. First joint reaching just to the end of the side-plate, shorter than the second and third united.

Second Peræopods.—Side-plates a little longer than those of the preceding pair, not double the width at the acute lower angle of the hinder excavation. First joint not

reaching the end of the side-plate, the limb in general like that of the preceding pair, with the fifth joint rather shorter.

Third Peraopods.—Branchial vesicles large, with a long slender appendage arising near the top of the main sac. The first joint longer than broad, with the front margin nearly straight.

Fourth Peraopods.—First joint long, not much broader above than below.

Fifth Peraopods.—The first joint large, of even breadth for much of its length, below less abruptly narrowed than in *Orchomene musculosus*, with which in general this and the other pairs of peraeopods closely agree.

Pleopods.—The two coupling spines are very small, each with three lateral retroverted teeth in addition to the terminal hook. In the first pair the inner ramus carries seven cleft spines, in the third pair six; the joints of the rami number from sixteen to twenty.

Uropods.—Peduncles of the third pair much longer than the subequal, slender, stiliform rami, which carry very few and small spines; peduncles of the second pair longer than the rami; the outer ramus longer and broader than the inner, with twelve small spines set closely along its upper margin, the inner ramus with three spines on its upper margin at a distance from the apex; peduncles of the third pair as long as the shorter ramus, the rami broad, lanceolate, reaching much beyond the preceding pairs, the lower rather longer than the upper, ending with a nail, the spines on both few and small, some plumose setæ on the margins.

Telson much longer than its greatest breadth, reaching beyond the peduncles of the third uropods, cleft beyond the middle, slightly dehiscent almost the whole length of the cleft portion, each apex carrying a small spine; three small spines at intervals along each lateral margin.

Length.—The specimen, in the position figured, measured, from the front of the head to the back of the third pleon-segment, exclusively therefore of the antennæ, three-tenths of an inch.

Locality.—Station 323, east of Bucnos Ayres, February 28, 1876; lat. $35^{\circ} 39' S.$, long. $50^{\circ} 47' W.$; depth, 1900 fathoms; bottom, blue mud; bottom temperature, $33^{\circ} 1$. One specimen, male.

Remarks.—The specific name has been given in allusion to the great depth from which the species is reported to have come. The single specimen, a male (as shown by the ventral appendages of the seventh segment of the peraeon), was mounted during the voyage. Had this species been taken within any reasonable distance of *Orchomene musculosus*, the resemblance is so great that one might have been tempted to disregard the points of difference as due to some other cause than difference of species. It might be an accident that has caused one to be reported from the surface, and the other

from so great a depth as 1900 fathoms, but that the Stations at which the two species were obtained are separated by nearly half the circumference of the globe is a circumstance not open to any such explanation. The first pair of side-plates, the hands of the second gnathopods, and the postero-lateral angles of the third pleon-segment are serviceable marks for distinguishing the two species.

Orchomene cavimanus, n. sp. (Pl. XXII.).

Rostrum obsolete, lateral lobes of the head produced, much rounded; postero-lateral angles of the third pleon-segment scarcely rounded, fourth pleon-segment with a dorsal depression, and the hinder part of the dorsal margin forming a sharpened point slightly tip-tilted and raised above the succeeding segment; sixth segment ridged on each side of the telson.

Eyes large, placed near the front of the head, wider below than above.

Upper Antennæ.—First joint tumid, second and third very short, third excavated below; flagellum of thirteen joints, the first as long as five of the following joints together, the brush of cylinders in ten or eleven rows, cylinders on many of the other joints also; secondary flagellum of five joints, of which the first is much the longest.

Lower Antennæ.—Gland-cone moderately prominent but small, third joint longer than the composite first and second, and as long as the fifth joint; fourth joint longer than the fifth, both being furred on the upper margin; flagellum of fifteen or sixteen small joints in the female specimen here described.

Epistome prominent, with a rounded lobe curving down just over and in front of the top of the upper lip. The Plate gives a figure representing the epistome between the palps of the two mandibles, with the upper lip, two mandibles, and lower lip in position; the left mandible with its secondary plate is shown projecting a little in advance of the right mandible; the inner side of the right mandible is figured on the other side of the Plate.

The Mandibles and *Lower Lip* resemble those of *Orchomene musculosus*, but with the parts adjacent to the molar tubercle less furred, and the palps more slenderly built, the third joint being also shorter in comparison with the second.

First Maxillæ similar to those of *Orchomene musculosus*, but the inner plate more elongated.

Second Maxillæ.—Outer plate broader than inner, not very much longer, spine-fringed border not very oblique; armature of inner plate as in *Orchomene musculosus*.

Maxillipeds narrow, inner plates reaching nearly as far as the apex of the first joint of the palp, with three teeth on the straight apical margin; outer plates scarcely reaching as far forward as second joint of palp, with fourteen small nodulous teeth on the inner, and reaching round to the apical margin, with two much larger teeth on the outer part of

the apical margin, the outer of the two being the longer and thinner; the first joint of the palp substantial, nearly as long as the second, the fourth joint slender, with a small nail; a dorsal cilium near the nail, and a row of four cilia near it on the inner surface.

First Gnathopods.—Side-plates widened below but not much outdrawn in front; first joint of great thickness, exceeding in length the third, fourth and fifth united; the second, third and fourth subequal in length; the second with several setæ along its hind border, the third with no free front border, the hind border furred, carrying a group of spines near the apex; the small free hind margin of the triangular cup-like wrist furred; the hand oblong, but a good deal broader at the base than at the palm; both hand and finger very similar in the details to those of *Orehomene museulosus*.

Second Gnathopods.—These differ from those of *Orehomene museulosus* in that the wrist is not longer than the second joint, and, instead of being most expanded close to the apex, is here most expanded midway between the third and fifth joint, so as to have a plump instead of an elongate appearance; the hand is also less elongate, and the little palm is deeply excavate, the process which bounds it being squared and pectinate apically, carrying a pectinate spine; the inner end of the finger appears to be armed with a brush of microscopic cilia or denticles, and when this antagonizes with the hinder process of the palm there is a clear space left between the palm and inner margin of the finger. The marsupial plate is narrow, with very long setæ.

First Peraopods.—The oblong side-plates are of even width throughout. The branchial vesicles are very long and very broad except at the neck, without folds. The joints of the limb similar to those in *Orehomene museulosus*, with which in general the other limbs also agree.

Third Peraopods.—The side-plates rather less elongated behind.

Fourth Peraopods.—The branchial vesicle behind the neck presents two lobes, one ascending the other descending, below and in front of which the main part of the vesicle consists of a large circular expansion, against which lies a narrow accessory sac of about equal length, curved at the tip.

Fifth Peraopod.—The branchial vesicle is here a simple sac which rises a little above and descends a great way below its point of attachment; the outline is convex in front, concave behind, the straight upper margin running obliquely downwards to form a small but conspicuous backward-directed process. The first joint of the limb is extremely expanded behind and only very slightly narrowed below.

Pleopods of the third pair with four cleft spines on the first joint of the inner ramus, those of the second pair with five.

Uropods.—Peduncles of the first pair considerably longer than the rami; rami slender, with few spines, a series of five on one edge of the outer, of four on one edge of the shorter inner ramus; edges of the rami microscopically pectinate; peduncles of the second pair longer than the rami, which are equal in length to one another; peduncles of

the third pair shorter than the rami, rami lanceolate, with few spines, the inner finely pointed, not reaching to the nail of the outer, both bordered within with plumose setæ.

Telson extending fully as far back as the peduncles of the third uropods, cleft for three-quarters of its length, narrowed distally, a spine above and another below the middle of each outer margin, and one in each apex; all these with accessory threads.

Length, without the antennæ, two-fifths of an inch.

Locality.—Kerguelen Island. The particular place or depth was not recorded in regard to the specimen figured and described. A second specimen was taken at the surface in Betsy Cove, and a third at Station 149H, off Cumberland Bay; depth, 127 fathoms; bottom, volcanic mud.

Remarks.—The specific name refers to the cavity in the palm of the second gnathopods. In the course of the description the differences have been noticed between this and the very similar species, *Orchomene museulosus*, taken at an enormously distant station to the south of Japan. The present species agrees better with Boeck's definition of *Orchomene* in so far as the inner plate of the first maxillæ is elongate, but agrees worse with it, in so far as the large outer plates of the maxillipeds, though perhaps extending as far as the second joint of the palp, cannot be said, in accordance with the definition, to extend beyond it. Boeck himself does not seem to have laid much stress on the latter point, since, in describing *Orchomene serratus*, the type species, he says that the outer plates of the maxillipeds reach about to the end of the second joint of the palp.

Genus *Lysianax*, altered from *Lysianassa*, preoccupied.

Lysianassa, Milne-Edwards, 1830.

For the original definition, see Note on Milne-Edwards, 1830 (p. 141). Boeck, in 1872, thus defines this genus, which, since its first institution, has been much subdivided:—

“ Mandibulæ mala in margine anteriore dente parvo, sed longo, tenui instructa; palpo elongato, in eadem altitudine ac tuberculo molari minuto affixo.

“ Maxillæ 1mi paris lamina interna permagna, in apice setam parvam aut obsoletam gerenti.

“ Maxillæ 2di paris lamina interiore lata, exteriore angusta.

“ Pedes maxillares lamina exteriore ovata vixque in margine interiore nodulosa, non ad finem articuli 2di palpi elongati angustique porrecta; lamina interiore elongata.

“ Antennæ superiores articulo pedunculi 2do et 3to paulo elongatis.

“ Pedes 1mi paris manu non subcheliformi; articulo 5to elongato, apicem versus attenuato; ungue parvo.

“ Pedes saltatorii elongati; ramis paris ultimi brevioribus quam pedunculo, setosis.

"Appendix caudalis parva, integra, postice rotundata."

In this definition, in the account of the mandibular palp, I propose to insert the words *vel profundius* before *affixo*, in the description of the telson to place instead of *postice rotundata* the words *vel parum incisa*, and in that of the maxillipeds to omit the measurement of the outer plates.

Lysianax variegatus (Stimpson) (Pl. XXIII.).

1855. *Anonyx variegatus*, Stimpson, Proc. Acad. Nat. Sci. Philadelphia, p. 394,

1862. *Lysianassa variegata*, Sp. Bate, Brit. Mus. Catal. Amphip. Crust., p. 67, pl. x. fig. 7.

Head short, rostrum minute, lateral lobes produced into a rounded angle; back rounded, slightly hairy; third segment of the pleon with lower margin upturned, so that the postero-lateral tooth, which is not a very sharp one, comes high up on the hind margin; the fourth segment but little dorsally depressed, the sixth produced far along the sides of the telson.

Eyes large, reniform, bending round from the top of the head to the lateral lobes, very dark-coloured in the spirit-specimens, the ocelli numbering perhaps a hundred and fifty.

Upper Antennæ.—The first joint tumid, not very long, carrying some groups of setæ as well as a row of feathered eilia; the second joint, though much shorter and narrower than the first, is much longer than the third; the flagellum of eight joints, of which the first is rather shorter than the second of the peduncle, the cylinders of the brush forming some fifteen rows in this narrow space; the remaining joints, becoming successively shorter and much narrower, likewise have cylinders; the secondary flagellum is of four joints, the last minute, the first nearly as long as the first of the primary.

Lower Antennæ.—The gland-cone not very prominent, the third joint short, the proportions of the fourth and fifth not constant; in a specimen with an eight-jointed flagellum the fifth joint of the peduncle, as shown in fig. B, did not very greatly exceed the length of the fourth joint, whereas in the specimen represented in fig. C the fifth joint is double the length of the fourth, and the fourth is much inflated; both joints have groups of cilia on the upper edge, the fifth joint has its lower margin smoothly convex, and instead of being widened distally as in the smaller form, is distally narrowed; this is evidently the form belonging to the adult male; there are ealecoli with their attendant cilia on many of the fifty-three joints of the slender flagellum; the caleculus is of narrow oval form with continuous rim. With the form of the male antennæ above described may be compared the figures in the British Sessile-eyed Crustacea of the lower antennæ of the species there called *Lysianassa longicornis* and *Anonyx longicornis*; a similar form of the lower antennæ in the male is to be met with in genera outside of the Lysianassidae.

Epistome presents a rounded lobe ascending almost to meet the triangular lateral

lobes of the head; the front edge of its thin plate seems to be sharp, and is very straight. In one specimen there was a little tooth in the front part of the rounded top.

Upper Lip short, its distal edge densely fringed with short fur.

Mandibles.—These are very long and narrow; the cutting edge has at the top a little pointed tooth, the lower border almost or quite entire; I was not able to perceive any trace of a secondary plate, though the rudiment of one might have been present notwithstanding, concealed by the folding of the principal plate, but what could be seen of the new mandible in preparation, which is perfectly flat, gave no indication of this; the spine-row consists of three curved spines not far from the cutting-plate, followed by a long close-set row of short thick cilia, reaching to the small, triangular, ciliate, not dentate, molar tubercle; at a considerable distance behind this rises the palp, its first joint comparatively long, the long second joint with its lower part thickest, carrying a row of eight or nine pectinate spines at the distal end; the third joint curved, not twice as long as the first, the two together scarcely equalling the length of the second, with spines on the middle of the inner margin and on the apex, and adpressed cilia on the surfacee. The articular condyle, which in some genera overlaps the base of the palp, is here at an immense distance from it, being just over the three spines of the spine row.

Lower Lip much furred round the apex and long inner margins; the mandibular processes narrow, not much produced.

First Maxillæ.—Inner plate long, narrow, ciliated, with an almost pointed apex, without any setæ in the specimens examined; outer plate large, the somewhat sloping apical border fringed with eleven spines, of which seven are stout, those near the inner margin especially broad and multidentate, but inserted below the uppermost spines are four slender and curved ones apically forked but not otherwise dentate; the palp is slender, its second joint apically divided into five or six small teeth, beside which a spine rises from an indent on the outer margin.

Second Maxillæ.—The inner plate as long as the outer, and broader; a row of fifteen pectinate spines from the apex some way down its inner margin; the apical border of the outer plate is crowned with much longer spines which over-arch those of the inner plate.

Maxillipeds.—Inner plates very long, reaching beyond the middle of the second joint of the palp, inner margins densely clothed with cilia, in the adult hiding the apical outward-sloping margin, which in a young specimen can be seen to possess three minute teeth or prominences indicative of teeth; the outer plates very large, projecting rather beyond the second joint of the palp, with no sign of teeth or spines on the indented inner and apical border; of the setiform spines on the inner border of the third joint the shorter ones have unusually thick accessory threads; second joint of the palp much longer than the first; finger very small, much shorter than the third joint, with a slender adpressed denticle lying along the base of the small spiniform nail.

First Gnathopods.—Side-plates broad, much produced in front below; first joint scarcely reaching to the lower rim of the side-plate, of nearly equal breadth throughout, with setæ on the front margin; third joint short, triangular, hind margin convex, furred, with setæ near the apex; wrist stout, scarcely as long as the hand, with the front margin almost adjoining the second joint, the hind margin where free a little furred, with setæ at the apex; the hand at its base narrower than the wrist, distally scarcely broader than the base of the finger, where it has a tuft of small spines or setæ; the borders are rather sinuous (though considerably less so than in the figure *gn. 1. c.*), with some setæ on the hinder one; the finger is short, very slightly curved, seemingly with no capacity for bending against the hand; it has a denticle like that in the finger of the maxillipeds.

Second Gnathopods.—Side-plates widening gradually and slightly downwards; first joint as long as the third, fourth and fifth combined, distally widening and bending backwards; second joint rather longer than the wrist, third joint much shorter, narrow at the base, then expanding, the very convex hinder margin furred, and having a group of spiny setæ near the apex; the wrist starting with a narrow neck swells out and again narrows somewhat apically; it is densely furred almost all over, and has scale-like ornaments on the breast; the hand, narrow at the base, widens a good deal towards the distal end; it is densely furred, some of the cilia outstanding, others adpressed and gracefully waved; near the palm on the breast some scales are conspicuous; the convex palm is set on both sides with minute straight cilia, and forms a recess with the apical portion of the hind margin, into which the short finger closes down; the finger, set at some distance from the front margin of the hand, is thick at the base, over-arched with many spines set in rows upon the hand's front or apical margin, the spines of various lengths, but each seemingly having a short tooth on the convex side before the apex is reached. The branchial vesicles of this and the following pairs exhibit many cross folds or pockets; they narrow towards the distal end.

First Peræopods.—Side-plates similar to those of the preceding pair; third joint longer than fourth, apex produced downwards; long, finely plumose setæ on the hind borders of both third and fourth joints, and a row of ten spines along the hind border of the fifth joint, which equals the third in length; the third, fourth and fifth are edged on both borders with cilia apparently in simple rows, not thickly set so as to constitute furring; the finger curved, with clean edges, except for the dorsal cilium.

Second Peræopods.—Side-plates broad, the excavation not carried far down, the joints similar to those of the preceding pair, except that the fifth is a little shorter, with nine spines instead of ten. The branchial vesicle with a large accessory pocket at the top.

Third Peræopods.—Side-plates much broader than deep, broader below than above; first joint broad, rounded, the very convex front margin furred above, with long setæ below, some short spines on different parts; the serration of the hind margin presenting only five points above and three small indents lower down, each carrying a cilium; the

third joint dilated centrally and produced downwards behind, with setæ on both margins and spines on the front one; the fourth joint short, dilated below; the fifth joint much longer and narrower, both with groups of spines in front; the finger curved, clean-edged, but at the forward-bulging curve just below the hinge microscopically furred.

The Fourth and Fifth Peræopods are similar to the third, but with the various joints more elongate, the first joint in each being outdrawn downwards, narrowly in the fourth and more broadly in the fifth pair.

Pleopods.—The coupling spines, examined only in a small specimen, had two lateral teeth and a small one at the apex; the number of the eleventh spines was not ascertained.

Uropods.—The first pair extend back some way beyond the other two pairs; they have the peduncles longer than the rami, carrying a few curved spines, and are, like the whole group of these uropods, finely ciliated on the edges; the rami are straight, slender, edged with spines, equal in length, the tips scarcely curved; of the second pair the peduncles are equal to the longer of the two rami, which are slender and very slightly curved; the peduncles of the third pair are longer than the rami, and have spines on the outer and plumose setæ on the inner of their upper edges; of the rami, which are broadly lanceolate, the outer is rather the longer, both have long plumose setæ on the inner edges, the inner also some spines on its outer edge.

Telson short, not very much longer than broad, reaching but a little way down the peduncles of the third uropods, not much contracted distally, the distal end squared, broken by a gaping notch measuring not one-fifth of the total length of the telson; on either side just above the level of the top of the notch is a small spine, above this again a small and a larger feathered seta.

Length.—Specimen A measured, in the position figured, from the forehead to the end of the second segment of the pleon, two-fifths of an inch, so that the total length of this, which was not the largest specimen, would be nearly three-fifths of an inch.

Locality.—Simon's Bay, Cape of Good Hope; depth, 18 fathoms.

Remarks.—The account which Stimpson gives of his *Anonyx variegatus* is as follows:—"Large, slightly compressed; back rounded, smooth and glossy, with a sinus at the abdomen. Antennæ about equal in length, the superior ones thickened to the origin of the accessory flagellum, which is short and hair-like, equal in size with the true flagellum. Eyes large, black, reniform. First pair of legs with an elongated, tapering hand and a minute finger; basal joints of the posterior pairs smooth. Caudal stylets elongated and slender. Colour yellowish mottled with brown, with scattered white dots. Length, .08 inch. On sandy bottoms in the circumlittoral zone. Hab. Cape of Good Hope, at Simon's Bay."

Spence Bate gives the length of the specimen sent him by Stimpson as "about $\frac{12}{20}$ ths of an inch," in other words, about three-fifths of an inch. Since Stimpson himself

describes the species as large, it may be taken for granted that “·08 inch” in his account is a misprint for “·8 inch,” equivalent to four-fifths of an inch. There can, I think, be no doubt that the Challenger species is identical with Stimpson’s, and though the incised apex of the telson and the palp on the mandible set far behind the molar tubercle are features that will not agree with Boeck’s definition of *Lysianassa*, I think that Spence Bate rightly referred this species to that genus. It is the definition of the genus that must be modified, not the species that ought to suffer exclusion.

Genus *Lepidepecreum*, Bate and Westwood, 1868.

For the original definition of the genus, see Note on Bate and Westwood, 1868 (p. 373); now that the genus is somewhat better known, it may be defined as follows:—

Upper Antennæ with the secondary appendage small or rudimentary.

Lower Antennæ with the third joint comparatively long.

Mandibles with the palp narrow, set well behind the dentate molar tubercle.

First Maxillæ.—Inner plate not elongate, carrying two plumose setæ at the apex; outer plate with one of its eleven dentate spines standing a little apart from the rest; the palp carrying several little spine-teeth and one spine on the truncate apex.

Second Maxillæ.—The outer plate a little longer than the inner, both plates rather narrow and elongate.

Maxillipeds.—Outer plate with a few nodulous teeth on the inner margin, the plate reaching beyond the rather short second joint of the palp; the fourth joint of the palp ending in a sharp nail.

First Gnathopods not robust, hand and wrist subequal in length, hand subeheliform.

Second Gnathopods with the hinder margin of the hand outdrawn.

Telson more or less cleft.

There is only the minute rudiment of a secondary appendage on the upper antennæ of the type species of *Lepidepecreum*. A small and two-jointed appendage is figured for *Lysianassa umbo*, Goës, which Boeck calls *Orchomene umbo*, but which G. O. Sars would refer to *Lepidepecreum*. The species here referred to that genus has numerous points of similarity with the species described by Goës.

Lepidepecreum foraminiferum, n. sp. (Pl. XXIV.).

A small rostrum; lateral lobes of the head outdrawn, very long and narrow; the whole animal dorsally sharply ridged from one end to the other, on the last two segments of the peræon and first three of the pleon the ridge forming a distal tooth; the lower

edges of the first four pairs of side-plates and of the first joints of the last three pairs of pereopods brought so closely into contiguity from either side of the body as to form a straight ridge scarcely less sharp than the carina of the almost semicircular dorsal line. From the very narrow front the body bulges greatly to the fourth or fifth pereon-segment, and then again narrows to end as sharply as it begins. Of the pereon-segments the fourth, fifth, and sixth are the longest and deepest. The third segment of the pleon has the postero-lateral angles sharp, in the slightest degree upturned. The fourth segment has a deep dorsal depression, the part behind the dorsal depression strongly tip-tilted, the sixth ridged on the back on either side of the telson.

Eyes not discovered.

Upper Antennæ.—In the male, first joint large and broad, the upper ridge continued into a process overhanging the second joint; the second and third joints short, very much narrower than the first; the flagellum of six joints, the first broad at the base, tapering, as long as the other five united, with four rows of cylinders near the distal end; cylinders also on the next three joints; the secondary flagellum very slender, of three joints, together not equal in length to the first of the primary; of the three, the first longer than the second, the third minute. In the female these antennæ are slightly more slender, the flagellum of five joints, with the first not quite so long as the other four united, the secondary flagellum two-jointed.

Lower Antennæ.—Gland-cone prominent, third, fourth, and fifth joints subequal in length in the male, the fifth slightly the longest, the flagellum in one of the pair of antennæ attaining the number of thirty-six joints, the first longer than the next two together, the joints all gradually tapering, not bulging distally. In the female the third joint is as long as the fourth, and each of these much longer than the fifth, while the flagellum consists of four or five slender joints. In both sexes the fourth and fifth joints of the peduncle are more or less ciliated above.

Epistome.—The front of the animal is formed by the dorsal ridge of the first pereon-segment, the head and the upper antennæ, so that it would be inaccurate to speak of the epistome as prominent, but when the head and mouth-organs are detached and viewed without the antennæ, the expression would become appropriate.

Mandibles.—The cutting edge eonvex, with a small downward directed tooth at the top, and a very small forward directed tooth behind the rounded lower angle; secondary plate strap-shaped, bent, the apex cut seemingly into three denticles; spine-row of three slightly curved spines; the molar tubercle well forward near the spine-row, its oval crown set with rows of denticles, and a central row of four or five more prominent and isolated than the rest; the slender palp, set far back, has on the long second joint near the apex a row of six or seven spines, increasing successively in length as they approach the apex; on the upper half of the third joint eleven spines, the first six separated by a slight interval from the apical five.

Lower Lip.—Forward lobes strongly furred on the inner margins, their outer margins and the mandibular processes unciliated.

First Maxillæ.—The inner plate rather small, with two plumose setæ of unequal size at the apex; the outer plate large, the innermost of the apical spines standing out a little apart from the other six strong ones, these and the four more slender ones a little below all strongly dentate; the palp with seven small teeth and a ciliated spine on its truncate apex, the teeth in one of the pair of maxillæ appearing to be longer than those in the other.

Second Maxillæ.—The inner plate not much shorter than the outer, with six spines on the apex, three on the inner border, and a plumose seta, the border below this seta being, in common with the surface of the plate, very finely ciliated (not coarsely as in the figure *mx*, 2, ♂); several curved pectinate spines on the apex of the outer plate, one rising from the inner margin just below the apex.

Maxillipeds.—Inner plates reaching as far as the apex of the first joint of the palp, with plumose setæ on the inner margin, on the apical margin three teeth, followed by two curved pectinate spines, the shorter outermost; the outer plates reaching beyond the second joint of the palp, with eight small teeth on the inner margin, not adjoining but spaced, and a single less-embedded tooth on the apical margin; second joint of palp scarcely longer than first; fourth joint with a slender nail, a dorsal cilium near the centre, and a cilium on the inner margin near the nail.

First Gnathopods.—Side-plates triangular at the base, then oblong, with a slightly curved lower margin; the first joint longer than all the rest of the limb, a little expanded in the lower half; the third joint scarcely longer than the second, furred behind, with some spines near the apex; wrist long, furred behind; hand subequal in length to the wrist, nearly parallel-sided, much longer than broad; palm slightly concave and oblique, defined by two long spines; finger not longer than palm, with a dorsal cilium, and one or two cilia near the tooth on the inner margin.

Second Gnathopods.—Side-plates long. Branchial vesicle with a narrow lobe below. First joint slightly expanded and scarcely bent below, not reaching to the end of the side-plate, and not as long as the third, fourth and fifth joints united; second joint subequal in length to the wrist; third joint shorter, flask-shaped, furred behind, two short setæ near the rounded apex; wrist flask-shaped, lightly furred on the front margin, the side, and the breast, which has also the microscopic fan-shaped scales common in this family; the hand subequal to the third joint, narrow at the neck, then expanding, the hinder margin outdrawn so that the palm slopes inward with the minute finger resting close upon it, the anterior part of the apical margin occupied by a small number of the usual spines; on different parts of the hand there are cilia longer than those composing the fur; the finger is set back from the front margin of the hand, with the outdrawn hinder portion of which it forms a minute chela; it is

stout at its base, and ends in a narrow hooked nail ; the dorsal eilium is fixed at about the centre.

First Peræopods.—Side-plates long, expanding gradually from above ; first and second joints together not reaching to the end of the side-plates ; third joint broader but not so long as the fourth ; fourth not so long as the fifth, some fine setæ on the hinder margin of the second, third and fourth joints, on the fifth three or four eilia at intervals on each margin, and on the hinder two small inward-curving spines close to the finger-joint ; the finger long and slender, with a dorsal eilium close to the hinge.

Second Peræopods.—Side-plates with a rather deep but not wide excavation. Fourth and fifth joints rather shorter than in the preceding pair.

Third Peræopods.—Side-plates with breadth and depth subequal. First joint a little longer than broad, of nearly even diameter throughout, with spines on the front margin, the hinder serrate ; the third joint expanded, produced behind, longer and much broader than the fourth ; the fourth shorter than the fifth, which is straight, narrow, somewhat tapering ; one or two spines on each of the three last-mentioned joints ; the finger long, thin, and straight, but the whole of the limb beyond the first joint insignificant in size compared with that joint, and that joint itself considerably smaller than the side-plate.

Fourth Peræopods.—The side-plates with front and hind margins parallel, lower margin downturned behind in a rounded lobe ; first joint longer than that of preceding pair, front margin not spined above ; in other respects the joints very similar to those of the preceding pair, the third a little less expanded.

Fifth Peræopods.—First joint very large, upper and front margins nearly straight, hinder very convex, the narrowed part below partly overlapping the third joint, front margin spined nearly to the top, hinder serrate, this joint much longer than the other five united ; spines on both margins and some setæ on the front margin of the expanded third joint, which is produced downwards behind ; the fourth joint short, the fifth subequal in length to the third, the finger slender, slightly curved at the tip, not stumpy as it happened to be abnormally in the specimen figured.

Pleopods.—The cleft spines form a row of five in the first pair, of four in each of the following pairs. The round-headed spines on the peduncles of the first pair appeared to have three retroverted teeth. The joints of the rami numbered from fourteen to seventeen.

Uropods.—Peduncles of first pair longer than the rami, outer ramus with four spines along the margin, longer than the inner, which has two spines ; both peduncles and rami microscopically pectinate ; peduncles of the second pair slightly longer than the rami ; outer ramus longer than inner and with more numerous spines ; third pair with the rami broadly lanceolate, a little longer than the peduncles, each spined on one

border, the longer, which is the lower and inner, also with plumose setæ and a conspicuous nail.

Telson, in one specimen, female, not reaching the distal end of the peduncles of the third uropods, in another specimen, male, reaching beyond them; cleft not so far as the centre, not dehiscent, a spine in each half of the apex, a feathered cilium on each side about level with the top of the cleft, and two spines lower down.

Length of female, in the position figured, one-fifth of an inch; two other specimens the same size; two much smaller.

Locality.—Station 149H, off Cumberland Bay, Kerguelen, January 29, 1874; depth, 127 fathoms; bottom, volcanic mud. Five specimens. Dredged.

Remarks.—The specific name alludes both to the general appearance of this compact and rounded little species, and to the little bright spots looking like perforations in the integument, to each of which a microscopic cilium appears to be attached. The figure of the third pereopod indicates this character. The species seems to have some affinity with Boeck's genus *Menigrates*, but in that genus the mandibles are described as very short, with a short palp, and the first gnathopods as very robust, with the hand scarcely subcheliform. In *Orchomene*, which comes near to *Menigrates*, the hands in question are very short, robust, longer than the triangular carpus. *Ambasia* has the third joint of the lower antennæ elongate, but was in other respects unsuitable. *Lepidopecreum* seems to be the genus in which the present species can be most appropriately placed.

Genus *Soearnoides*, n. gen.

Mandibles very elongate.

Lower Lip with front and hind lobes outdrawn, narrow.

First Maxillæ having the inner plate devoid of plumose setæ, and the second joint of the palp without apical spine-teeth.

Maxillipeds with the inner and outer plates long, apically narrowed, the outer plates extending far along the third joint of the palp, without teeth or nodules on the inner margin; palp narrow, second joint very long.

Second Uropods with the inner branch incised.

Telson little cleft.

Remarks.—From Boeck's *Socarnes* (see Note on Boeck, 1870, p. 397) the present genus differs chiefly in the apically narrowed plates, both outer and inner, of the maxillipeds, and the smooth inner margin of their inner plates, as well as in the absence of setæ from the inner plates and of teeth from the palms of the first maxillæ.

Socarnoides kergueleni, n. sp. (Pl. XXV.).

A compact species with all the side-plates and the coxae of the last three pairs of peræopods well developed, but the terminal joints of the legs and the uropods of small size. Scattered hairs rise along the back from the head, the peræon and the three large anterior segments of the pleon. Rostrum obsolete; lateral angles of the head rounded, projecting. Third segment of pleon with lower hinder angles rounded.

Eyes large, reniform; crystal cones short, some sixty or seventy in number.

Upper Antennæ.—First joint tumid, longer than the two following joints of peduncle combined, carrying several feathered eilia on the convex upper margin; third joint scarcely if at all shorter than second, both narrowing distally; flagellum of eight joints, first shorter and much thinner than third joint of peduncle, as long as three that follow, but these and the remaining joints are quite small. They carry filamentary cylinders and cilia. The slender secondary flagellum of four joints is nearly as long as the first four joints of the primary, its first joint shorter than that of the primary, and its fourth joint minute.

Lower Antennæ.—Slender, first three joints very short, the fourth a little widened distally, as long as the fifth of the peduncle and the first of the flagellum together; flagellum tapering, consisting of seven joints, the first as long as the second and third united; the seventh minute.

Epistome prominent, the lower part drawn down into a sharp point in front of the furred and rounded distal border of the *Upper Lip*.

Mandibles narrow and elongated; cutting edge with a small tooth at the top; secondary plate of the left mandible linear, perhaps distally dentate; spine-row of three short curved spines; molar tubercle little prominent, with no show of teeth but bordered with short cilia. The articular condyle projects forward above the space between the spine-row and the molar tubercle. The palp is shorter than the trunk of the mandible, inserted far behind the molar tubercle; the first joint short, the third curved, shorter than the second; there are two small setæ at the apex of the third, and two near the distal end of the second. The third joint of the palp was accidentally missing in the specimen from which the figures *m.m.* were drawn.

Lower Lip prominently ciliated round the free borders except on the narrow mandibular processes, which have but few eilia. The eilia are crowded on the narrow distal portion of the front lobes; centrally these latter are wider in proportion than represented in the figure, the delicate texture and the structure of the organ making it difficult to flatten it out for drawing under the microscope. It should be remembered that the lips and maxillipeds *in situ* are often far from being the flattened objects to which it is necessary to reduce them in mounted preparations for drawing the details under high powers.

First Maxillæ.—Inner plate slender, distal portion ciliated; outer plate carrying distally seven thick dentate spines, the innermost having eight (and sometimes more) teeth on its edge besides the apical one; four other spines, much more slender, of varying length, and but little dentate, are ranged on the side of the plate; the surface of the plate is ciliated near the spines; the enlarged figure shows the growth of the new spines within the plate, in which it will be observed that the innermost spine above mentioned faces in the opposite direction to that which it has when set free. The palp is a thin broad plate set upon a very short first joint; the basal is much broader than the distal half, which is bluntly pointed, and has slight serrations round the apex.

Second Maxillæ.—Inner plate a little shorter than the outer, ciliated on the inner border, a row of seven or eight serrate spines at and near the apex. Outer plate ciliated, apically armed with setæ and spines; the spines more or less serrate distally with curved tips, one conspicuously longer than the rest, not serrate, a little clubbed at the end.

Maxillipeds.—Inner plates reaching as far as the distal end of the second joint of palp, tapering almost to a point, with one little spine-tooth on the inner side of the apex, and one or two similar teeth and some small setæ on the distally serrate outer margin. Outer plate large, reaching far along the third joint of the palp or beyond it, the apex obtusely pointed, the inner margin with a solitary seta. There is an appearance of canals within the substance of the plate radiating towards the outer margin and distal part of the inner margin, the margin itself being microscopically indented in correspondence with the ends of these canals. First joint of palp with a seta at the distal end of its very short inner margin; second joint with its inner border twice as long as the outer border of the first joint, having three long and one or two short setæ at and near the distal end; third joint longer than first, longer and less dilated than shown in the foreshortened figure, borders naked except distally; fourth joint small, tapering, second half narrowed somewhat suddenly, ending in a short sharp nail with a cilium on each side of it.

First Gnathopods.—Side-plates broad, with a few cilia on the surface near the front and lower margins, and a small notch near the distal end of the hind margin. First joint a little curved, widened distally, having five setæ on the front border; second joint with five on the hind margin, two of them very short; third joint triangular, hinder part a little furred, with a group of setæ distally; wrist (not furred as it is in *Lysianassa kidderi*, S. I. Smith), subequal in length to the hand, but stouter, with distally a small group of setæ in front and a large one behind; hand tapering, having in front some slight setæ, and a row of six behind along the inner side of the margin, with three longer and two short ones on the outer side of it. Most of these setæ narrow a little abruptly near the middle as if two-jointed. The finger short, with a curved nail, set on the extremity of the hand so as to leave no palm.

Second Gnathopods.—Side-plates narrower than those of first segment, ciliated and

notched in the same way, outer margin convex, hinder nearly straight. Branchial vesicle with a fold near the base. First joint a little curved, slightly dilated distally, with one or two fine setæ on the antero-distal part of the margin; second joint much longer than third, with the lower half of hinder part furred, and one terminal seta; third joint short, shaped like a pipe-bowl, furred behind, carrying one or two setæ; wrist equal in length to second joint, considerably longer than the hand, thickly furred nearly all over; hand longer than broad, densely furred, hinder margin running out into a small thumb beset with short spines; close to the thumb is set the short finger, thick at the base, the much-curved nail over-arching the thumb. Between the front margin of the hand and the finger is a bunch of straight spines, greatly varying in length, with curved tips.

First Peræopods.—Side-plates like those of the second segment. Two setæ on hind border of second joint; third joint longer and much wider than the fourth joint or the fifth, with one seta on the outdrawn antero-distal angle, and four on the hind margin; fourth joint wider but shorter than fifth, with four setæ on the hind margin; fifth joint narrow, with four short setæ on the hind margin and a spine at the junction with the finger, a cilium in front not one-third of the margin's length from the end, a bunch of cilia at the end; finger curved, with the usual cilium near the beginning of the front margin.

Second Peræopods.—Side-plates broad, excavated behind. The leg not materially differing from the preceding.

Third Peræopods.—Side-plates broad, front margin very convex, front lobe descending decidedly below the hinder one; first joint very large, very convex in front, widest above; front margin carrying two spines in the upper part, in the lower serrate part spines and setæ alternating; hinder margin notched, with cilia in the notches; the short second joint is overlapped by the hinder lobe of the first joint; the third joint is shorter than the fifth, distended in the middle, having three setæ on the front margin, and two spines on the hinder one; fourth joint shorter than third, with one or two spines and setæ; fifth joint slender, with three pairs of spines on the front border, the hinder margin and finger as in the first peræopods.

Fourth Peræopods.—First joint much longer and a little wider than that of the third peræopods; its third joint on a larger scale, longer than the fifth joint, the armature of the joints in general similar to that of the preceding and following pairs of legs.

Fifth Peræopods.—First joint a very irregular oval, much longer and considerably wider than the first joint of the fourth peræopods, the third joint less developed than in that limb; on the hinder margin of the third joint a row of three spines, on the outdrawn apex two and a seta.

Pleopods.—Eight to ten articulations compose the rami; there are ten plumose setæ on the dilated basal joint of the outer ramus.

Uropods.—Peduncle of first pair rather longer than the rami, outer ramus rather

longer than inner, the latter with one spine, the former with three spines on the margin; second pair shorter than first, peduncle a little longer than rami, rami subequal, outer with four spines on the margin, inner with a small one before the middle and a larger one some way beyond the middle of the margin, at a point where the ramus is deeply notched and narrowed, as in species of *Ichnopus* and some other genera. Third pair shorter than second, peduncle drawn out to a spine-tipped point on the inner side; outer ramus longer than inner, with a nail bearing an accessory thread near the tip on the outer side; adjoining the nail on the inner side is a spine with an accessory thread on the inner side. The inner ramus has a cilium on the inner margin near the base, and one in a small slit in its sharp apex. In the smaller specimen the details of spines and cilia showed some variation; for example, in the second uropods the outer ramus had two spines instead of four, the inner had one instead of two.

Telson small, reaching beyond the drawn-out sides of the sixth pleon-segment, narrowing distally, carrying near the border on each side, beyond the middle, a long and a short plumose cilium; a little beyond these the slit begins, each terminal triangle having in its blunt apex a cilium and a spine with an accessory thread rising nearer the base of the spine than its apex.

Length of larger specimen, with tail folded in and antennæ bent down, less than a quarter of an inch.

Locality.—Station 149E, Greenland Harbour, Kerguelen, January 21, 1874; depth, 30 fathoms; bottom, volcanic mud. Two specimens. Dredged.

Station 149H, off Cumberland Bay, Kerguelen, January 29, 1874; depth, 127 fathoms; bottom, volcanic mud. One specimen. Dredged.

Remarks.—Through the kindness of Professor S. I. Smith, I have had the opportunity of comparing this species with a specimen of *Lysianassa kidderi*, to which it shows some resemblance, but the differences are very decisive. In that species the outer plate of the maxillipeds is rounded; in the first gnathopods the first joint is not bent; in the second gnathopods the wrist is not so long as in the present species; the side-plates in the fourth segment, and the first joints of the last three pairs of pereiopods, all differ strikingly; the telson is slightly excavated, not flat.

Genus *Ambasia*, A. Boeck, 1870.

For the original definition of this genus, see Note on Boeck, 1870 (p. 397). To include the species here described, it must be modified by omitting the epithet "minima" from the description of the inner plate of the first pair of maxillæ, and the epithet "fissa" from the description of the telson.

Ambasia integricauda, n. sp. (Pl. XXVI.).

This minute species externally, except in colour, so much resembled *Socarnoides kergueleni*, that the single specimen was dissected before the differences were appreciated, hence no whole figure could be given, and the line in the plate indicating the natural size is an estimate instead of a measurement. The specimen was a female with eggs.

There are some small scattered hairs on the back. The hinder lateral angle is rounded in each of the first three segments of the pleon, rather sharply so in the third, which has the lower half of the lateral margin outdrawn; the fourth segment without any dorsal saddle-shaped depression.

Eyes present; shape not observed.

Upper Antennæ tapering, first joint long and stout, with a few fine scattered hairs, second joint half the length of first, third not much shorter than second, flagellum of five joints together shorter than first joint of peduncle. To these joints are attached cylindrical appendages, most of which surpass in length the whole flagellum. In the slender two-jointed secondary flagellum the first joint is slightly longer than the first joint of the primary, the second shorter than the second of the same, tipped with fine hairs.

Lower Antennæ.—The opening of the coiled gland not conical; the third joint as long as the fourth; the latter a little curved and rather longer than the fifth; the whole peduncle slender, not tapering; the flagellum of four joints, the last one minute; there are long tapering setæ on the three last joints both of the peduncle and of the flagellum.

Mandibles broad at the base, narrowing to a neck in advance of the cutting edge. The cutting edge is convex, rounded below, with a slightly prominent angle or tooth above. Behind this angle a sort of dentation or wrinkling appears; the secondary plate of the left mandible rather broad, with a convex front edge. In the Plate the outer surfaces of the mandibles are shown, so that the left mandible is represented by the figure *m* on the right hand; the true shape of its cutting-edge and secondary plate will be best discerned in the interior of the figure, which shows the new mandible in preparation for appearance after the next skin-shedding. The spine-row consists of three very short serrate spines. The palp has the first joint unusually long, subequal in length to the third; the margins are naked, the second joint has a small spine or seta close to the distal end, the third joint is tipped with two setæ of about its own length, and has on the side the fine appressed hairs usual in this joint.

Lower Lip.—Mandibular processes elongate.

First Maxillæ.—Inner plate broad, distally rounded, with one short hair-like seta at the inner distal angle; outer plate rather broad, distally edged with a row of seven variously denticulate spines, the outer ones stoutest and least denticulate, and a row of four smaller spines, scarcely denticulate; palp with first joint short, second long, over-

topping the outer plate, tipped with four short slightly sinuous spines, and having its inner margin and sides hairy. The figure shows the growth of the new inner and outer plates within the old ones.

Second Maxilla.—Outer plate a little broader than inner and a little overtopping it, distally tipped with seven or eight weak spines a little curved, and about the same number of shorter straight ones. The distal end of the inner plate bordered with six or seven weak spines, the row ending up with a seta on the inner margin. Fine hairs project along the major part of the otherwise smooth inner margin.

Maxillipeds.—Inner plates long, narrow, with outer margin slightly bowed, reaching beyond the first joint of the palp; distal margin indented, and perhaps armed with three small teeth, a few small setæ on the inner distal and near the distal margin; outer plates very large, broad, the rounded distal edges reaching halfway along the third joint of the palp; inner and distal margins faintly crenulated, quite naked, though within the border there is a show of preparation for spines or setæ; some way within the inner and not very far from the distal border there is one spinule. Palp with first joint broadest, outer edge much longer than inner, the latter carrying distally one seta; second joint with outer edge shorter than inner, the latter fringed with ten or eleven setæ; third joint narrow, with five setæ, three on distal half of inner margin; fourth joint very small, divided between nail and finger.

The little *triturating organs* show on each of the pair a row of from nine to ten serrate spines.

First Gnathopods.—Side-plate irregularly triangular, with some short hairs within the broad distal border and a noteh at the posterior distal angle. First joint a little widened distally, two short hairs on front margin; hinder part of the short second and third joints furred with short hairs, wrist and hand subequal in length, wrist a little widened distally, front margin curved, two or three setæ at infero-posterior angle; hand tapering, setæ on or near hinder margin few and short, no noticeable palm; finger short.

Second Gnathopods.—Side-plates less widened below than those of the first segment so as to form more of a parallelogram than a triangle, otherwise similar; first joint narrow, with one seta on the front margin; second joint longer than third; third shaped like the bowl of a pipe; wrist longer than hand, a brush of fine hairs on the hinder side followed by one seta near the distal end; hand furred almost all over, hinder margin longer than front, running out into a small thumb, close to which is placed the finger with a broad base and a narrow terminal hook beset with short eilia. The sloping distal margin of the hand in front of the finger carries four large spines graduated in length from before backwards, all with terminal accessory threads; other less powerful spines are set more on the side of the hand, and the hinder border is fringed with tooth-like spines.

First Peræopods.—Side-plates like those of the second segment; they fully cover the

first two joints of the leg; third joint longer than fourth, shorter than fifth, wider than either, a little outdrawn antero-distally, with three longer and two shorter setæ on the hind margin; fourth and fifth joints slender, with few setæ, and one spinule at the postero-distal angle of the fifth joint; finger long and curved.

Second Peræopods.—Side-plates deeply excavate behind, deeper than their greatest breadth; branchiæ on this pair, no doubt accidentally, very small.

Third Peræopods.—Side-plate much larger than first joint of leg, only slightly bilobed, hinder much less curved than anterior margin; first joint subcircular, some cilia on lower part of anterior margin; second and third joints both considerably shorter than in the two preceding pairs.

Fourth Peræopods.—Side-plate squarish, smaller than first joint; the latter ovoid, infero-posteriorly produced, ciliated in front; the third joint wider, not longer than in the preceding pair.

Fifth Peræopods.—Side-plates smaller than the preceding pair, having like them a minute infero-posterior notch; first joint much broader and longer than in the preceding pair, front margin naked except at the lower angle, hinder margin irregularly rounded, crenulate, produced below. The two next joints as in the preceding pair. The fourth, fifth, and sixth joints were missing from the last four pairs of peræopods.

Pleopods.—These are rather peculiar in structure. The broad peduncle carries two branches very differently shaped; the outer branch has its first joint nearly as long as the peduncle, very broad near the base, ciliated on the outer edge round the broadest part, and with six plumose bristles along the lower part, increasing in length as they approach the short second joint; the third joint is narrower than the second; the fourth, much narrower and shorter than the third, concludes the series. They are furnished with the usual long plumose setæ. The inner branch has the first joint long and narrow, together with the short second joint equaling the length of the first joint of the outer branch, like which it has a third and fourth joint but no more; in the third pair the second joint is coalesced with the first. The two coupling spines are very small and slender and appear to be quite straight. A single short bent spine at the distal end of the first joint of the inner ramus seems to be the representative of the eleventh spines.

Uropods.—The first pair have the peduncle equal in length to the outer ramus; the inner ramus is a little shorter. On the peduncle there are three spines with accessory threads near the tips; there is one on the outer and probably also one on the inner ramus. The second pair are shorter than the first; the peduncle subequal in length to the outer ramus, which is rather longer than the inner; each ramus has one spine and the inner edge finely pectinate. The third pair is much shorter than the second, the outer ramus longer than the inner, and about as long as the peduncle, with a terminal nail so large as almost to look like a second joint. On the inner ramus there is a cilium near the base. The edges of both rami are like those of the second pair.

Telson.—Broad at base, tapering to a rounded end, without suture or emargination; on either side of the apex there is a long cilium, and a very short one on either side higher up.

Length less than three-twentieths of an inch.

Locality.—Station 149D, Royal Sound, Kerguelen, January 20, 1874; depth, 28 fathoms; bottom, volcanic mud. One specimen.

Remarks.—The colour of the specimen in spirit was greyish. The Challenger species differs from Boeck's *Ambasia danielssenii* by having the inner plate of the first maxillæ moderately large, the first joint of the flagellum of the upper antennæ but little longer than the second, the fourth pleon-segment without a dorsal depression, and the telson not cleft. The specific name *integricauda* is intended to call attention to this last-mentioned circumstance.

Genus *Amaryllis*, Haswell, 1880.

1880. *Amaryllis*, Haswell, On Australian Amphipoda, Proc. Linn. Soc. N.S.W., vol. iv. p. 253.

1882. *Amaryllis*, Haswell, Catalogue of the Australian Stalk and Sessile-eyed Crustacea, p. 227.

Mr. Haswell's definition is as follows:—

“Superior antennæ with a well-developed appendage. Mandibles with a palp. Maxillipedes with well-developed squamiform plates. Anterior gnathopoda subpediform. Posterior gnathopoda imperfectly subchelate. Rami of the fourth and fifth pleopoda styliform; those of sixth pair broad, lanceolate. Telson squamiform, cleft.”

He places it in the subfamily Stegocephalides of the British Museum Catalogue, the definition of which he gives in Spence Bate's words:—

“Superior and inferior antennæ subequal. Coxæ of the second pair of gnathopoda and of the first and second pairs of perciopoda monstrously developed; second pair broader than the preceding. Pereiopoda subequal. Last three pairs of pleopoda styliform. Telson single.”

From the Stegocephalides of Spence Bate, however, *Amaryllis* differs in having only the coxæ or side-plates of the second peræopods monstrously developed, and in having a well-developed secondary appendage on the upper antennæ, while the genera assigned to the Stegocephalides have none or only a rudimentary one.

From the Stegocephalinæ of Boeck *Amaryllis* is separated by having a three-jointed palp on the mandibles and by not having a palp on the first maxillæ, as well as by other characters. It can better stand among the Lysianassidæ. In the definition which Boeck gives of his subfamily Lysianassinae, it will be necessary, with a view to this genus, and in a less degree with a view to Boeck's own genus *Aristias*, to prefix the word *plerumque* to the epithet *perparvo* applied to the second and third joints of the peduncle of the

upper antennæ. In regard to the first joint of the flagellum of the upper antennæ, *Amaryllis* must stand as an exception within the family.

To suit the transfer of the genus to a different family, the following new definition is proposed :—

Upper Antennæ, contrary to the general character of the family, having the second joint of the peduncle not very short, and the first of the flagellum not very long, devoid of a conspicuous brush.

Mandibles.—The spine-row containing many spines; the molar tubercle ciliated, not dentate; the palp set behind the middle of the trunk.

First Maxillæ.—The inner plate carrying two plumose setæ; palp wanting.

Maxillipeds.—The inner plates reaching beyond the first joint of the palp; the outer plates large, without spine-teeth; the fourth joint of the palp small, obtuse, without a nail.

First Gnathopods, not subchelate.

Side-plates of the fourth pereon-segment greatly developed.

Telson eleft.

Amaryllis bathycephalus, n. sp. (Pl. XXVII.).

Head very deep, rostrum minute, the sides of the head scarcely outdrawn in a flattened lobe between the upper and lower antennæ, this sinuous portion being marked off from the lower part by a small incision; the last two segments of the pereon deeper than those preceding them; the first three segments of the pleon with the postero-lateral angles acute, in the third segment abruptly upturned so as to leave a little poeket low down in the hinder margin of the segment; the dorsal depression of the fourth segment very shallow.

Eyes large, inversely lageniform, being larger above than below, the ocelli small.

Upper Antennæ.—First joint cylindrical, more than twiee as long as broad, equalling in length the two following joints of the peduncle added to the first of the flagellum; the seond joint rather longer than the third, the third longer than the first of the flagellum; the flagellum of ten or eleven joints successively decreasing in thickness, all provided with long cylinders, the first joint not longer than the second; the secondary flagellum of three joints equalling in length the first three of the primary.

Lower Antennæ shorter than the upper, the peduncle rather longer than that of the upper antennæ; first joint strongly lobed below, gland-eone slight but prominent, third joint short, fourth rather longer and thicker than fifth, equalling in length the first three of the flagellum; flagellum slender, of nine joints, of which the first is the longest.

Mandibles.—Cutting edge very slightly convex, with a tooth above and another below; secondary plate of the left mandible widened distally and divided into five or six not very prominent teeth; spine-row of several short spines set among eilia; molar tuberele weak,

armed apparently only with cilia, many of which are directed backwards; palp set some way back, over the backward-turned molar tubercle; first joint short, second without spines (in our specimen), third short, together with the first not equalling the length of the second, with four or five spines on or close to the apex, and many adpressed cilia on its surface; there is a small raised process of the trunk midway between the palp and the cutting edge.

Lower Lip with the cilia on the apex of the forward lobes almost spiniform; a small projecting lobe on the inner margin a little below the apex.

First Maxillæ.—Inner plate short, an irregular oval, with two short, unequal, plumose setæ on the inner side of the rounded apex; outer plate long, with some cilia-like spines just below the apical margin, the dentate spines strong, no doubt eleven in number, but so crowded together that they cannot easily be counted; the lowest and innermost spine with four or five lateral teeth, that represented in the Plate with only one being no doubt accidentally broken; the next spine to this in the lower row has eleven small lateral teeth, the others fewer. I have not been able to find any trace of a palp, unless a little fold of the outer margin of the outer plate may point to a lost inheritance.

Second Maxillæ.—The outer plate longer than the inner, and rather broader, both narrowing distally, the spines of the outer plate descending further along the inner border than those of the inner plate; the outer plate also with three or four small feathered spines descending its outer margin.

Maxillipeds.—Inner prismatic plates extending much beyond the first joint of the palp, the upper part of the inner margin strongly furred with cilia which pass over to the outer corner of the apex; apical margin undulating into three prominences, the most advanced being the inner one, each having a spine-tooth which in our specimen does not project beyond the margin; a small spine is on the outer margin just below the apex; the outer plates of thin texture, broad, apically rounded, extending beyond the second joint of the palp, seemingly unarmed except for fine hairs on the surface and for cilia-like spines within the inner margin, not reaching beyond it; first joint of the palp short, with a seta at the apex on each side, second joint longer than first, but itself rather short, with half a dozen setæ on the inner margin; third joint longer than the first, with a few setæ at and near the apex; finger somewhat conical, very short, without a nail, at the apex carrying two long setæ.

First Gnathopods.—Side-plates small, triangular, much overlapped by those of the second segment, not reaching down to the lower part of the head or base of the lower antennæ. First joint of the limb attached low down on the side-plate, beyond which it projects far, narrow, longer than the third, fourth, and fifth joints united, with very short setæ at intervals on the front margin; second joint longer than the third, not quite so long as the fourth; the third triangular, with the point downwards; the wrist more or less triangular, with the point upwards; there are pectinate spines on the hind margin of

this and the two preceding joints ; the hand considerably longer than the wrist, tapering distally so as to have no palm, almost the whole of the hinder margin pectinate, with setæ at intervals, and a few pectinate spines on the side ; finger short, curved, with a dorsal cilium near the hinge, one on the inner margin, and one or two at the nail.

Second Gnathopods.—Side-plates small and narrow, longer than those of the first segment. First joint narrow, a little bent back distally, about equal in length to the wrist and hand united ; second joint longer than the third, shorter than the hand ; third joint with a solitary cilia-like spine near the pointed apex ; wrist longer than the hand, with the hind margin straight, furred, and carrying some pectinate spines, chiefly at the lower end, the front margin nearly parallel with it, smooth ; the hand long, dilating gradually towards the palm, wider than the wrist, furred on the hinder margin, with groups of pectinate spines on the lower part of it ; the palm oblique, slightly sinuous, with a row of three short stout spines near the angle on one side and one or two more on the other, cilia along its course, and some minute pectination ; the small, curved finger, hinged very near the front margin amid over-arching pectinate spines, does not nearly reach the end of the palm ; its dorsal cilium is very long.

First Peraopods.—Side-plates narrow, oblong, with a distally narrowed termination, a little longer than those of the preceding segment. First joint shorter than the side-plate, its front margin straight, the hind convex, with very short setæ at intervals ; third joint broader than fourth, equal in length, scarcely decurrent ; fourth joint shorter than the fifth, with three spines along the hind margin ; fifth joint with the hind margin straight, front convex, armed only with some minute cilia ; finger straight to the sharp, slightly curved tip ; dorsal cilium close to the hinge, very small.

Second Peraopods.—Side-plates greatly developed, the front margin straight, extending forward below the head, the side-plates of the three previous segments forming a triangle, the apex of which is shut in below by the lower angle of the head on one side and the fourth side-plate on the other ; its lower margin is curved, and the curve is continued so as to form a large rounded lobe behind, where the excavation causes the upper part of the side-plate to be not more than one-third the width of the lower part ; there are minute cilia set round the edge and on some other parts ; the joints of the limb are similar to those of the preceding pair, but the fourth and fifth joints are here a little shorter.

Third Peraopods.—The side-plates with the hinder lobe produced much below the front one ; the first joint with the front margin nearly straight and armed with a few small spines, the hinder margin sinuous, running out into a smooth-edged, rounded, backward-directed lobe, so as to be much broader below than above ; second joint overlapped behind by the lobe just mentioned ; the third joint very much broader than the fourth, decurrent, spined on both borders ; fourth joint shorter than the hand, spined on the front margin, largely overlapped behind by the decurrent part of the third joint ;

hand with some small spines on the front margin, this joint and the finger very similar to these in the two preceding pairs.

Fourth Peraopods.—Side-plates small, somewhat produced downwards behind. First joint a broad oval, the lower lobe behind overlapping the second joint, the front margin with strong spines except at the upper part, the hinder margin not strongly serrate; the third joint broad, decurrent, spined on both margins; the rest of the limb missing.

Fifth Peraopods.—The first joint broader and longer than that of the preceding pair, front margin spined, hinder serrate, with its broadly rounded lower lobe produced beyond the second joint; third joint narrower than in the two preceding pairs; in other respects the joints similar to those of the third peraeopods.

Pleopods.—There are some slender spines on the margins of the peduncles; the coupling spines are slender, with two lateral retroverted teeth and the apices acute, little bent; there are two cleft spines in the second pair, only one in the third pair; the arms of the cleft are nearly equal, apparently neither of them having a spoon-shaped termination; the joints of the rami number from eight to eleven.

Uropods.—The peduncles of the first pair longer than the rami; the rami stiliform, with few marginal spines, the outer ramus longer than the inner; peduncles of the second pair about equal to the rami, inner ramus longer than the outer, projecting beyond the rami of the third pair; peduncles of the third pair shorter than the rami, which are subequal, not very broadly lanceolate, with three marginal spines on the outer side of the outer ramus.

Telson not reaching nearly to the end of the peduncles of the third uropods, longer than broad, eleft scarcely beyond the centre, not dehiscent, with convex sides narrowing distally, the apices rounded.

Length.—The specimen, in the position figured, measured from the rostrum to the back of third pleon-segment a little over one-fifth of an inch.

Locality.—Station 161, off Melbourne, April 1, 1874; depth, 33 fathoms; bottom, sand. One specimen. Trawled.

Remarks.—The specific name, from *βαθύς*, deep, and *κεφαλή*, a head, refers to the very conspicuous depth of the head in this species.

Through the kindness of Mr. W. A. Haswell I have had an opportunity of comparing the present species with a specimen of his *Amaryllis brevicornis*, which he distinguishes from his *Amaryllis macrophthalmus* only by the greater shortness of the antennæ. The specimen he sent me was a female with young, and there can be in my opinion no doubt that *brevicornis* should be entered as a synonym of *macrophthalmus*. From this the Challenger species differs, not only in having much less numerously jointed flagella to the antennæ, the secondary of the upper having three joints instead of thirteen (in the

specimen sent me by Mr. Haswell), but also in several details of the mouth-organs, and in having a shorter wrist to the first gnathopods, the hand of the second more expanded distally, the side-plates of the fourth peraeon-segment rounded behind instead of squared, those of the fifth segment more and more narrowly produced downwards behind, and the first joint of the third pereopods pear-shaped, being narrow above and postero-distally expanded.

Amaryllis haswelli, n. sp. (Pl. XXVIII.).

Head similar to that of *Amaryllis bathycephalus*, with a rather stronger rostrum, the whole animal of rather narrower habit than that species; postero-lateral angles of the third pleon-segment acute, not upturned, the hinder margin bulging a little beyond the point and so forming a little pocket, which occurs in all the three species of the genus at present known.

Eyes probably present, but not clearly observed.

Upper Antennæ.—The first joint of the peduncle elongate, with a depression above near the base, distally prolonged on the inner side into a tooth more than half the length of the following joint; the second joint shorter and much thinner than the first, about three times as long as the third, having a short distal tooth; third a little longer than the first joint of the twenty-four-jointed flagellum, the joints of which carry not very conspicuous cylinders; the secondary flagellum of four slender joints, the first two together scarcely exceeding in length the first of the primary.

Lower Antennæ.—The first joint very much outdrawn below, the gland-cone small, the third joint short; the fourth joint nearly twice as long as the fifth, as long as the first of the upper antennæ without the tooth; the fifth joint rather longer than the first four of the twenty-two joints of the flagellum.

Triturating Organs.—These present a row of a few spine-teeth, short, stout, serrate on both margins, followed by a row of similar spines, but more numerous and rather longer and thinner, beyond these again a close-set fringe of bristles appearing.

Mandibles.—The cutting edge slightly convex, with a small tooth at the top, the secondary plate of the left mandible with the distal edge obscurely dentate; the spine-row as in the preceding species consisting of numerous spines among cilia; that some of the ten spines were slender and others stumpy was probably due to the more worn condition of the latter; molar tubercle weak, directed backwards, set only with cilia; the articular condyle advanced over the spine-row; the palp set rather far back over the molar tubercle, the long second joint without spines; the third joint, together with the first not quite equalling the length of the second, having nine spines along the upper part of the inner margin, one at the apex very large, and adpressed cilia as usual on the surface. In the Plate the outside of the left mandible is represented in the lower

figure *m*, so that the secondary plate, spine-row, and molar tubercle are not in view except so far as their position may be gathered through the partial transparency of the mandible.

Lower Lip.—The forward lobes strongly ciliated on the apical and inner margins, scarcely dehiscent; the mandibular processes long, narrow, curving outwards.

First Maxillæ.—Inner plate small, with two unequal plumose setæ on the apex; the outer plate also closely resembling that in *Amaryllis bathycephalus*, with eleven strong, variously dentate spines at the distal end, and a small fold of the outer margin near the base.

Second Maxillæ scarcely differing from those of *Amaryllis bathycephalus*, the outer plate less narrowed apically than the inner.

Maxillipeds.—Similar to those of the species just mentioned, but differing in having the inner plates rather shorter and broader, with the apical margin less oblique, and in having the apical margin of the outer plates less evenly rounded. The fourth joint of the palp is narrow, its obtuse apex carrying two setæ; it is not quite so small as in the two companion species.

First Gnathopods.—Side-plates small, more than half concealed by those of the next segment, the length and breadth equal, the front and lower margins rounded, the hinder straight, the first joint attached at the lower hinder extremity, greater in breadth throughout than any other joint, and nearly or quite equalling the united length of the four following; numerous setæ on the sinuous front margin, a few on the straight hind margin, which has a long tuft at the end; the second joint widened below, as long as the third; the third pointed below; the wrist longer than the long tapering hand, carrying on its hinder margin several groups of spiniform setæ such as occur in smaller numbers on the two previous joints; the hand is strongly pectinate along the hind border, where it also has spines and setæ; there are also groups of setæ along the surface, besides some small ones on the front border; there is no palm; the small curved finger has a tooth lying along the inner edge near the nail; it has also a dorsal cilium near the hinge, and one or two cilia on the inner margin.

Second Gnathopods.—Side-plates more than twice as long as those of the preceding segment, the back border angled below the centre, the lower border a little serrate and crenulate, not ragged as in the figure *gn. 2*. The branchial vesicles from a narrow neck expanding at once to the greatest breadth, thence narrow gently downwards, and are as long as the first joint of the limb. The marsupial plates narrow, with small cilia on the front margin; on the hind margin and apex no setæ were present in our specimen, but the points of attachment indicated that they either had been or were to be. The first joint of the limb not so long as wrist and hand united, attached just above the angle of the hind margin of the side-plate, below bending a little backwards; the second joint longer than the third; the third ending in a long triangle with three or four cilia-like setæ on the hind margin; the wrist very long and narrow, nearly twice as long as the

hand, the hind margin densely furred for most of its length, the setæ few, some long ones at the apex; the hand long and narrow, furred densely along the hind margin; with several spine-like setæ on the lower part; on the lower part of the front margin some very long spines, besides smaller ones, over-arching the small much-curved finger, which nearly covers the narrow apical or palm margin of the hand.

First Peræopods.—Side-plates oblong, narrow, reaching over the lower front angle of the head, the lower border serrate at each end and slightly crenate in the middle. The marsupial plates longer than the first joint of the limb, distally bent. The first joint long and narrow, reaching beyond the side-plate; the third joint not so long as the fourth or fifth, with five groups of setæ on the hinder, and two or three on the front margin; the fourth and fifth joints equal in length, both carrying setæ and spines, the fifth having a row of eight spines on the hind margin; the finger short, worn at the tip.

Second Peræopods.—Side-plates very broad, except at the excavation, which does not extend far down, the front margin straight, and so also the hind margin below the excavation, the front and hind margins slightly diverging downwards; the first joint not reaching beyond the side-plate, the third, fourth, and fifth joints subequal; the limb in general like that of the preceding segment.

Third Peræopods.—The side-plates much wider than the first joint of the limb, the back lobe produced considerably below the front one. The first joint scarcely longer than broad, front margin a little convex, with spines at six points, the hind margin irregular, not much serrate, producing the greatest width two-thirds of the way down, then with an oblique curve reaching but not overlapping the second joint; the third joint somewhat decurrent, longer and much broader than the following joint, with spines at five points in front and three behind; the fourth joint shorter than the fifth and scarcely broader, with spines at four points in front; the fifth joint somewhat longer than the third, with spines at seven points in front; finger not a third of the length of the preceding joint, with a rounded end as if worn by use.

Fourth Peræopods.—Side-plates broader below than above, with the angles behind rounded, but squarish in general appearance. Branchial vesicles of the general form of an oval, bent very much forwards and in front, at the neck having an accessory vesicle attached, of something the same shape, on a very much smaller scale. The first joint is oblong, with a rounded lower margin just overlapping the short second joint, the front margin spined, the hind margin irregularly serrate; the lower joints of the limb missing.

Fifth Peræopods.—The side-plates with the hind margin more convex than in the preceding segment. Branchial vesicles small, looking like a wide flask, narrow-mouthed, attached by its handle. The first joint similar to that of the preceding pair, but larger, and with the lower margin squared and roughly serrate, the third joint

a little decurrent, with four groups of spines on each margin; the remaining joints as in the third pair, but they are now missing.

Pleopods.—Peduncles with a few setæ or slender spines on the peduncles; no coupling spines perceived; the eleventh spines of the inner ramus four in number; the joints of the rami about sixteen to eighteen in number.

Uropods.—The peduncles of the first pair somewhat longer than the stiliform rami; the peduncles of the second pair shorter than the lower ramus, which stands a little within the shorter upper ramus; the latter is bordered with eight strong spines, the former has half a dozen on its inner edge, and below these a longer one on a rounded point, below which the ramus is suddenly constricted, as in *Ichnopus* and various other genera; the peduncles of the third pair shorter than the stiliform, subequal rami, both of which have some spines on the margins.

Telson not reaching the end of the peduncles of the third pair, narrowed below, eleventh a little beyond the centre, a little dehiscent below, especially at the apices, where the inner margins curve a little outwards; cilia on the apices and near the lateral margins some way below the top of the eleventh.

Length of the specimen, seven-fifteenths of an inch.

Locality.—Station 78, off the Azores, July 10, 1873; lat. $37^{\circ} 26' N.$, long. $25^{\circ} 13' W.$; depth, 1000 fathoms; bottom, volcanic mud. One specimen; female. Dredged.

Remarks.—The specific name is given in compliment to Mr. W. A. Haswell, by whom the genus *Amaryllis* was instituted.

From the other two species of the same genus, as well as from all other known species of the Lysianassidae, this is remarkably distinguished by the long second joint of the upper antennæ. The exceptional character of the form gives a sort of guarantee that it was actually obtained from the exceptional depth of 1000 fathoms.

Amaryllis macroura, Haswell, juv. (Pl. XXIX.).

It was not till very long after the Plate had been engraved for this species that I received a specimen of Mr. Haswell's *Amaryllis brevicornis*, which is in my opinion synonymous with his *Amaryllis macroura*. The little specimen now to be described was taken at an enormous distance from Australia, and if no regard be paid to the differences which exist between the young and adults of Amphipoda, as of most other animals, it would be easy to consider it a new species.

The body compact; head deep, reaching to the fourth side-plate, between which and the head the other three side-plates are as it were shut in; the mouth-organs projecting conspicuously; the postero-lateral angles of the third pleon-segment acute, not upturned.

Eyes small.

Upper Antennæ.—First joint scarcely longer than the two following united; flagellum of five joints, together not longer than the peduncle; secondary flagellum of two joints, not so long as the first two of the primary.

Lower Antennæ.—Gland-eone prominent, third joint very short, fourth longer and thicker than fifth; flagellum tapering, of five joints, the first as long as the fifth joint of the peduncle.

Mandibles.—Cutting edge smooth, with a small tooth at the upper corner; secondary plate of the left mandible with the broad apieal margin cut into four or five denticles facing towards the cutting edge; the spine-row of six or seven small spines; the molar tubercle not prominent, directed backwards, a little elevated; the palp set rather far back, just over the molar tubercle, the third joint not much shorter than the second, with conspicuous adpressed eilia, and at the apex three setæ. The shaft of the mandible is rather less slender than it appears in the position represented in the figures *m.m.*

First Maxillæ.—Inner plate oval, only one plumose seta observed on the apex; outer plate seemingly with nine denticulate spines, no palp.

Second Maxillæ.—Inner plate with seven or eight apieal spines or setæ; outer plate rather longer than the inner, similarly furnished.

Maxillipeds.—Inner plates very long, the apieal margin with two little cavities between the three teeth, below which are some spines on the outer margin; outer plates broad and long, one long seta far down on the inner margin, the rest of which is smooth, the apieal margin scarcely erenate; the third joint of the palp nearly equal in length to the second; the fourth minute, without a nail, tipped with two setæ.

First Gnathopods.—The first joint longer than the next three together, the second longer than the third, and as long as the fourth, all these four carrying apieal spines behind; the hand longer than the wrist, tapering distally, with a few setæ on or near the hind margin and apieally in front; the hind margin strongly peetinate, with no palm margin; the finger short, a little curved, with a dorsal eilium near the hinge, and one or two lying along the inner edge by the nail.

Second Gnathopods.—First joint projecting beyond the side-plate, not as long as the wrist and hand together; second joint longer than the third, the wrist longer than the hand, parallel-sided for most of its length, tufted with fur on the hind margin, where also apieally it has some long setæ; hand long, almost parallel-sided, furred behind, with long spines at and near the apex on each margin; palm convex, bordered with minute eilia and defined by two short spines; the finger thick at the base, curving over the palm, with a dorsal eilium and some eilia on the inner edge near the nail.

First Peraopods.—Side-plates oblong, the front margin straight, the hinder a little sinuous and the lower convex; the first joint not reaching the end of the side-plate, the third rather longer than the fourth and shorter than the fifth; the nail curved, more than half the length of the fifth joint.

Second Peræopods.—Side-plates broad, front and hind margins straight, almost parallel, the excavation behind not carried far down; the joints of the limb as in the preceding pair.

Third Peræopods.—Side-plates broader than the first joint, the hinder lobe produced below the front one; first joint irregularly rounded, the front margin being almost straight, with one spine at the lower apex, the rounded lower margin overlapping the second joint, which also has a spine at the apex in front; the third joint broad, decurrent, with spines at two points on each margin; the fourth joint shorter than third or fifth, with spines at the apex; fifth joint longer than third, with spines at two points in front, eilia behind; finger curved, more than half the length of the fifth joint.

Fourth Peræopods.—Side-plates not bilobed. First joint broader than side-plate, with two spines in front, a little serration on the hind margin; the limb resembles in general character that of the preceding segment, but with the various joints rather larger.

Fifth Peræopods.—Side-plate consisting of a single lobe, rounded behind and below, narrowed in front; first joint broader and longer than in the preceding pair, the rest of the limb similar but smaller, the third joint being smaller than the third in the third peræopods, while the remaining joints are rather longer than in that pair.

Pleopods.—In all the pairs two coupling spines with two retroverted hooks, a single eleft spine on the long first joint of the inner ramus, the inner ramus three-jointed, the outer five-jointed.

Uropods.—Peduncles of the first pair but little longer than the rami; lower ramus a little longer than the upper, each with a spine at some distance from the acute, little-curved apex; peduncles of the second pair shorter than the rami; lower ramus with a nail, longer than the upper, each with a spine at some distance from the apex, that on the longer ramus marking the point at which the ramus is abruptly narrowed, a feature belonging, I think, to all the species of this genus; peduncles of the third pair shorter than the rami, lower ramus longer than the upper, with a nail, both finely pectinate on the edges.

Telson projecting beyond the peduncles of the third uropods, eleft a little beyond the centre, carrying a couple of eilia inserted a little above each apex, and a couple also on each side below the level of the top of the eleft.

Length of the specimen, from the front of the head to the end of the third pleon-segment, in the position figured, about one-fifth of an inch.

Locality.—Station 313, off Cape Virgins, Patagonia, January 20, 1876; lat. $52^{\circ} 20'$ S., long. $67^{\circ} 39'$ W.; depth, 55 fathoms; bottom, sand. One specimen. Trawled.

Remarks.—Between this specimen and the much larger adult female from Australia, for which I am indebted to the kindness of Mr. Haswell, the chief differences are in the eyes and antennæ. The eyes in the Australian specimen accord with Mr. Haswell's

description of those in his *Amaryllis macrophthalmus*, in being "vertically elongated, sub-crescentic"; the upper antennæ have seventeen joints to the primary flagellum, and thirteen to the secondary. In Mr. Haswell's own description he assigns to the principal flagellum "about thirty segments," and seven to the secondary; in the form which he calls *Amaryllis brevicornis* he says that the principal flagellum has eighteen joints, and the secondary five. This part would appear, therefore, to be very variable in the species.

Genus *Acontostoma*, n. gen.

Body compact, head scarcely or not at all visible laterally.

Upper Lip with a pointed apex.

Mandibles long and narrow, without molar tubercle; a small three-jointed palp set close to the base.

First Maxillæ with the inner plate small, carrying one seta at the apex, the outer plate with the apical spines set close together, the palp small, not reaching the end of the outer plate.

Second Maxillæ with narrow plates.

Maxillipeds with the shaft strong and bulky, the inner plates with a pointed apex; the outer plates more or less apically angular, without marginal spine-teeth, the palp with its third joint longest, its fourth very small or rudimentary.

First Gnathopods with the hands narrowing apically, not subchelate.

Second Gnathopods with the hand and finger forming a feeble chela.

Uropods short, those of the third pair with no more than a single tuberculiform ramus.

Telson short, whole or emarginate.

The generic name is derived from ἀκόντιον, a dart, στόμα, a mouth, in allusion to the shape of the upper lip, and to point to the connection between this genus and *Acidostoma* of Lilljeborg. Type species, *Acontostoma marionis*.

By Boeck, as well as by Lilljeborg (see Note on Lilljeborg, 1865, p. 362), *Acidostoma* is said to be without palp on the first maxillæ; it has in fact a tubercle to represent this palp, which in *Acontostoma*, though small, is more decidedly in evidence; in the new genus the spines of the outer plate are not abnormal in structure and position as in *Acidostoma*; the palp of the mandibles is short instead of long; in the palp of the maxillipeds the first joint is shorter instead of longer than the second; the third uropods are almost or quite without rami, and the telson, instead of being deeply cleft, is whole, or only a little emarginate.

Acontostoma marionis, n. sp. (Pl. XXX.).

Animal compact, with a remarkably solid integument, opaque, speckled with roundish semi-transparent spots; the head totally concealed in a lateral view, in which the animal

has the appearance of a deep dish-cover; the first peraeon-segment much longer than the second, forming in front a low narrow arch over the antennæ; behind it projects backwards with a rounded lobe beyond its own side-plate; the first three segments of the pleon with a sharp, very slightly elevated, dorsal carina on the distal end of each, the first two with the postero-lateral angles rounded, the third having them squared; the fourth segment with a dorsal depression, the afterpart with an elevated carina produced a little backwards; the two following segments very small.

Eyes comparatively large, oval, with the front margin somewhat flattened, situated near to the slightly convex medio-lateral margin of the head, dark, with the usual light rim.

Upper Antennæ.—First joint large, cylindric, equalling in length the rest of the antenna; second joint almost as long as the flagellum, third narrower and rather shorter than the second; flagellum of seven short joints with stout cylinders, five or six on the first joint, which is not greatly longer than the second; secondary flagellum slender, of two joints, the first about as long as the first of the primary, the second minute.

Lower Antennæ.—The gland-cone very prominent, standing at right angles to the third joint; fourth joint much longer than the fifth, a little curved, and expanding a little distally, some setæ on the side and at the apex; fifth joint not quite so long as the tapering, seven-jointed flagellum.

Upper Lip broad at the base, centrally ridged, narrowing gradually at first, towards the end more abruptly, as if to end in a broadly rounded point; in our specimen the apex shows a serrate emargination, but whether this is normal or due to fracture I cannot say for certain; there is furring within and on either side of the apex, also the inner plate, which does not quite reach the apex of the outer, has its own rounded apex densely furred.

Mandibles very long and narrow and straight; the cutting edge smooth; the secondary plate of the left mandible not perceived, probably very small; spine-row of three or four small spines, followed by a long furry tract of cilia, the only representative of a molar tubercle; above is a projection corresponding apparently to the "articular condyle" of Schiødte, and to the part of the mandible of *Acidostoma obesum* which Lilljeborg, on *Lysianassa magellanica* (pl. v. fig. 56), calls the molar tubercle, but which from its position can scarcely have anything to do with that organ either in origin or function; far to the rear is placed the small three-jointed palp, the base of the mandible being a little dilated behind it; the first joint of the palp comparatively long, with one seta attached near the outer apex; the second joint with two pectinate setæ or spines at the outer apex; the third joint slender, curved, as long as the second, with numerous adpressed cilia, and at the apex two unequal pectinate spines.

Lower Lip strongly ciliated on the forward lobes, which are much narrowed distally; the mandibular processes also ciliated.

First Maxillæ.—Inner plate slender, with one spine-like seta on the apex; outer plate long, straight, apically bordered with eleven (?) dentate spines, the upper and outer very strongly toothed with few teeth, the lowest on the inner margin having nine to eleven lateral denticles; a little brush of cilia below the latter; the palp seemingly one-jointed, rising on the outer margin of the outer plate at a level with the top of the inner plate, and reaching with a smooth pointed apex nearly to the base of the outermost spines of the outer plate.

Second Maxillæ not well observed, both plates probably slender, apically narrowed, the inner rather shorter than the outer.

Maxillipeds.—The shaft large and strong; the inner plates narrowing distally, the outer margin rounded at the shoulder, and the apical running obliquely forwards and forming an elongate tooth on the inner side; two strong acute spines and a cilium are attached to the side of this tooth-like process; the outer plates of solid structure, reaching a long way beyond the inner, the inner margin unarmed but for a seta near the middle, the apex almost acute, the apical region, much of the hind margin, and a tract within the front margin covered with short cilia in regular rows; first joint of the palp small, with some long setæ at the inner apex; second joint shorter than the third, with some setæ on the inner and apical margins; third joint nearly straight, with setæ or spines on both margins, a group of six pairs near the inner apex; the fourth joint very short, its nail consisting of a small oval spine sheltered by a cap which the tip of the fourth joint forms for it; were the palp straightened, the third joint would reach beyond the outer plate.

First Gnathopods.—Side-plates massive, covered with scale-like markings, of nearly oblong shape, with the lower front angle rounded off. First joint not reaching the end of the side-plate, in length about equal to the next four joints, with setæ on its rather sinuous front margin; second joint stout except at the base, as long as the wrist; third joint very short, with five pairs of setæ on the hind margin; wrist shorter than the hand, but broader, fringed with setæ behind, and carrying them at two points in front; the hand long, widest near the base, then tapering slightly, fringed with setæ on the hind margin, groups at three points in front, no palm; the finger half the length of the hand, the nail curved, the inner margin of the finger peculiar in being set with four distinct spines at intervals.

Second Gnathopods.—The side-plates gently curved, long and narrow, furry on the middle part of the hinder margin. The first joint not reaching the end of the side-plate, a little dilated in its lower half, length fully equalling the third, fourth, and fifth joints outstretched together; the second joint longer than the wrist; the third joint short, but much longer than the third of the first pair, lightly furred on the very convex hind margin; the wrist a little longer than the hand, and stouter, furred with scales on both margins, and carrying one or two setæ on the hind apex; the hand elongate, widest

distally, much furred with scales, the hinder part produced beyond the front for the full length of the tiny finger; the apex of the front margin is occupied by a group of short pectinate spines or setæ, beyond which the finger is set and almost lost when closed in its close contact with the projecting part of the hand already mentioned.

First Peræopods.—The side-plates with straight hind margin, otherwise similar to those of the preceding segment, but broader and longer. The first joint attached lower down than in the two preceding pairs, very broad, not nearly reaching the end of the side-plate, carrying one group of setæ at the apex of the convex hinder margin; second joint subequal in length to the fourth; third joint as broad as the first, and not very much shorter, with setæ along the hind margin, and at the apex in front; fourth joint only half as broad, similarly armed; fifth joint much longer than fourth, but shorter than third, with seven spines along the hinder margin, that at the hinge of the finger being the largest, and having a smaller one in its company; the finger stout, with strongly curved nail, together about half the length of the fifth joint.

Second Peræopods.—Side-plates not very much longer or broader than those of preceding segment, excavation behind not wide but carried far down, the hind margin below it being directed slightly forwards, so that the plate is scarcely broader below than at the base. The first joint reaching little below the excavation, the second decidedly longer than the fourth, and with several setæ on the hind margin; the third joint of tolerably even width throughout, not greatly expanded below the base as in the preceding pair, which this in general resembles.

Third Peræopods.—The side-plates rather wider than deep, the front margin more convex than the hinder. The first joint broadly oval, with numerous setæ on the front margin, the hinder very shallowly crenulate, with small cilia in the pits; the second joint overlapped behind by the first, many setæ and half a dozen spines along its front border; the third joint greatly expanded and decurrent, with some twenty spines and a few setæ distributed on the front margin and apex; the hinder expansion is rhomboidal, the lower edge descending below the fourth joint, the hinder margin being serrate, and the apex carrying a spine; the small fourth joint has spines in front at two points on the margin and a group at the apex; the fifth joint is smaller than in the preceding pair, with spines at five points of the front margin; the finger like that of the preceding pair, with the dorsal cilium small, very near the base. A slender accessory vesicle belongs, I think, to the branchiae of this pair.

Fourth Peræopods.—Side-plates with straight, almost parallel sides, the hinder lobe produced below the front one. The branchial vesicle small, descending little below the side-plate. The first joint larger than the side-plate, broader than deep, rounded, larger than the first joint of the preceding pair, the third joint also larger, but the general structure and armature of the limb similar.

Fifth Peræopods.—Side-plates with the hind margin nearly straight, much longer

than the front one. The first joint much larger than the side-plate, larger than the first joint of the preceding pair, longer than broad, widest below, the front margin unarmed in the upper part, the hind margin slightly erenulate, the lower margin overlapping the second joint, convex, smooth ; the third joint decurrent, with spines on the inner side of the decurrent part, and a large one at the apex, this joint twice as wide as the small fourth joint which it overlaps, but without the wide expansion seen in the two preceding pairs ; all the joints of this limb except the first are shorter than those of the fourth pair, the armature not very different.

Pleopods.—The peduncle short, almost as broad as long, coupling spines very small ; outer rami with thirteen to fourteen joints, with eighteen plumose setæ on the first joint ; the inner rami with eleven joints, the first joint broader at the base than its length, narrowed rather abruptly ; the cleft spines three or four in number.

Uropods.—Peduncles of the first pair equal in length to the outer ramus, which is bordered with seven spines, and is longer than the inner, which has but two ; each has a small indistinct nail ; second pair shorter than the first, peduncles very stout, longer than the rami, outer ramus longer and stronger than the inner, with a row of four spines, the inner without spines, but like the outer tipped with a small nail ; third pair in a lateral view presenting the appearance of an equilateral triangle, with spines round most of the upper side to the apex and without any perceptible rami.

Telson not much longer than broad, of the shape of half an egg, the apical part underneath set about with a collar of some eighteen spines, only those nearest the apex projecting beyond the margin, each spine carrying an accessory thread ; an additional group of spines near the apex is placed within the collar.

Length.—The specimen in the position figured was three-tenths of an inch long, with a depth at the centre of rather more than two-tenths.

Locality.—Station 145, off Marion Island, December 27, 1873 ; depth, between 50 and 75 fathoms. One specimen ; male (?). Dredged.

Remarks.—The specific name refers to the place of capture.

The species is distinguished from the others of the same genus by its much more considerable bulk, and the greater solidity of the integument. From *Acontostoma magellanicum* it differs in numerous details of the armature of the joints and in some of the proportions, but resembles it in so many particulars that some doubt arises whether *Acontostoma magellanicum* may not simply be the young of *Acontostoma marionis*. They were, however, taken at Stations far apart ; it is, moreover, in the smaller form that the mandibular spine-row appears to have the larger number of spines, and the maxilliped-palp to have the finger and nail most developed. Both these forms are distinguished from the other two species of the genus by the difference in the palp of the first maxillæ, as well as by the more developed finger of the maxilliped-palp.

Acontiostoma magellanicum, n. sp. (Pl. XXXI.).

Head almost entirely covered by the first pereon-segment and its side-plate; back round, animal compact; postero-lateral angles of the first two pleon-segments well rounded, of the third also rounded but forming almost right angles, with the lower margin straight; fourth segment with a dorsal depression followed by a small hump overhanging the very small fifth and sixth segments; on each of the first four segments a dorsal hair is visible.

Eyes small, visible through the transparent side-plate; each eye is composed of about fifteen comparatively large oeelli.

Upper Antennæ.—First joint twice as long as broad or longer; second joint nearly as broad but much shorter, third joint nearly as long as second, narrowing distally; flagellum of four very short joints, successively narrower but scarcely shorter; the first with two long stout cylinders, the second and third each with one; the fourth tipped with a tuft of setæ; secondary flagellum of two short joints.

Lower Antennæ not quite so long as the upper; gland-cone prominent, blunt-ended, third joint short, fourth longer than fifth, fifth almost as long as the small four-jointed flagellum; some spiniform setæ on the terminal joints of the flagellum, also at the base of the peduncle a curious parasitic growth, described below.

Mandibles of the same shape as those described in *Acontiostoma pepinii*, but here there is an undoubted secondary plate on the left mandible, small, strap-shaped, a little expanded distally; the spine-row consists of half a dozen small spines, followed by a long furry tract of short cilia; the setæ at the apex of the third joint of the palp have the parasitic growth.

Lower Lip with the forward lobes apically ciliated, very slightly dehiscent.

First Maxillæ.—Inner plate slender, tipped with a long, straight seta; outer plate long and narrow, with seven or eight dentate spines closely set on the apical margin, with a little group of elia just below on the inner margin; the unarmed palp appears to be one-jointed, reaching with its point nearly to the base of the outer spines on the outer plate, a little constriction below the point giving it in some points of view the appearance of the nib of a pen; the curved inner spine of the outer plate has from nine to ten lateral denticles.

Second Maxillæ with both plates slender, the outer rather longer than the inner; each with eight or nine apical spines.

Maxillipeds.—Inner plates short, ending in a long tooth which just projects beyond the short first joint of the palp, and has a long seta fixed at its base; outer plates projecting beyond the second joint of the palp, inner border with a spine about midway, some others within the margin on the outer surface near the narrowed apex; the forward part of the hinder margin scarcely serrate; the third joint of the palp longer than the

second, followed by a small but very distinct finger, straight, tapering, ending in a sharp nail with cilia on either side. At the apices of the third and fourth joints of the palp are two or three setæ; on most of these the parasitic growth already alluded to is conspicuously displayed, the seta throughout its length being plumose with long, flexible cylinders, tapering distally, and presenting a minutely beaded appearance.

First Gnathopods.—Side-plates broad, rounded at the lower front angle, the cilium-carrying incision of the hinder angle raised a little above the lower margin. The first joint of the limb attached high up and only just reaching below the side-plate; the second joint as long as the wrist, the third very short; the wrist broader but much shorter than the hand; the hand tapering, with no palm; the finger curved, about half the length of the hand, with a spine on its inner partially pectinate margin near the nail. The second and third joints each have a long apical seta behind, the wrist has two, the hand has a row of three not so long, and two on the front apex, besides a cilium in the middle of the convex front margin. Many of the setæ have the anguilliform appendages.

Second Gnathopods.—Side-plates much narrower and not much deeper than those of the preceding segment; first joint not reaching to the end of the side-plate; second joint as long as the wrist; third shorter than the wrist, lightly furred on the very convex hind margin; wrist shorter than the hand, slightly furred on both margins; hand long, widest towards the distal end, furred on both sides, the marginal cilia having something of a scale-like appearance; the finger minute, as it were an equilateral triangle with a little hooked nail at the apex, this organ forming a tiny chela with the produced hind margin of the hand. There are no long spines or setæ upon these gnathopods, here and there a seta is found that might be called a cilium, except for the sake of distinguishing it from the neighbouring cilia with which some of the joints are furred; on the front apex of the hand the most important group consists of three or four straight and seemingly simple spines or setæ.

First Peræopods.—Side-plates similar to those of the preceding segment, but somewhat larger. The first joint not reaching to the end of the side-plate.

Second Peræopods similar to the first. Side-plates not very broad, the excavation behind slight, descending far down, the hind margin being then directed forwards, and being incised for a cilium just before meeting the lower margin; one of the minute cilia within the lower margin carries anguilliform appendages. The first joint rather broad, not long, not nearly reaching the lower end of the side-plate; the second joint longer than the fourth; the third broad, not decurrent, as long as the fifth, with one or two setæ on each margin; the fourth with one apical seta behind, and some microscopical scales on the breast; the fifth with its straight hind margin pectinate or squamose like the preceding joint, the convex front margin smooth, except for a seta at the apex, which on the other margin carries a spine; the finger stout, curved, with a strong nail.

Third Peræopods.—Side-plates broader than deep. First joint rounded, not so large as the side-plate, a spine and seta at the lower end of the front margin, a minute eilium high up on the hinder; the second joint with a seta followed by a spine on the lower part of the front margin, and some microscopic pectination between; the third joint broadly expanded, decurrent behind the fourth joint, with two spines on each border; the rest of the limb similar to that of the preceding pair.

Fourth Peræopods.—Side-plates with the convex hinder margin considerably longer than the straight front one. The first joint much larger than the side-plate. All the joints constructed as in the preceding pair, but somewhat larger, especially the first and third.

Fifth Peræopods.—Side-plates smaller than those of the preceding segment, hind margin not much longer than the front one. First joint a little larger than that of the preceding pair, the eilium of the hind margin lower down; third and following joints smaller than those of the adjoining pair.

Pleopods.—Peduncular spines two, perhaps more, the rami with four or five joints.

Uropods.—Peduncles of the first pair as long as the longer ramus, the rami short, pointed, the longer with one spine near the centre of its margin, the edges finely pectinate, the shorter ramus seemingly with smooth edges; the second pair smaller than the first, the peduncle about equal in length to the longer ramus, which has pectinate edges but no spine, the shorter ramus has a eilium near the base; no rami were discerned on the third pair.

The Telson appears to be short and broad with a small cleft or terminal emargination, having each apex capped by two spines, the outer one the larger, each carrying an accessory thread.

Length.—The specimen in the position figured measured rather over a tenth of an inch.

Locality.—Station 313, off Cape Virgins, Patagonia, January 20, 1876; lat. $52^{\circ} 20' S.$, long. $67^{\circ} 39' W.$; depth, 55 fathoms; bottom, sand. One specimen. Trawled.

Remarks.—The specific name refers to the place of capture, at the entrance to the Strait of Magellan.

Acontistoma pepinii, n. sp. (Pl. XXXII.).

A little, compact, hairy species; back of peræon well-rounded and broad, afterpart of pleon pinched in; the head almost covered by, though partially visible through, the semitransparent first peræon-segment and its side-plate; the fourth to the seventh peræon-segments deep; the third pleon-segment dorsally rounded, distally rising above the

fourth segment, which has a deep dorsal excavation, the end being strongly upturned, with the process rounded behind.

Eyes very small, components numerous, perhaps thirty.

Upper Antennæ.—Peduncle tumid, hairy above, the first joint as long as the rest of the antennæ, the second rather longer than the third; the flagellum of five joints, with a few cylinders, three or four on the first joint, which is shorter than the last of the peduncle; secondary flagellum of two short joints tipped with setæ.

Lower Antennæ.—Gland-cone moderately prominent, with squared apex, third joint short, fourth and fifth furred above, and carrying a few small setæ, the fourth joint longer than the fifth, the fifth as long as the four-jointed, rapidly tapering flagellum.

Upper Lip hairy.

Mandibles long and narrow, broadest at the base, cutting edge smoothly convex, with a tooth above and a dentieulate point below, spine-row containing apparently seven spines in each mandible, unless the uppermost spine on the left mandible may be supposed to represent a secondary plate; the spine-row is followed immediately by a ciliated tract perhaps representing the molar tubercle, above which is placed the process which I regard as the equivalent of the articular condyle; the whole shaft is dotted with small cilia; far from the spine-row, close to the base, rises the small three-jointed palp, the first joint longer than usual, the third but little shorter than the second, tipped with two setæ, and having on the surface the customary adpressed cilia.

Lower Lip with the mandibular processes ciliated.

First Maxillæ.—Inner plate narrow, with a single short seta on the apex; outer plate elongate, crowned with eight closely-set dentate spines, the innermost showing eight lateral denticles; the palp minute, two-jointed, so placed on the outer margin of the outer plate that the tapering ciliated second joint projects a little beyond the apex of the inner plate.

Second Maxillæ.—The outer plates rather longer than the inner, both with long spines on the apices, the spines a little curved at the tips.

Maxillipeds.—The inner plates not much shorter than the outer, the apical margin running out furthest on the inner side, there carrying one or more teeth, followed by two long spines at intervals on the outer margin; the outer plate having a small spine or seta on the inner margin about one-third of its length from the base, a group of three setæ at two-thirds, two or three little nodules close to the apex, and the outer rim serrate or dentate for some distance down, lines or channels in the surface of the plate leading to the serrations; the first joint of the palp quite short, the second shorter than the third, with a cilium and a seta near the top of the inner margin; the third joint slenderer than the second, but as long as first and second combined, with an apical tuft of six or seven setæ, and perhaps a minute rudiment of a fourth joint; the palp forms an

obtuse angle where the third joint hinges on the second, and in this bent position scarcely overtops the outer plates.

First Gnathopods.—Side-plates widest at the centre, closely ciliated on the broadly rounded lower margin; first joint extending beyond the side-plate, nearly as long as the next four joints united; second joint longer than third, as long as the fourth, with two setæ on the hind margin; third joint very small, a little furred behind, with two setæ near the apex; the wrist broader but shorter than the hand, slightly furred behind, with two setæ in front at the apex and three at the back; the hand long, tapering, without a palm, finely peetinate along the hind margin, with seta-like spines at three points on that, and at two on the front margin; finger fully half as long as the hand, with a sharp, slender nail.

Second Gnathopods.—Side-plates oblong, and, like the preceding pair, furred, especially on the lower margin, besides carrying some stronger cilia. The first joint as long as the third, fourth, and fifth united; the second much longer than the third, subequal to the wrist; the short third joint with very convex hinder margin, carrying one cilium at a little distance from the apex; the wrist subequal in length to the hand, with six or seven scale-like cilia on the centre of the hind margin; the hand long, oval, finely furred almost all over, also with the squamose cilia on the lower two-thirds of the hind margin, which is produced considerably beyond the front margin, forming with the palm a triangular process against which the finger closes; the finger, which is backed by three or four setæ, is short and stout, the hooked nail, which forms more than a third of its length, not extending beyond the palm. On a diminutive scale the hand and finger form a feeble chela.

First Peraopods.—Side-plates similar to those of the preceding segment, but larger. The first joint broad, not reaching nearly to the end of the side-plate, shorter than the fourth and fifth joints united; third joint broad, not decurrent, much longer than the fourth, not quite so long as the fifth; the fourth joint short, hind margin straight, peetinate, with a spine and two cilia at the apex; fifth joint long, slightly tapering, hind margin nearly straight, peetinate, with acute spines at two points, and at the apex a pair of blunt spines curving towards the edge of the finger; the front margin of the hand convex, with one or two cilia; the finger strong, curved, with a very small dorsal cilium, and one or two cilia near the nail.

Second Peraopods.—Side-plates broader and deeper than the preceding pair, the excavation behind shallow, carried far down, the margin below it taking a forward direction to join the lower border, so that the upper and lower margins of the plate are of equal breadth; the joints of the limb similar to those in the preceding pair.

Third Peraopods.—Side-plates very broad and deep, with the breadth and depth subequal, rather deeper in front than behind. First joint irregularly rounded, two long setæ and a spine on the lower part of the furred front margin, the hind margin

carrying a cilium in a little emargination at the top; its rounded lower margin overlapping the next joint; the third joint much dilated, with spines at three points of the furred front margin, the convex hind margin so decurrent as to overlap not only the next joint but part also of the fifth; the fourth joint very short, a pair of spines at the apex in front; the fifth joint shorter than in the preceding pair, similarly formed, the pair of spines at the finger-hinge sharp instead of blunt; the finger as in the preceding pair.

Fourth Peraopods.—The side-plates with front and hind margins straight, lower margin roundly produced behind; first joint rounded, broader than deep, broader than the side-plate, an emargination with a cilium in the middle of the hind margin; third joint less decurrent than in the preceding pair, the limb in general similar.

Fifth Peraopods.—Side-plates small; first joint of the limb larger than in the preceding pair, a little wider than deep, front margin very convex, with several setæ on the lower part, the hind margin nearly straight, with a little cilium-bearing incision at the lower end, the convex lower margin very broad behind the second joint, which it overlaps; the third joint less expanded than in the two preceding pairs, the fifth joint shorter, with no spines on the front margin except the apical pair; the finger also shorter.

Pleopods.—A single cleft spine on the first joint of the inner ramus, which has four joints, while the outer has five. In the larger specimen mentioned below it was perceived that the peduncles of the pleopods carried two small spines, each with three retroverted teeth, the rami had six joints to the inner, eight to the outer, the first joint of the inner carrying two small cleft spines low down.

Uropods.—Peduncles of the first pair equal in length to the rami, the rami subequal, the inner with a small nail not reaching quite so far back as the outer; peduncles of the second shorter than those of the first, also about equal in length to the rami, of which the inner is a little shorter than the outer; peduncles of the third pair very short, the rami represented by a solitary tubercle, with a cilium at the apex.

Telson short and small; in the lateral view it is convex below and concave above, with strong spines and cilia about the apex.

Length.—The specimen in the position figured measured scarcely one-tenth of an inch; another specimen measured nearly three-twentieths.

Locality.—Station 149B, Royal Sound, Kerguelen, January 20, 1874; depth, 28 fathoms; bottom, volcanic mud. Three specimens.

Remarks.—The specific name is derived from Pepin, surnamed le Bre, the celebrated King of the Franks.

This species is distinguished from the following species, *Acontostoma kergueleni*, by its much firmer integument, its much greater hairiness, its much smaller eyes, the much smaller first joint to the flagellum of the upper antennæ, the more developed spines of the first maxillæ, the bulge in the front margin of the first side-plate, the

different armature of the first joints in the last three pairs of pereopods, the incision in the infero-posterior angle of the first joint in the last pereopods, and by the shorter and stouter first uropods.

Acontistoma kergueleni, n. sp. (Pl. XXXIII.).

Head almost covered by the first peraeon-segment and its side-plate; the postero-lateral angles of the first two pleon-segments well rounded, of the third more squared; these three segments a little hairy dorsally near the distal end; the third segment distally raised above the fourth, ending with a little upturned tip; the fourth segment with a deep dorsal depression, followed by an upturned process, the dorsal margin of which is hairy and faces forwards.

Eyes large, oval.

Upper Antennæ.—First joint broad, as long as the two following and first of the flagellum united, second joint broad, not long, third short, not broad; flagellum rapidly tapering, of five joints, of which the first is the longest, with a brush of very long cylinders; the following joints except the last also have cylinders; secondary flagellum of two small joints, together not equalling the first of the primary.

Lower Antennæ.—Gland-cone fairly prominent, with blunt apex, third joint very short, fourth longer than fifth, with some feathered cilia on the side, fifth as long as the four joints of the short, slender flagellum united.

Upper Lip a long, triangular plate.

Mandibles.—A prominent tooth at the upper part of the cutting edge; the secondary plate of the left mandible small, deeply bifid; spine-row not clearly made out, seemingly of two or three minute spines; no molar tubercle of any kind perceived; palp set close to the base, the first not very short joint rising from a process which gives the palp a four-jointed look; second joint with one spine near the inner margin far from the apex; third joint very nearly as long as the second, with a constriction near the base, adpressed cilia on the surface, two plumose setæ at apex. The secondary plate (seen through the semitransparent trunk) of the left mandible is drawn in the right hand figure on the Plate, the outside of the mandible being here given instead of the inside.

Lower Lip.—The forward lobes seem to be very slightly ciliated and not very deliscent.

First Maxillæ.—Inner plate narrowing distally, with one small seta at the apex; outer plate long, apically capped with very short spines, probably denticulate; a minute two-jointed palp on the outer margin some way below the apex.

Second Maxillæ.—Inner plate a little shorter than the outer, each with about half-a-dozen spines or setæ on the apex.

Maxillipeds.—The inner plate long, reaching beyond the second joint of the palp,

to a pointed or bifid apex, with two spines on the outer margin; outer plates rather longer than the inner, with a small seta at about one-third of the length of the inner margin from the base, and two larger at about two-thirds; the apex almost pointed, spinules at intervals on the slightly serrate outer margin. First joint of the palp the same width as the second, with one small seta on the inner margin; the second with a small one, followed by a larger on the inner margin not far from the apex; the third joint more slender, rather longer than the second, furred, apically tipped with four or five setae, and carrying one or two on the inner margin below the apex; perhaps a minute rudiment of a finger.

First Gnathopods.—Side-plates not very broad, incision for cilium on the hind margin a little above the rounded lower margin. First joint reaching a little below the side-plate; second joint rather longer than the wrist, with setæ at two points on the hind margin; third joint minutely furred behind, with one apical seta; wrist broader, but much shorter than the hand, furred behind, with one apical seta; hand tapering, without palm, carrying spines or setæ at five points on the hinder minutely pectinate margin, the front margin having two or three cilia; the finger more than half the length of the hand, slender, with a slender nail.

Second Gnathopods.—Side-plates narrower, a little longer than those of the preceding segment. The branchial vesicles as long as the first joint of the limb, which reaches below the side-plate, and about equals in length the third, fourth, and fifth united; the second joint as long as the hand, not quite so long as the wrist; the third joint short, but longer than the third joint of the first gnathopods; the wrist furred, without spines or setæ; the hand elongate, widening a little towards the apex, furred, carrying scale-like cilia on the breast; the apex of the front margin carries three or four spines over-arching the minute finger, this being a small triangle with hooked nail at the apex, which antagonizes with the produced front portion of the hand, thus forming a feeble chela.

First Peraopods.—Side-plates narrow, similar to those of the preceding segment. First joint not reaching the lower margin of the side-plate; third joint broad, as long as the fifth, not decurrent, with a seta on the hinder margin, and an apical seta or spine on the front; fourth joint a little broader but much shorter than the fifth, hind margin pectinate and apically carrying a spine, a cilium, and a setiform spine; fifth joint scarcely tapering, hind margin pectinate, carrying at two points short acute spines, and at the hinge of the finger a pair of blunt curved ones; finger more than half the length of the fifth joint.

Second Peraopods.—Side-plates longer and somewhat broader than those of the preceding segment, the excavation behind not broad but carried far down, the margin below it bending forwards. The branchial vesicles simple, much longer than broad. The joints of the limb similar to those of the preceding pair.

Third Peræopods.—Side-plates subequal in breadth and depth, large, the front lobe descending a little below the hinder one. The first joint smaller than the side-plate, rounded; on the lower part of the front margin setæ at three points, the lowest accompanied by an apical spine, the hind margin smoothly rounded but for two or three minute cilia near the top; two or three spinules on the front of the second joint; third joint much expanded, and decurrent on both sides of the fourth joint, four spines at four points in front, and at three behind, the two upper ones behind being minute; a group of three spines on the front apex of the short fourth joint; the fifth joint much longer than the fourth, with one spine at the centre, two at the hinge of the finger; finger more than half the length of the hand, with a curved nail; the front margin of the fourth and fifth joints is fringed with rows of minute spinules or prickles.

Fourth Peræopods.—Side-plates squarish, hind margin longer than the front. First joint a little larger than the side-plate, rounded, the lower part of the front margin with setæ at three or four points, followed by an apical spine, four cilia on the upper half of the hind margin; the other joints much as in the preceding pair, but with the fringing spinules much larger on the fourth joint, and less continuous on the fifth.

Fifth Peræopods.—Hind margin of the side-plates much longer than the front. First joint larger than in the preceding pair, front margin nearly straight, with several cilia along the lower part, the hind margin with two cilium-bearing indents at the lower end; the surface, as in the corresponding joint of the two preceding pairs, is downy; the third joint is less expanded but equally decurrent, with a spine on the inner side of the decurrent part; the fifth joint, pectinate on both margins, has a cilium at the centre of the hinder margin.

Pleopods.—Peduncles short, coupling spines two, with three or four retroverted teeth on one edge and two on the other; cleft spines on the inner ramus two to three, the two divisions of the cleft part of equal length; the joints of the inner rami from five to six, of the outer from seven to eight in number.

Uropods.—Peduncles of the first pair equal in length to the longer ramus; the rami stiliform, the lower the longer, each with a spine on the margin at some distance from the apex; the second pair much shorter than the first, peduncles as long as the lower longer ramus, the rami finely pectinate; the third pair very short, with a tubercular ramus.

Telson extending beyond the third uropods, short, narrowing distally, with an emargination of about a quarter of its length, rather deeper than wide, the apices tipped with spines.

Length of the specimen in the position figured, from the front of the head to the end of the third pleon-segment, three-twentieths of an inch.

Locality.—Station 149D, Royal Sound, Kerguelen, January 20, 1874; depth, 28 fathoms; bottom, volcanic mud. One specimen. Dredged.

Remarks.—The specific name refers to the place of capture. The numerous differences between this species and *Acontostoma pepinii* have been already mentioned, but it is rather remarkable that two species of a new genus should have been taken at the same time and place, represented by specimens of the same size and resembling one another in so many particulars.

Family VALETTIDÆ, n. fam.

Mandibles.—The cutting edge strongly dentate; a secondary plate only on the left mandible; molar tubercle prominent; palp three-jointed; articular condyle wanting.

First Maxillæ.—Spines of the outer plate fewer than eleven; the palp two-jointed.

Maxillipeds.—The inner plates with more than three apical spine-teeth.

Upper Antennæ.—The peduncle short and stout, the second and third joints very short, the first joint of the flagellum long, carrying a large brush of cylindric filaments; a secondary flagellum present.

Second Gnathopods subchelate, slightly weaker than the first.

The body and side-plates not deep.

Peræopods of the last three pairs with the first joints not overlapping.

Remark.—In establishing a new family for a single genus containing a single species, the choice of characters must be to a certain extent arbitrary; in the above definition it is the combination of the forms there described for the mandibles and the upper antennæ that may be regarded as the most essential part.

Genus *Valettia*, n. gen.

First Maxillæ with the inner plate carrying more than two plumose setæ.

Second Maxillæ with the plates short, not narrow.

Maxillipeds with the inner margin of the outer plates almost smooth, apically produced; palp four-jointed, second joint not longer than the first.

Gnathopods of the first and second pairs similar, subchelate, both with strong oblong hands and definite palms.

Uropods biramous, successively shorter; the upper ramus in each pair shorter than the under.

Telson short and broad, partially cleft.

The generic name is chosen in compliment to the Baron Adolphe de la Valette, who early displayed his acuteness as a naturalist in investigating Amphipoda.

By its antennæ and pleon this genus might belong to the Lysianassidæ of Boeck. The mandibles would rather place it among the Pontoporidæ, but that

the right mandible, as in the Lysianassidæ, is without an accessory plate. From both of these groups it seems to be set far apart by the firm and definite structure of the hand and nail in the second gnathopods, and by the general shallowness of the body and side-plates.

Valettia eoheres, n. sp. (Pl. XXXIV.).

Rostrum rudimentary; back round, but not broad; postero-lateral angles of the third pleon-segment acute, a little upturned; fourth pleon-segment with a dorsal depression, followed by a small distal hump; sixth segment dorsally ridged on either side of the telson. The commissures of the ganglionie chain stand distinctly apart; the ganglia have at each corner a globular paeket of cells.

Eyes not observed.

Upper Antennæ.—Peduncle tumid, barrel-like, first joint scarcely longer than broad, but much longer than the other two united, both of these being short, but broad; the flagellum of thirteen joints in one of the pair, of fourteen in the other; the first joint subequal in length to the peduncle, tapering, with a brush of cylinders in numerous rows, the small joints that follow varying in length irregularly; the secondary flagellum slender, of four joints, which reach to the end of the second of the primary, the first of the four equalling in length the other three united.

Lower Antennæ subequal in length to the upper; first joint broad; gland-eone of the second joint prominent, acute; third joint short, fourth joint as long as the preceding three united, longer and stouter than the fifth, with setæ along the upper edge and a tuft at the lower distal angle; the fifth joint about as long as the first three of the fourteen joints of the flagellum, which, as in the upper antennæ, vary in length irregularly.

Upper Lip.—Viewed laterally, two distal lobes are seen, one set with small priekles, the other having a prominent tuft of eilia; between the two lobes a curved margin descends, which is also fringed with minute eilia.

Mandibles short, with a broad shaft, cutting edge narrowly produced, not convex, but divided into five sharp teeth of unequal size; secondary plate of the left mandible elongate, projecting nearly as far as the cutting edge, similarly divided into teeth, the longest tooth being slightly curved backwards; spine-row of four short spines, of which the first on the left mandible is bifurcate; molar tuberele prominent, the crown more or less dentate, with seven or eight spine-like eilia at the baek and a long plumose seta; the palp set well forward, just over the molar tuberele, the first joint short, the second stout, very little longer than the third, with twelve spines on the upper part of the inner margin, the third joint distally pointed, with twelve spines on the upper part of the inner margin, most of them smaller than those of the second joint. I can find no

trace of a secondary plate on the right mandible, nor any trace of an articular condyle on either.

Lower Lip, seemingly very short, not strongly ciliated, but with a strong tuft of cilia at the apex of the forward lobes; the mandibular processes unusually broad.

First Maxillæ.—Inner plate short, irregularly oval, with five plumose setæ of no great length on the apical border; outer plate oblong, of no great length, the apical border almost straight, with eight (or ? nine) slender, slightly curved spines, no one of which seems to have more than two lateral denticles, the denticles being minute; the long second joint of the palp over-arching the outer plate, with six spine-teeth on the apical margin, the outermost one or two being considerably the longest; there are besides one or two spiny cilia on the inner side.

Second Maxillæ short and rather broad, the inner plate with curved spines and plumose setæ, about a dozen in all, passing from the apex half-way down the inner margin; the outer plate but little overtopping the inner, its inner margin straight, its apical margin carrying a dozen spines of various sizes, curved at the tips.

Maxillipeds.—The broad prismatic inner plates not reaching quite so far as the apex of the first joint of the palp; the plumose setæ beginning high up on the inner margin; the apical margin most advanced centrally, carrying five not closely-set spine-teeth on the inner slope and some elongate slender spines on the outer, also one or two spine-teeth just below the apex on the inner margin; outer plates extending beyond the second joint of the palp, inner margin almost unarmed, but apically produced into a long acute process, at the base of which on the outer side is a small cilium, followed some way further down the outer margin by a single long, feathered spine; within the inner margin are some small spines, not visible in the figure because they are on the outer surface; the second joint of the palp not longer than the first, the third not longer than the fourth; the first, second, and third with setæ only on the apices, the fourth with a distinct nail.

First Gnathopods.—Side-plates short and broad, much rounded in front, not reaching to cover the base of the lower antennæ. First joint of the limb projecting much beyond the side-plate, broad, widening below, the front margin straight, the hinder convex, with long, distally plumose setæ on both margins; the second joint broader than the third, and as long or longer, with pectinate spines at the apex; the third with no free front margin, distally acute, hind margin bent, the lower part bordered with pectinate spines; the wrist not as long as the hand, becoming very broad distally, where it has pectinate spines before and behind; the hand broad, with front margin convex, longer than the straight hind margin, some pectinate spines on both, and a few short ones on the inner surface; the palm rather deeply concave, defined by a large and a small spine and some cilia at the projecting end of the hind margin; the finger not massive, long enough to reach the end of the palm; some cilia near the origin of the nail on the inner margin, the dorsal cilium small, placed near the hinge.

Second Gnathopods very similar in general character to the first. Side-plates rather longer than those of the preceding segment, with three small spines on the margin just above the cilium of the lower hinder angle. The branchial vesicles expanding at once from the neck and continuing of nearly equal breadth to the lower, almost straight margin. First, second, and third joints as in the preceding pair, except that the first and second are somewhat longer and narrower; the wrist is here longer than the hand, and the distal half wider, with some spines on the hind margin as well as at the apex; the hand oblong, front margin a little convex, hind a little sinuous, with pectinate spines on the lower part; the palm sloping somewhat inwards, defined as in the previous pair, not concave, but with an irregularly crenate margin, which the finger would apparently a little overlap.

First Peræopods.—Side-plates broad, most so at the centre, the front margin convex. The first joint reaching beyond the side-plate, broadest distally, with setæ on both margins, of which the front is concave, the hinder convex; third joint much longer than the fourth, broad, very slightly decurrent, spines at six points on the hind margin, at two in front; fourth joint shorter and broader than fifth, with a few spines on the back margin, and an apical tuft in front; fifth joint tapering a little distally, slightly armed on the straight hind margin, and having some spines at, and a little way above, the apex in front; finger short, the sharp nail forming a large part of its length.

Second Peræopods.—Side-plates with length and breadth equal, very slightly excavate behind. The joints of the limb similar to those of the preceding pair.

Third Peræopods.—Side-plates much wider than deep, the hind lobe descending rather lower than the front, and carrying two or three spines. Branchial vesicles a long oval, standing out from the narrow neck at the top. First joint a narrow oval, smaller than the branchial vesicle, with spines on the lower half of the front margin, the hind margin showing only two notches, not expanded below; the four following joints with spines on the front margin; the third joint broader than the fourth, subequal in length, with spines behind at two points; fourth joint broader than fifth, slightly longer, with spinules behind; the fifth joint straight; the finger small and slender, not nearly half as long as the fifth joint, the nail short.

Fourth Peræopods.—Side-plates similar to those of the preceding segment, but on a smaller scale. Branchial vesicles similar in shape to those of the preceding segment, but smaller, and, instead of descending, being directed abruptly forward, a fold starting from the neck, as if to form a small accessory sac, reunites with the main vesicle. First joint longer than in the preceding pair, front margin straighter, with more spines, a seta near the base, hind margin notched at five points; the rest of the limb similar to the preceding, but all parts longer except the finger, and the third and fourth joints decidedly longer than the fifth.

Fifth Peræopods.—Side-plates not bilobed. Branchial vesicles small, twisted upwards

and backwards. First joint with the front margin very straight, carrying two setæ or cilia above and a few spines along its course, behind much expanded, serrate, narrowing below and not overlapping the next joint; the third joint a little shorter than in the preceding pair, the rest similar. Owing to the comparative narrowness of the first joints in the third and fourth pereiopods, and the breadth of the side-plates to which they are attached, the third, fourth, and fifth pereiopods stand well apart, instead of overlapping above, as they so commonly do.

Pleopods.—The peduncles powerful, with some setæ, and four very slender coupling spines in which the retroverted teeth are small, seemingly three or four in number; the cleft spines are three in number, placed high up on the long first joint of the inner ramus; the joints of the inner ramus number thirteen, those of the outer fifteen.

Uropods.—The peduncles of the first pair longer than the rami, the rami unequal, the lower with more spines and longer than the upper; the peduncles of the second pair equal to the shorter ramus in length; peduncles of the third pair shorter than the rami, which are short and broad, armed with a few cilia-like spines, pectinate on the edges like those of the other two pairs, the lower longer ramus with a nail.

Telson extending a little beyond the peduncles of the third uropods, not much longer than its breadth at the base, cleft rather beyond the centre, not dehiscent, with one or two cilia on each rather broad rounded apex, and one or two on the lateral margins lower down than the top of the cleft.

Length of the outstretched specimen, without the antennæ, half an inch.

Locality.—Station 156, Antarctic Ocean, February 26, 1874; lat. $62^{\circ} 26' S.$, long. $95^{\circ} 44' E.$; depth, 1975 fathoms; bottom, Diatom ooze. One specimen. Trawled.

Remarks.—It seems not inconsistent with the great depth from which this species is reported to have been obtained that it should exhibit some striking peculiarities. The specific name, *coheres*, intimates that it has gone shares with various groups in the inheritance of its characters, as already explained in the note upon the generic description. The outer plates of the maxillipeds are very remarkable, and so also is the absence of the accessory plate on the right mandible in combination with the character of a strongly dentate cutting edge. As the observations are based upon a single specimen, however, it is necessary to allow for the possibility of the plate being accidentally absent, though there is no appearance in the specimen of any such loss.

Family STEGOCEPHALIDÆ, G. O. Sars, 1882.

Dana in 1852 makes the Stegocephalinæ a subfamily of the family Gammaridæ; Boeck in 1876 makes them a subfamily of the Leucothoidæ; Sars in 1882 makes them an independent family. Boeck gives the following definition:—

- “ *Hypostome* produced.
- “ *Upper Lip* broad, cleft at the apex ; the lobes of unequal length.
- “ *Mandibles* elongate, without molar tubercle or palp, apically very broad, much or little dentate, not a uniform pair ; the left mandible having an accessory plate.
- “ *Lower Lip* narrow, elongate, without inner plates, but furnished at the apex with a dentate appendage (*articulo appendiculare*).
- “ *First Maxillæ* very broad ; outer plate apically furnished with strong but simple spines (*ungvibus*) ; palp one- or two-jointed ; inner plate very broad, very setose.
- “ *Second Maxillæ* with the inner plate very broad, the outer narrow or very small.
- “ *Maxillipeds* with very broad plates ; the outer plate furnished with weak teeth or only serrate ; the palps slender, narrow ; the last joint of the palp unguiform.
- “ Body very deep, but thick. Four anterior side-plates much increasing in size (successively) ; the fourth side-plate very large. The head very short, but deep.
- “ *Antennæ* short, but robust ; the upper with a small secondary appendage ; the first joint of the flagellum elongate and thick.
- “ *First and Second Gnathopods* almost of the same shape and size, scarcely subchelate.
- “ *Third and Fourth Peræopods* with the first joint little or not at all dilated.
- “ *Fifth Peræopods* shorter than the preceding ; the first joint much dilated and elongate.
- “ The *Uropods* each furnished with two cylindrical rami.
- “ *Telson* little, sometimes slightly cleft.”

Genus *Stegocephalus*,¹ Krøyer, 1842.

Stegocephalus inflatus, Krøyer (Pl. CXXXVII. A.).

Locality.—Station 49, south of Halifax, Nova Scotia, May 20, 1873; lat. $43^{\circ} 3'$ N., long. $63^{\circ} 39'$ W.; depth, 85 fathoms; bottom, gravel, stones; bottom temperature, 35° . Two specimens, the larger a female, nearly three-quarters of an inch long. Dredged. Colour as in Voy. en Seand., pl. 20, fig. 2.

Remarks.—Commenting on specimens from the Kara Sea, many of which were distinguished for their size, one being 47 mm. long, Dr. Hansen (*loc. cit.*) observes, “the species is easy to distinguish from the *Steg. Kessleri* figured by Stuxberg (Vega B. I., p. 713), which last pretty certainly is the same as the ‘forma altera’ of *Steg. ampulla*, established by Goes (*Op. cit.*, p. 521, Fig. 9). Specimens of *Steg. ampulla* have the fourth pair of side-plates deeper than long, and the fifth pereiopods’ expanded second joint (first joint, auctor) ending in a right, or even slightly acute, angle. Young, taken from the pouch of the female and sufficiently developed to leave it, are distinguished by the circumstance that the fifth pereiopods’ second joint has its expanded plate prolonged somewhat downwards and evenly rounded, and the side-plates of the third pleon-segment rounded below; they are, however, easily distinguishable from *Steg. christianensis*, Boeck, in that the fourth pereiopods’ second (Boeck’s first) joint is expanded, and from the species described by Sars by the fourth pair of side-plates, which are quite like those of the adult (see above), and by several other points, which are easily seen in Sars’ figures.” A footnote already quoted (p. 599) explains that Dr. Hansen’s specimens ought to have been described as *Stegocephalus inflatus*, Kröyer, and that “*Stegocephalus Kessleri*, Stuxberg,” is the true synonym of *Cancer ampulla*, Phipps.¹

¹ Since Phipps’ specimens (*uncialia et biuncialia*) were as large as Dr. Hansen’s, I do not know why Dr. Hansen refers to the size as a distinction between the two species. Phipps may have had both forms, for his account of the last pereiopods (*femora postrcmi pars postice acuta*) scarcely agrees with the figure. In the synonymy given above the references to Kröyer, Hansen, and Goës (fig. 8) clearly refer to *Stegocephalus inflatus*; in most of the others the name *ampulla* has doubtless been used without knowledge of the distinctions which Dr. Hansen draws between the forms *ampulla* and *inflatus*.

Genus *Andania*, Boeck, 1870.

Mandibles with the cutting edge for the most part smooth; only one mandible with a secondary plate, and that minute.

First Maxillæ with a two-jointed palp, which does not always reach so far as the outer plate.

Second Maxillæ with the outer plate shorter and much narrower than the inner.

Telson very small, whole or slightly incised.

Boeck founded this genus for the two species *Andania abyssi* and *Andania nordlandica*; to these Sars in 1882 added a third, *Andania pectinata*;¹ for the three new species now included, it has been necessary slightly to modify the wording of Boeck's definition (see p. 399). Indeed, his expression, "Maxillæ 1mi paris palpo elongato, lato, 2-articulato," does not seem to agree with his description of the first maxillæ of *Andania nordlandica*, of which he says, "Palpen er liden, uden Børster."

Andania gigantea, Stebbing (Pl. XXXV.).

1883. *Andania gigantea*, Stebbing, Ann. and Mag. Nat. Hist., ser. 5, vol. xi. p. 206.

The head almost concealed beneath the large overhanging first segment of the peræon, the forehead obtusely angled; the peræon broad and deep, especially from the second to the fifth segment; the first segment longer than the rest, from before backwards increasing rapidly in depth; from the sixth segment of the peræon the width and depth of the segments decrease rapidly towards the telson; the segments of the pleon not exceeding the average length of those of the peræon, the third segment with the rounded hind margin dorsally produced over the dorsal depression of the fourth segment, the sixth segment dorsally emarginate to receive the telson; the postero-lateral angles acute in the second segment, but not in the first, and scarcely in the third, though in that segment a little outdrawn. In spirit the integument shows prismatic colouring. The larger specimen is brown and very thin-skinned, while the smaller has a less flexible integument, and, as is commonly the case with specimens in spirits, is a sort of creamy-white in colour.

Eyes not made out, probably wanting.

Upper Antennæ.—The first joint stout and short, broader than long; the second joint a little narrower and much shorter; the third showing little more than a rounded lobe on each side, the smaller lobe on the inner side having a group of setæ; the flagellum three-sided, tapering, of about fourteen joints, of which the first is very large, much longer than either the peduncle or the remainder of the flagellum; it tapers strongly with a slight curve, and in addition to a row of nine or ten large spine-like setæ along

¹ In regard to this, see Note on *Aurivillius*, 1885 (p. 558).

its surface, its lower side carries a brush of long hairs or cylinders, consisting of some seventy rows; the remaining joints are short, especially the earlier ones; in a groove on the inner side of the first joint lies the narrow ribbon-like accessory flagellum, consisting of one very long joint and two minute terminal joints, the terminal spines or setæ reaching to the end of the first joint of the primary.

Lower Antennæ.—The first three joints very short, the first somewhat inflated, the gland-cone of the second small; the fourth joint between two and three times as long as broad, three-sided, with several groups of spines along one side; the fifth joint much longer and thinner than the fourth, three-sided, rather wider at each end than in the middle; the flagellum longer than that of the upper antennæ, shorter than the peduncle, consisting of twenty-five joints, of which the first is the longest.

The Epistome carinate; the distal lobes of the upper lip slightly unsymmetrical. In fig. C the upper lip is seen just above the cutting edges of the mandibles, which are in close juxtaposition; the flagella of the lower antennæ, and the terminal portions of those of the upper, are omitted; the first pair of side-plates are seen in profile.

Mandibles.—Cutting edge broad, almost straight, but with a little convexity, having a denticle at the upper end (the lower end in fig. C) with a small tooth on the upper margin just behind it; at the lower end the margin is produced rather into a small tooth-process than a tooth, the lower margin being finely denticulate nearly as far as the base of the secondary plate; this is found only on one mandible, as far as I could judge on the right, not on the left, mandible; it lies along the lower side of the principal plate, is much longer than broad, and has the distal edge dentieulate with about ten closely set denticles, together with three or four on the lower edge; the neighbouring tract of the principal plate shows some ciliation; and beyond this the lower margin runs out to an obtuse angle, apart from which the mandible would have the figure of a parallelogram; the angle or projection perhaps represents the otherwise absent molar tubercle. In the Plate, figures *m.m.*, the outside surfaces of the mandibles are represented, the right mandible being on the left hand, with the secondary plate seen through the transparent trunk; the curved depression in the corresponding part of the left mandible is likewise seen through from the inner surface.

Lower Lip.—The front lobes broad, widely dehiscent, strongly ciliated on the outer margin, less so on the flattened distal margin, and the inner margin smooth; across each plate from the outer margin to near the centre of the base runs a curved line of short, stiff bristles, which at either end of the line are very numerous; the mandibular processes are not flat but form a fold with the hollow inwards, the distal end rounded.

First Maxillæ.—Inner plates very large, the inner margin fringed with about thirty strong plumose setæ; the truncate distal margin of the outer plate is armed with six larger and three smaller spines, variously, but none strongly, denticulate, with numerous spine-like cilia about their bases; the palp has a few spines at the apex of the indistinctly

articulated first joint, and very many long slightly feathered spines on the serrate margins of the triangular apex of the second joint, which scarcely reaches the bases of the spines of the outer plate.

Second Maxillæ.—The inner plate rather longer than the outer and immensely broader, especially at the base, from which it narrows gradually to the apex; the inner margin armed with about thirty-six long, spine-like, plumose setæ, the tips unfeathered, and a parallel row of some twenty shorter spines, with the distal portion denticulate; these spines increase in length as they approach the apex, where there are some long spines, plumose below, denticulate above; the outer plate, of tolerably even width throughout, has many large spines on the apex, slightly denticulate, and a few slender and setiform at the tip of the inner margin.

Maxillipeds.—The inner plates greatly inflated, not reaching so far as the distal end of the first joint of the palp; the inner margins convex, distally dehiscent, fringed with long minutely feathered spines rather than setæ, the series passing round to the outer distal angle, where the flattened distal margin carries a thin spine bending over two little straight spinules; some way down the outer margin there are two strong spines; the outer plates narrow, not reaching the distal end of the second joint of the palp, armed along the serrate inner and distal margins with long slender spines, of which there are groups also on the outer surface near the inner margin; first joint of the palp subequal in length to the second; both armed on the inner margin, the second also on the outer apex, with long slender spines; the third joint much shorter than the second, very slender, with slender spines along the inner margin and about the apex, one or two of the latter longer than the finger; the finger thin and nail-like, with a very small dorsal cilium at a fourth of the finger's length from the base.

First Gnathopods.—The side-plates small, almost triangular, with the free margin a little curved. The first joint about as long as the next four joints united, the front margin straight, fringed with setæ, the hinder a little sinuous, with many very long slightly plumose setæ on or near it; the second joint short, with plumose setæ at the hinder apex; the third joint with plumose setæ at two points of the hind margin, and along the distal border, which forms a pointed apex in front; the wrist is longer than the hand and distally broader, with several strong spines on the hinder margin, as well as groups of setæ here and on both surfaces, and at the apex of the front margin; the hand tapers much towards the distal end; the serrate hind margin is nearly straight, carrying ten or eleven groups of long spines and setæ, and several groups of long setæ also on the surface and on the front margin, the distal part of which is serrate; the finger is small and slender, about half the length of the hand, at the apex of which it is fixed, having no palm to close against, the long spines and stiff setæ of the hind margin perhaps for some purposes serving instead of a palm.

Second Gnathopods.—Side-plates parallel-sided, the lower margin continuing the

curve of the preceding pair. The branchial vesicles, here and throughout, broad and inflated; this pair about as long as the first joint. The limb very similar to that of the first gnathopods; the first joint a little shorter, and at the top a little narrower; the third, fourth, and fifth joints rather longer, the fourth and fifth slightly narrower, subequal to one another in length; the armature similar.

First Peraeopods.—Side-plates similar to the preceding pair, but rather longer and broader, in each pair the front margin a little convex, and the hinder a little concave. Limb as in the next pair.

Second Peraeopods.—Side-plates scarcely longer than the preceding pair, but below the excavation equal in breadth to the two preceding pairs, the lower margin continuous with theirs, the hind margin rounded below the excavation. The first joint about the same size as that of the second gnathopod; short feathered setæ along the front margin, numerous long ones on the lower part of both margins; the short second joint having the lower half of the hind margin and its apex crowded with them; the third joint nearly as long as the first, with a group of long setæ on the slightly decurrent apex of the front margin, the hind margin straight, slightly serrate, fringed with numerous setæ; the fourth joint subequal in length to the fifth, the apical group of the front margin shorter than in the third joint, with a small group a little higher up, the hind margin rather deeply serrate, fringed with long spines and setæ of various lengths; the fifth joint narrow, slightly curved, with five groups of setæ on the convex front margin, and many groups of spines on the serrate hind margin; the finger short and slender, scarcely more than a third of the length of the fifth joint. In the Plate this and the succeeding peraeopods are drawn on a larger scale than the two gnathopods; to give warning of this, as well as could conveniently be managed, on the Plate itself, I have added figures of the natural size to show the comparative proportions of the second gnathopod and fifth peraeopod.

Third Peraeopods.—The hind lobe of the side-plates deeper than the front one. The limb is very similar to that of the two preceding pairs, the undilated first joint rather longer, the third shorter, with both margins serrate and fringed with setæ, some of those on the front being so strong as rather to deserve the name of spines; the fourth joint has on the hind margin an apical group of spines and setæ, and two groups of setæ higher up; the fifth joint is longer than the fourth or third, and longer than the fifth joint of the preceding pair.

Fourth Peraeopods.—The side-plates behind nearly as deep as the hind lobe in the preceding segment. The first joint expanded, the margins nearly parallel, scarcely serrate; numerous very long setæ arise on the inner surface along the hind margin within the wing; there is a fold of the integument on the outer surface at the upper part near the front margin; upon this margin there are various setæ; the remainder of the limb resembles the corresponding part of the preceding pair, but with the third and fifth

joints longer, the fourth pair of pcræopods being the longest, while the fifth is the shortest.

Fifth Peræopods.—Side-plates small. Branchial vesicles well developed. First joint of the limb shorter in front than that of the preceding pair, but longer behind, the lower well-rounded lobe being produced considerably below the second joint; the third joint is shorter than the fourth or fifth, with small groups of spines or setæ on both margins; the fourth joint rather longer than the fifth, with the hind margin nearly straight, with an apical group of small spines, and one higher up, the front margin strongly serrate, armed with many groups of long spines; the fifth joint straight, with five sets of small spines behind, and nine or ten groups of spines, large and small, on the serrate front margin; the finger straight.

Uropods.—The peduncles of all three pairs are very long, much longer than the rami, reaching nearly equally far back, the first pair slightly further than the third and the third than the second; they are carinate below and channelled above, with small spines along the upper edges, and in the first pair with setæ at the upper part; the rami are lanceolate, subequal, with the outer margin of the outer and the inner of the inner ramus nearly straight, the other two being more convex, all edged with small spines, and each having a nail at the apex, which seems to be of no very rigid texture.

Telson very small, the length very little exceeding the breadth, the shape almost triangular, with curved sides, cleft for a short distance, the apices rounded, scarcely dehiscent.

Length.—The two specimens are figured in the Plate of the natural size, the larger in the position figured measuring in a straight line from the forehead to the extremity of the third uropods just two inches, with a depth at the third peræon-segment of an inch and a half; the smaller specimen, being extended, measured within the same points over an inch and a half in length, with a depth of seven-tenths of an inch.

Locality.—Station 146, near Marion Island, December 29, 1873; lat. $46^{\circ} 46' S.$, long. $45^{\circ} 31' E.$; depth, 1375 fathoms; bottom, Globigerina ooze; bottom temperature, $35^{\circ} 6$. One specimen (the larger). Trawled.

Station 147, east of Marion Island, December 30, 1874; lat. $46^{\circ} 16' S.$, long. $48^{\circ} 27' E.$; depth, 1600 fathoms; bottom, Diatom ooze; bottom temperature, $34^{\circ} 2$. One specimen (the smaller). Trawled.

Remarks.—The specific name refers to the striking difference in size between this and the earlier known species of the genus, which range from little more than the fifth of an inch down to the tenth of an inch. Boeck's *Andania abyssi*, it may be noted, is reported from depths between 100 and 300 fathoms.

Andania boecki, n. sp. (Pl. XXXVI.).

The head almost concealed beneath the overhanging first segment of the peraeon; the first three segments of the pleon longer than any of the peraeon except the first, their postero-lateral angles not acute, yet scarcely rounded; the second, third, and fourth segments with a transverse dorsal depression, the second and third with small spines along the lower margin; the animal more elongate in proportion to its depth than *Andania gigantea*; the integument showing prismatic hues in spirit, much or all of it covered with hexagonal markings.

Eyes not perceived.

Upper Antennæ.—The three joints of the peduncle very short and thick, the first as long as the other two, the third being shaped as in the preceding species; the flagellum of fourteen joints, the first longer than the rest united and longer than the peduncle, very broad at the base, tapering, bordered with a thick brush of cylinders in about sixty broad rows, serrate towards the distal end and armed with long spines; the other joints have distal rows of spinules; the secondary flagellum is nearly as long as the first joint of the primary, in the channelling of which it is lodged; it is strongly curved, ribbon-like, fringed with setules or spinules, and carrying at the apex some very long spines; there may be a minute second joint.

Lower Antennæ considerably longer than the upper. First three joints very short, gland-cone small, decurrent, blunt; fourth joint longer than the preceding three united, with several setæ on the surface and lower margin; fifth joint more than twice as long as the fourth, thickest at the base, its upper side covered with fine hairs; flagellum of more than twenty-five joints, the first the longest, the distal margins of the first eighteen oblique.

Epistome carinate; upper lip with two unsymmetrical lobes, which in the Plate are folded back, but whether that represents their natural position, I cannot say for certain.

Mandibles.—The cutting edge of great breadth, with a small denticle at the top and with a much smaller just below, and a sort of tooth on the upper margin behind it; the edge itself is scarcely convex, drawn out below into a blunt tooth; the lower margin is cut into fine teeth or serrations for a short space; it then presents a forward-directed tooth, from which a curved beaded line runs up the surface, the margin itself forming two overlapping curves; this applies to what is apparently the left mandible; that which I suppose to be the right is rather shorter, otherwise very similar, but without the prominent tooth of the lower margin, having on the other hand on the surface near the lower apical tooth a curved groove or fold of the integument suggestive of an inchoate secondary plate; moreover, near the inner angle of the lower margin there is a small opening in the integument from within which issues a seta; at the inner corner of the upper margin each mandible has what appears to be an articulating process.

Lower Lip.—The principal lobes very broad, flat-topped, with a large outstanding tooth at the outer corner, with some strong cilia behind it, but the margin immediately in front of it free from cilia; from the outer corner a curved band of long cilia runs across the lobe towards the centre of the base; the inner margin is free from cilia, but has a small projecting process some way down; the mandibular processes are broad, folded as in *Andania gigantea*.

First Maxillæ.—The inner plate having about twenty strongly plumose setæ along the inner margin, some of the lower ones rather longer than the upper; the outer plate as in *Andania gigantea*; the first joint of the palp very short, the second joint with its apex more rounded than in the preceding species, the spines less elongate, and very slightly feathered.

Second Maxillæ similar to those of *Andania gigantea*, the row of longer plumose setæ or spines numbering about five and twenty, set in a sinuous row, the centre part of which is removed from the margin; the shorter spines almost as numerous, plumose below, denticulate above; the narrow outer plate with about twenty spines of different sizes round its distal margin, and two near the middle of the outer margin, of which there is no trace in the other species.

Maxillipeds.—Inner plates broad and inflated, not reaching as far as the distal end of the first joint of the palp, the inner margin and adjacent surface having numerous very long plumose spines, the broad, truncate, indented distal margin also carrying six or seven similar spines, and the series being continued by seven shorter spines round the distal part of the outer margin; the outer plates and palp similar to those of the preceding species; the first joint of the palp has, like the second, apical spines on the outer margin, which in this species is much longer than the inner; the second joint has one or two groups of spines on the outer border besides those at the apex, and the narrow third joint has two or three such groups, the arrangement not being entirely symmetrical. The dorsal cilium of the finger not perceived.

First Gnathopods.—The side-plates in this species agree with those described in *Andania gigantea*. The first joint reaches beyond the side-plate, the front margin fringed with short spines, the hind margin carrying long setæ on the upper part, and a small apical group of spines; the second joint with a few spines on the hind margin and its apex; the third joint nearly rhomboidal, with a few feathered spines on the front and hind margins, many and long on the distal; the wrist triangular, distally cup-like, broader than the hand, subequal to it in length, with long spines round the serrate hind margin, a long row round the distal margin, a long row parallel to this on the outer surface, with a smaller row nearer the base, while on the inner surface there are two long oblique rows; the hand tapers distally, with a somewhat ovate form, the hind margin fringed with finely feathered spines, the front margin having spines at the apex and at two points above it, the inner surface having two longitudinal slightly oblique rows, or

succeession of groups of spines, the outer surface being similarly adorned, but with rather less fulness; the finger slender, short, curved, not nearly half the length of the hand, with a minute dorsal cilium close to the base.

Second Gnathopods.—Branchial vesicles large and inflated. First joint of the limb reaching beyond the narrow side-plate, the upper part narrow for a short space, then making a bend and widening slightly, the front margin almost unarmed, the hinder with long setæ and an apical group of spines; the second with two small groups of plumose setæ on the hind margin and a large group at its apex; the remaining joints similar to those of the first gnathopods, but the third joint is without spines on the front margin, the wrist is narrower, the hand is narrower and longer, the armature of both wrist and hand being slighter, though the same in general character.

First Peræopods.—First joint scarcely reaching beyond the side-plates, the front margin straight, with three small spines near the apex, the convex hind margin carrying long setæ about the centre, and some spines on the lower part; the second joint with four or five setiform spines on the hind margin; the third joint longer than the fourth or fifth, fringed with spines on the hind margin, and carrying some spinules on the adjoining surface, with eight short spines placed along the convex front margin, the apex decurrent, fringed on the inner side with spines; the fourth joint longer than the fifth, fringed behind like the preceding joint, and also having rows of spinules on the surfacee, the front margin carrying four groups of short spines; the fifth joint slightly curved, narrowed distally, with nine groups of short spines along the serrate hind margin and five small groups on the adjoining surfacee, the convex front margin having spinules at five or six points; the finger slender, slightly curved, not half the length of the fifth joint.

Second Peræopods.—Side-plates at the widest point, just below the excavation, very much wider than the two preceding plates together, the breadth and depth subequal. The broad branchial vesicles not extending below the side-plates. The first joint not reaching the lower margin of the side-plate, the long setæ of the hind margin extending to the apex; the limb in general like that of the first peræopods.

Third Peræopods.—Hind lobe of the side-plates the larger, the front one closely fitting into the excavation of the preceding plate. The branchial vesicles of this and the next pair very large. The first joint not dilated, but a little wider above than below, both margins bordered with rather short curved spines, the lower half of the hind margin fringed with very plumose setæ; the four following joints all serrate and fringed with groups of spines in front; the third joint longer than the fourth, subequal in length to the fifth, its hind margin slightly serrate, with seven single spines along it and a group about the decurrent apex; the fourth joint with three groups of spines on the hind margin; the fifth joint slender, slightly curved, with some spinules behind; the finger as in the preceding pair.

Fourth Peræopods.—Side-plates rather broadly and deeply lobed behind. The first
(ZOOL. CHALL. EXP.—PART LXVII.—1887.)

joint expanded, though not very widely, the hind margin almost straight, scarcely serrate, the front margin a little convex, fringed with spines, the inner surface carrying a fringe of long plumose setæ, the lower margin rounded behind, overlapping the second joint; the armature of the following joints very similar to that in the preceding pair, but the fourth joint considerably longer and slightly curved; the fifth joint also much longer, this exceeding the length of the fourth, and the fourth that of the third.

Fifth Peraopods.—Side-plates not very deep. Branchial vesicles well developed. First joint much broader above than below, with the front margin much shorter than the hinder, convex above, straight below, armed with few spines; the hind margin very convex, slightly serrate, the lower lobe greatly overlapping the second joint; the second joint with a distal row of small spines in front; the next three joints much shorter than in the preceding pair; the third joint subequal in length to the fourth and also to the fifth, fringed in front with many small spines and some larger at the apex, carrying five spines on the hind margin, and an apical group; the fourth joint straight, with seven groups of large spines in front, and four of small ones behind; the fifth joint with eight groups of long slender spines in front, and three of spinules behind; the finger very slender, straight, longer than half the fifth joint.

Pleopods.—Coupling spines long and slender, the shafts plumose, the bent apex small, one margin having four, the other three, small retroverted teeth just below the apex. Immediately below the coupling spines, there are some slender acute spines, setiform, plumose. The cleft spines form a series of six; they are long, especially the lower ones, but the arms of the cleft are short, the acute arm being coarsely serrate on the inner side. The peduncles, as usual, are longest in the first pair, shortest in the third; the joints of the rami number about twenty-two on the inner, and about twenty-five on the outer, somewhat curved, ramus.

Uropods.—The peduncles of all three pairs broad and long, those of the first and third pairs reaching slightly beyond those of the second, all of them much longer than the rami, and seemingly all of them carinate and channelled as in the preceding species; the first two pairs have very numerous spines fringing the edges, those on the inner side being the longer; they have also along the centre fringes of long setæ; the peduncles of the third pair seem to be almost unarmed; in each pair the rami are a little unequal, those of the first and second pairs carinate, with many small spines on the edges; those of the third pair are broader but not longer than those of the two preceding pairs, not carinate, carrying but few spines, with the inner edge of the outer and the outer edge of the inner pectinate, while in the other two pairs the outer edge of each ramus is pectinate.

Telson very small, very little longer than broad, the convex sides converging to an almost pointed apex.

Length.—The specimen, in the position figured, measured, from the front of the head to the apex of the third uropods, close upon nine-tenths of an inch.

Locality.—Station 120, off Pernambuco, September 9, 1873; lat. $8^{\circ} 37'$ S., long. $34^{\circ} 28'$ W.; depth, 675 fathoms; bottom, red mud. One specimen. Trawled.

Remark.—The specific name is given in honour of the late Axel Boeck, who instituted the genus *Andania*, and who stands in the very foremost rank among the investigators of the Amphipoda.

Andania abyssorum, n. sp. (Pl. XXXVII.).

Lateral lobes of the head rather prominent; first segment of the pereon as long as the next two united, less overhanging than in the two preceding species; the postero-lateral angles of the first three pleon-segments not acute, a little rounded; the following segments abruptly shallower, the fourth almost concealed beneath the third, the sixth longer than the fifth, with two longitudinal ridges running from the base of the segment to either side of the base of the telson.

No Eyes perceived.

Upper Antennæ.—Peduncle shorter than the flagellum, the first joint very stout, scarcely longer than broad, longer than the two next joints united; the flagellum tapering, of four joints, the first as long as the other three together, rather longer than the first joint of the peduncle, with a brush of cylinders, and at the apex some spinules and a long spine; the narrow, slightly curved, secondary flagellum is not half as long as the first joint of the primary, seemingly one-jointed, with a long subapical spine.

Lower Antennæ.—First joint a little dilated; gland-cone very small; third joint forming an angle with the fourth; fourth rather longer than the fifth; the two together longer than the slender six-jointed flagellum.

Mandibles.—The cutting edge broad, almost straight, with a very minute denticle at the top, but sharply upturned below, with some conspicuous though microscopic denticles; on the inner surface near the lower angle, but connected by a groove with the upper, is a small triangular secondary plate on the right mandible, and some distance behind this on the outer surface there is a seta; on the left mandible there is no secondary plate, but the seta is present, arising from a curved groove on the outer surface.

Lower Lip.—The principal lobes apically narrow, with a small tuft of cilia or setules standing out at about the centre of the apical margin; a band of long cilia appears to cross the surface as in the other two species.

First Maxillæ.—The inner plate carrying seven stout strongly plumose setæ along the inner margin; the truncate distal margin of the outer plate armed with nine denticulate spines, rising amidst very long and spine-like cilia; the first joint of the palp not very short, the second reaching as far as the outer plate, its outer margin convex, its

apex armed with six spines, of which the outermost is minute, but the two adjoining it are very large.

Second Maxillæ.—The inner plate longer and much broader than the outer, with many plumose setæ and spines on the inner margin, probably twenty or thirty in all; the outer plate carrying eight long spines on the truncate apex.

Maxillipeds.—The inner plates not nearly reaching as far as the distal end of the first joint of the palp, the inner margin apically produced into a tooth surmounted by a spine-tooth; the outward sloping distal margin having two smaller processes, each with a small spine-tooth, and the outer corner carrying three spines; the outer plates rather long and narrow, but not reaching the end of the second joint of the palp; the nearly straight, serrate, inner margin fringed with about fifteen short spines; there is one on the almost pointed apex, and a few on the surfaces; the first joint of the palp rather shorter than the second, with two plumose setæ on the inner margin; the second joint with seven setæ on the inner margin and two on the outer apex; the third joint very slender, with some apical spines or setæ; the finger also very slender, slightly curved, shorter than the preceding joint.

First Gnathopods.—Side-plates triangular, deeper than broad, with the front margin curved, and below forming an acute angle with the hinder margin. First joint reaching beyond the side-plate, broader below than above, the front margin fringed with small spines, the lower ones rather longer and plumose; the hind margin carrying many long setæ, and an apical group of spines; the second joint much longer than broad, with some spinules in front and behind, and a group of spines on the hinder apex; the third joint scarcely so long as the second, with a large apical group of spines and some smaller groups on the hind margin; the wrist as long as the hand and much broader, with groups of spines on the hind margin near and about the apex, also with spines at two points of the front margin near the apex, and a large group round the apex, some of these being longer than the hand on one of the gnathopods, though not upon the one figured in the Plate; the hand with the distal portion much narrowed, the serrate hind margin strongly fringed with various spines, one of which near the finger is more strongly plumose than the rest; the front margin is more convex near the base than distally, the two tracts being separated in one of the gnathopods by a group of several spines, in the other by two spines with an interval between them; there are some apical setules on this margin; the finger is slender and curved, not nearly half the length of the hand.

Second Gnathopods.—Side-plates narrow and elongate, the front margin very slightly convex, the hind margin closely interlocking with the following plate, as seems usual in this genus, the lower margin oblique, helping to form the continuous curve from the upper front corner of the first side-plate to the excavation of the fourth. The marsupial plates narrow, with a few setæ round the apex. First joint of the limb narrow, reaching beyond the side-plate, narrowest near the base, then making a bend forwards, with some

long setæ at various points upon the hind margin, the front but slightly curved; the second joint elongate, with long plumose setæ at four points of the hind margin; the third joint much shorter than the second, with a group of apical spines behind; the wrist scarcely as long as the hand, and but little broader, with spines on the lower part and apex of the hind margin, and on the apex of the front; the hand with the front margin almost straight, carrying spines at the apex; the hind margin smooth for a space, then serrate, with many groups of spines, many of those which are near the short strongly curved finger being strongly denticulate; the bending of the hind margin in this hand makes an approach to a palm.

First Peræopods.—Side-plates and branchial vesicles similar to those of the preceding pair, but a little longer, the side-plates also broader. The first joint scarcely reaching beyond the side-plates, considerably broader than that of the second gnathopods, carrying a few spinules on the front margin, and a spine on the hinder apex; the second joint with two setæ on the hind margin and an apical spine; the third longer than the fourth, rather shorter than the fifth, with a spinule on the decurrent front apex and one on the margin a little higher up; the fourth joint slightly curved, each apex pointed; the fifth joint slender, curved, almost unarmed, with a tendency to pectination on the hind margin; the finger very short, curved.

Second Peræopods.—Side-plates very broad, very deep in front, with a small interlocking process near the top of the front margin. Branchial vesicles not very broad, not as long as the side-plates. Marsupial plates much narrower than the branchial vesicles, and about as long. First joint of the limb not reaching the end of the side-plate; the limb in general like the preceding, but the fourth and fifth joints smaller, the third being longer than either.

Third Peræopods.—Side-plates small, the hinder lobe the larger, the front one when *in situ* obscured by the preceding plate. The branchial vesicles oval, not very large. The marsupial plates short, with eleven setæ round the apex. The first joint not expanded, a little narrowed at the centre, with a few spines or spinules on the margins; the second joint, as in the preceding pairs, not so short as usual, with two or three small spines on the front margin; the third joint much longer than the fourth, a little longer than the fifth, with short spines at four points of the very decurrent hind margin, and the same number of spinules on the front; the fourth joint with some microscopic spinules on the straight, apically acute, front margin; the fifth joint a little curved, the front margin finely pectinate; finger nearly half the length of the fifth joint.

Fourth Peræopods.—Side-plates rather deeper than broad, front margin straight, hinder a little convex. Branchial vesicles widening distally. First joint expanded, rather wider below than above, front margin nearly straight, furnished with a few spinules; the hind margin very slightly convex and scarcely serrate, the lower margin smoothly rounded and partially overlapping the second joint; the remainder of the limb similar to

the corresponding part of the preceding pair, but with the third joint still more decurrent, and the fourth and fifth joints rather longer.

Fifth Peræopods.—Side-plates similar to the preceding pair, but smaller. Branchial vesicles small. First joint greatly expanded, longer than broad, its length surpassing that of the next four joints united; the front margin nearly straight, carrying a few small spines, the hind margin serrate, very convex, the lower margin rounded, partially overlapping the short second joint, which has spines at two points of the front margin; the third joint has spines at two or three points in front, and at four points of the hind margin, which is decurrent almost to the apex of the fourth joint; the fourth joint has spines at four points of the front margin, the apex of which is acute; the fifth joint, which is longer than the fourth, but shorter than the third, has a single spine near the centre of the pectinate front margin; the finger is more than half the length of the fifth joint, its inner margin pectinate.

Pleopods.—The coupling spines are very slender, with three or four minute teeth on either side close to the apex; near them is a plumose seta; from a process at the top of the peduncle another plumose seta projects; the first joint of the inner ramus has two cleft spines, in which the branches are nearly equal, the outer, as usual, serrate on its inner margin; the inner ramus has seven, the outer eight joints.

Uropods.—As in the two preceding species, the peduncles appear to be carinate and channelled; the first pair both as regards the peduncles and the rami reaching a very little beyond the second, and the second beyond the third; the first and second pairs, but not the third, have some spines on the edges of the peduncles; all the rami have pectinate edges; in the first pair the longer outer ramus has two spines on the upper part of the outer margin, in the second pair there is but one spine; in the third pair the rami are nearly equal in length to the peduncles, the outer ramus being a little longer than the inner, its distal portion consisting of a nail which is more than a third of the total length.

Telson about as broad as long, very small, not nearly reaching the end of the peduncles of the third uropods, its curved sides converging to an acute apex, which is cleft for about a third of the length of the telson, not dchiscent.

Length.—The specimen, in the position figured, measured, from the front of the head to the back of the second segment of the pleon, one-fifth of an inch.

Locality.—Station 168, off New Zealand, July 8, 1874; lat. $40^{\circ} 28' S.$, long. $177^{\circ} 43' E.$; depth, 1100 fathoms; bottom, blue mud; bottom temperature, $37^{\circ} 2$. One specimen; female. Trawled.

Remark.—The specific name refers to the great depth from which this little creature was obtained, but is principally designed to call attention to its close relationship with the northern species, *Andania abyssi*, Boeck.

Family AMPHILOCHIDÆ, G. O. Sars, 1882.

Boeck in 1876 constituted the Amphilochinæ the second subfamily of the family Leucothoidæ, assigning to it the genera *Amphiloehus*, *Gitana* and *Astyra*; in 1882 Sars changed the subfamily into a family, and added the new genus *Stegoplax*, which is near to the earlier *Cyprloidia*, Haswell, and the still earlier but somewhat obscure *Peltoeoixa*, Catta. Boeck's definition is as follows:—

“Upper Lip much incised at the apex.

“Mandibles strong, not uniform, apically dilated; one mandible with, the other without, an accessory plate (ramo interno); the molar tubercle more or less prominent; the palp three-jointed, elongate.

“First Maxillæ with the inner plate small; the palp generally two-jointed, apically armed with spines.

“Second Maxillæ with the outer plate a good deal narrower than the inner.

“Maxillipeds with the inner plates long, narrow; the outer plates of moderate size or small; the palp more or less elongate; its last joint unguiform.

“The body tolerably deep, thick; the side-plates large.

“Upper Antennæ short, the secondary flagellum absent or small.

“First and Second Gnathopods generally of the same shape, either subchelate—sometimes powerful sometimes feeble—or scarcely subchelate.

“First and Second Peraopods slender, filiform.

“Last three pairs of Peraopods successively longer.

“Uropods biramous; the second pair very short, the outer branch shorter than the inner.

“Telson whole or incised at the apex.”

Genus *Amphiloehus*, Spence Bate, 1862.

For the original definition see Note on Spence Bate, 1862 (p. 333). Boeck defines it as follows:—

“Mandibles with the third joint of the palp as long as the second or longer.

“First Maxillæ with the palp two-jointed; the second joint broad at the apex.

“First and Second Gnathopods with large subchelate hands.”

Remark.—The name of this genus must not be confounded with *Amphiloeus*, the name of a genus of Coleoptera.

Amphiloehus marionis, n. sp. (Pl. XXXVIII.).

Animal compact; first three segments of the pleon with the postero-lateral angles nearly right angles, those of the third segment projecting when the following segments

are ventrally flexed; the sixth segment outdrawn on either side as far as the apex of the telson.

Eyes small, oval.

Antennæ broken.

Upper Lip.—The two distal lobes very unsymmetrical.

Mandibles.—The cutting plate is a rather narrow plate attached as it were by a neck to the trunk of the mandible, having the distal border cut into about ten small teeth; the secondary plate on the left mandible is similar to the principal, but on a smaller scale; the spine-row consists of ten curved dentieulate spines, graduated in size, the larger being near to the cutting plate; the molar tubercle (not shown in the figures *m.m.*) is conical, scarcely if at all dentate; the palp is set far back, its first joint short, the second straight and moderately long, but the two together not equaling the length of the thin, curved third joint, which is a little ciliated at the acute apex.

Lower Lip.—The front lobes distally narrow, armed with strong but short cilia, widely dehiscent; the inner lobes narrow; the mandibular processes short, distally pointed.

First Maxillæ.—Inner plate small, oval, with a single short seta at the apex; outer plate with, I think, seven spines, some of them dentieulate, on the oblique apical margin, together with some spine-like cilia at the inner corner; the palp rather broad, the second joint having four short spines on the truncale distal margin, which is produced into a small tooth at one corner.

Second Maxillæ.—The plates about equal in width, the inner with a few setules or spines at the apex and passing a little way down the inner margin; outer plates damaged in dissection.

Maxillipeds.—Inner plates long and narrow, not reaching the distal end of the first joint of the palp, the inner margin ending apically in a little tooth, besides which the distal margin seems to have two scarcely visible spine-teeth; there are long fine cilia to be made out with difficulty on various parts of the plate; the outer plates are very broad, not reaching the end of the second joint of the palp, with a very few spinules on the surface within the straight, smooth, inner margin; the broad, rounded, distal margin is finely pectinate on the inner part; about the centre it carries a single conspicuous serrate spine, and the outer part is strongly ciliated; the first joint of the palp, which is the longest, has some apical spines on both sides; the second joint has more; the third joint is longer than the second, but narrower, with spines at two points on the outer margin, and many round the serrate distal margin; the finger is short, tapering to a very fine point, its inner margin pectinately fringed with cilia as far as the nail.

First Gnathopods.—Side-plates small, almost concealed by the following pair, the hind margin straight, the front almost semicircular. The first joint equal in length to the hand, with an apical spine on the hind margin, and one or two spinules along the

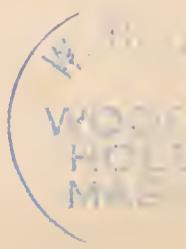

front; the short second joint with one apical spine behind, the rhomboidal third joint with three, and one at the centre of the hind margin; the wrist short, broad, distally cup-like, with nine or ten spines on the inner side of the hind apex, which is produced along the hind margin of the hand, the tips of the spines reaching the palm; the hand large, widest at the palm, the front margin convex, with a submarginal cilium near the centre, a subapical seta and cilium, and rounded apex, the hind margin sinuous, smooth or microscopically downy; the palm broad, convex, finely pectinate, at right angles with the hind margin, having two palmar spines at the commencement, followed by a row of nine submarginal spinules, and two setules close to the hinge; there are a very few slender spines on the surface; the finger is long, a little curved, tapering to an extremely fine point, reaching beyond the palm, the inner margin of the broader half near the base set with about fifteen little spiny teeth.

Second Gnathopods.—Side-plates longer and broader than the first, rather wider below than above, lower margin rounded and slightly erenate as in the two following pairs. The branchial vesicles in this and the following segments small, oval. The marsupial plates very small, and, so far as observed, without setae. First joint of the limb longer than the hand, slightly curved, with a few setules along the concave front margin, the hind margin with an apical spine, the first half of which is broad, the distal half narrow, the corresponding spine on the first gnathopods having probably the same character; the second and third joints resemble those of the preceding pair, except that the third joint has three short but stout spines along its hind margin, the largest near the apex, which has one slender spine; the wrist is distally eup-like, short except for the very long hinder process, the apex of which nearly reaches the palm of the hand and is tipped with three or four spines; the hand resembles that of the preceding pair, but like the rest of the limb is very much larger, the submarginal spinules eighteen in number, the front margin having a little cilium-bearing apical point which is not produced; the finger has twenty teeth, some of which are submarginal but the majority marginal as in the preceding pair; the series ends with a much larger tooth or spine; there is a minute dorsal cilium very far from the base of the finger.

First Peræopods.—Side-plates larger than the preceding pair, but similar. The first joint reaching below the side-plate, carrying some setules on the front margin, and an apical spine on the hinder; the second joint with two setules on the hind margin; the third joint slightly curved, with small spines at four points on each margin, the front margin apically decurrent. The rest of the limb missing, a defect shared by all the peræopods.

Second Peræopods.—Side-plates much broader than the preceding pair, the excavation behind not descending far, the broadest part of the plate just below it. The limb like that of the preceding pair, but the first joint not reaching beyond the side-plate.

Third Peræopods.—The hind lobe of the side-plate deeper than the front. The
(ZOOL. CHALL. EXP.—PART LXVII.—1887.)

branchial vesicles scarcely reaching beyond the hind lobe of the side-plate. The first joint expanded, of nearly even width throughout, but with convex margins, the front fringed with eight small spines, the hinder serrate, carrying cilia; the short second joint has two spines on the front margin; the third has five on the straight front margin, three or four on the hind margin, and a group at its very decurrent apex.

Fourth Peraopods similar to the third, but rather larger.

Fifth Peraopods.—The first joint broader than the preceding, and behind much longer, the hind margin rising above and descending below the front; both margins very convex; the second and third joints similar to those of the fourth pereopods.

Pleopods.—The coupling spines very short, with two strong, lateral, retroverted teeth besides that at the apex; on the peduncle of the third pair there was observed an apical spine; the inner ramus carries apparently only one eleventh spine; the joints of the inner ramus seven in number, of the outer eight.

Uropods.—Peduncles of the second pair as long as the inner ramus, reaching as far as or a little beyond the apex of the telson; the inner ramus much longer than the outer, slender, with three or four spines on either margin, and ending in a sharp nail; the outer ramus more than half the length of the inner, with three spines on the inner margin, not ending in a nail but very acute. The other pairs missing.

Telson not twice as long as broad, the sides a little curved, converging to a pointed apex.

Length.—The specimen, in the position figured, measured, from the top of the head facing forwards to the top of the third segment of the pleon facing backwards, scarcely one-tenth of an inch, a size which may suggest an excuse for the imperfect account of the mouth-organs.

Locality.—Station 145, off Marion Island, December 27, 1873; depth, 100 fathoms; bottom, volcanic sand. One specimen; a female, with eggs.

Remarks.—The specific name refers to the place of capture. A specimen of *Amphilochus* from the Clyde, kindly sent to me by Mr. David Robertson, agrees in most respects with Boeck's description of his *Amphilochus tenuimanus*, and has also a great resemblance to the present species; the maxillipeds in the Seoteh form and in that from the Southern Ocean are remarkably alike, but in the smaller Challenger species the outer plates of these organs are distally broader, and though having the same armature have it differently arranged; the third joint of the mandibular palp is much longer than the second, instead of about equal to it; the finger in each pair of gnathopods is prolonged beyond the palm, and is very different from that of the larger species; there appear also to be differences in the shape of the side-plates, and altogether the sum of the differences, added to the great distance between the localities at which the specimens occur, makes it unsafe to place the northern and southern examples in one and the same species.

Family STENOTHOIDÆ, G. O. Sars, 1882.

Boeck in 1876 constituted the Stenothoinæ the third subfamily of the Leueothoidæ, assigning to it the genera *Stenothoë*, *Metopa*, *Cressa*, and by implication *Danaia*, if that should prove to be distinct from *Cressa*.¹ In 1882 Sars changed the subfamily into a family. Boeck defined the subfamily as follows :—

“ *Upper Lip* apieally cleft.

“ *Mandibles* elongate, apieally broad, dentate, not uniform ; the left mandible with an accessory plate ; the molar tubercle minute or absent ; the palp absent, or long, three-jointed.

“ *Lower Lip* little.

“ *First Maxillæ* with the palp one- or two-jointed ; the inner plate small or wanting.

“ *Maxillipeds* with long palps ; the inner plate very small, the outer almost obsolete.

“ The body compressed, but yet thick ; the first side-plate little, covered ; the rest of the side-plates much increasing in size ; the fourth generally very large, shield-shaped.

“ *Antennæ* moderately elongate ; the upper devoid of accessory flagellum.

“ *First Gnathopods* slender ; hand often not subchelate.

“ *Second Gnathopods* with the hand strongly subchelate.

“ *Third, Fourth, and Fifth Peræopods* of the same shape ; first joint of the *Third* and *Fourth* generally not dilated.

“ *Last Uropods* uniramous ; the ramus two-jointed ; the last joint stiliform.

“ *Telson* small, not cleft.”

Remark.—A rudimentary accessory flagellum is sometimes present on the upper antennæ. The right mandible, at any rate in some species, has a secondary plate, though it is less conspicuous than that on the left mandible.

¹ Spence Bate says that the mandibles in *Danaia* are without a palpiform appendage (Brit. Mus. Cat. Amph. Crust., p. 59; Brit. Sess. Crust., p. 67); the genus *Cressa* of Boeck is distinguished from *Danaia* solely by its possession of a three-jointed mandibular palp; it is therefore worth while to notice that in Spence Bate's British Museum Catalogue, on pl. x., there is a figure of a mandible with a three-jointed palp in close proximity to the figure of *Danaia dubia*; unfortunately the mandible is by some accident unnumbered, but the figure shows it to be of such a character that, unless it belongs to *Danaia*, it cannot belong to any of the species figured on pl. x. It becomes therefore highly probable that the definition of *Danaia* requires amendment, and that *Cressa* of Boeck is a synonym of it, as already on other grounds it has been considered by Sars.

For the original definition see Note on Dana, 1852 (p. 257). Boeck's definition is as follows :—

- " *Mandibles* without palp or molar tubercle.
- " *First Maxillæ* with the palp two-jointed.
- " *Third Peræopods* with the first joint not dilated behind.
- " *Fourth Side-plates* not excavate behind, but much rounded."

Stenothoe adhærens, n. s. (Pl. XXXIX.).

Rostrum and lateral lobes of the head not very conspicuously outdrawn ; the postero-lateral angles of the first and second pleon-segments acute, but not outdrawn, those of the third segment blunt, the fourth segment with a small dorsal depression, the fifth segment very short.

Eyes between round and oval, low down on the sides of the head, the crystal cones very bright ; the figure *oc.* does not show the whole number.

Upper Antennæ.—First joint longer than broad, much broader than the second, as long as the second and third united ; the third not half the length of the second ; the flagellum of seventeen joints, of which the first is longer than the third joint of the peduncle ; they have apical setules and some of them cylinders.

Lower Antennæ.—First joint expanded, second very distinct from the first, gland-conc very small, third scarcely longer than the second, the fourth longer and broader than the fifth, with some small spines and setules on the convex upper, and setules on the straight lower, margin ; both margins of the fifth straight, carrying a few setules ;

flagellum of fifteen joints, of which the first is the longest, all united rather shorter than the peduncle.

Upper Lip.—The distal end unsymmetrically bilobed, the edges not furred.

Mandibles having an appearance as if the front part were folded or a little inflated so that the spine-row while projecting from an inner edge nevertheless rests against the inner unbulged surface. The cutting edge of the left mandible (represented on the right of the Plate) has a broad sinuous edge cut into about eighteen denticles; the secondary plate has a broad edge cut into about a dozen denticles; on the right hand mandible the cutting edge appears to have only seven or eight denticles, but some of these, especially two at the centre, considerably larger than those on the opposite mandible; there appears to be a very thin broad-edged secondary plate, with the edge finely dentate, wearing a striated appearance; the spine-row of ten or eleven spines; molar tubercle and palp absent.

First Maxillæ.—Inner plate with an almost acute apex and a single subapical seta; the outer plate short, carrying six spines on the truncated distal margin, the inner one much shorter than the rest, smooth, the next two long, finely denticulate, the fourth long, smooth, the fifth very slender, the sixth more slender than the fifth; the inner margin almost straight, conspicuously ciliated or edged with spinules; the first joint of the palp as broad as long, the second not twice the length of the first, with two or three spine-teeth on the apex, a subapical seta, and five small spines along the serrate inner margin.

Second Maxillæ not well made out in the specimen figured. A second specimen shows them to be short, the outer plate bending over the very short inner one; the inner plate has four setæ spaced upon its margin, one of them being on the rounded apex; the inner plate has four setæ on its somewhat truncale apex and one on the outer margin, this margin being convex, much longer than the smooth inner margin.

Maxillipeds.—The inner plates minute, elliptic, with two apical setæ, reaching a very little way along the inner margin of the broad second joint, which carries no plate, but appears to be part of the elongate palp, having two apical spines on the outer side, and half a dozen spines or setæ on or near its inner margin; the first joint of the palp rather longer than broad, equal in length to the third, longer than the second, all three carrying a few spines on the inner margin, the third having a long spine on the inner apex, three long ones near the outer apex, and the distal part strongly ciliated; the finger broad at the base, tapering, with the inner margin carrying some ten spine-like cilia, the remaining half narrow, part of it fringed with short cilia, the inner margin being double for a short distance; there are two cilia near the tip.

First Gnathopods.—Side-plates very small, completely covered by the following pair; there are one or two setules on the front margin; the lower margin not projecting on either side of the first joint. The first joint entirely clear of the side-plate, equalling

in length the third, fourth, and fifth joints united; it has some setæ along the front margin, and a short apical seta on the hinder; the short second joint has two small spines or setules on the hind margin; the third joint is longer than the wrist, which it overlaps, subequal to the hand, its free front margin very short, the hind margin straight, carrying three spines, a little furred below; the rounded apical margin carrying a group of spines; the wrist triangular, distally cup-like, with an apical group of spines behind; the hand with a convex front margin much longer than the hind margin, which carries short stout spines at two points, and a third group at the commencement of the broad, oblique, finely pectinate palm, which is fringed with a few submarginal setæ; the finger is broad almost to the end, which is sharp, closing down upon the palmar spines; it has two dorsal cilia near the centre, the dorsal margin being much more convex than the finely pectinate inner margin.

Second Gnathopods much larger than the first. Side-plates large, almost semi-circular. The branchial vesicles sac-like, much smaller than the side-plate. Marsupial plates very large, very broad, and very thin. First joint reaching beyond the side-plate, a little longer than the hand, distally widened and curved slightly forwards, with some spines on the hind margin; the second joint short, with one or two setules on the hind margin; the third joint short, with no free front margin, the hinder apically acute; the wrist short, cup-like, with a group of spines on the ciliated hinder apex; the hand large, not twice as long as broad, with a few spines on the basal half of the front margin; the hind margin continuous with the convex palm, which is but slightly toothed or indented, the chief prominence being a small one near the hinge of the finger; the finger is very long and broad, its apex passing beyond the palmar spines and resting against the surface of the hand just within the margin; its inner edge is smooth, with one or two cilia and a small decurrent tooth preceding the sharp apex.

First Peræopods.—Side-plates very broad, rather broader below than above, the hind margin longer than the front, the lower margin convex. Branchial vesicles pear-shaped, nearly as long but not nearly so wide as the side-plates. Marsupial plates smaller than the preceding pair. The first joint of the limb scarcely reaching beyond the side-plate, with spines along the front margin and lower part of the hinder; as in the preceding pair, this joint is distally lobed in front on two edges; the second joint is short, with a spine or two on the hind margin; the third is longer than the fourth, about equal to the fifth, with five spines on the front margin, and a group on its decurrent apex, some spinules in front and an apical spine; the fourth joint has spines at five points of the straight hind margin; the fifth joint is curved, and carries some seven groups of spines on the concave hind margin, the accessory thread in these and many of those previously mentioned arising at the centre of the spine; there are spinules or setules at four points of the hind margin; the finger is short and curved, little more than half the length of the fifth joint.

Second Peræopods.—Side-plates very large, broader than deep, the front margin but little convex, the upper and lower margins roughly forming with it a very much rounded triangle. The first joint not nearly reaching the end of the side-plate; the limb in general like that of the first peræopods, the third joint with three spines on the hind margin, four on the front, and an apical group.

Third Peræopods.—Side-plates small, rather deeper behind than in front. Branchial vesicles broad, broadest about the centre. First joint evenly wide, not expanded, much narrower than the branchial vesicles, with spines on both margins; the short second joint with two or three spines on the front margin; the third joint longer than the fourth or fifth, not very much shorter than the first, with five or six sets of spines on the straight front margin, and six spines along the convex hind margin, besides a small group on the blunt, very deurrent apex; the fourth joint with four groups of spines on the straight front margin, and a spinule at the apex of the hinder margin, which is almost completely overlapped by the preceding joint; the fifth joint curved, longer than the fourth, with five groups of spines in front, some spinules behind; the finger curved, more than half the length of the fifth joint.

Fourth Peræopods.—Side-plates small, lobed behind. Branchial vesicles sharply bent. First joint widely and evenly expanded, with spines at six points of the front margin, and some others within the margin, the hind margin very slightly erenate; the rest of the limb resembling the preceding pair, but exceeding it in size.

Fifth Peræopods.—Side-plates smaller than the preceding. The first joint larger than in the preceding pair, not evenly expanded, the breadth contracting below, and the lower lobe behind much overlapping the second joint; the rest of the limb similar to the preceding pair.

Pleopods.—Coupling spines very slender, much bent at the apex, with one or two lateral teeth; the peduncles narrow, the rami closely interlocked at their bases; a single cleft spine on the inner ramus; joints of the rami numbering from ten to fourteen.

Uropods.—Peduncles of the first pair longer than the rami, fringed with spines; the rami nearly equal, the outer a little the longer, both pectinate on the upper edge, apically acute, carrying a few marginal spines; the peduncles of the second pair equal in length to the longer ramus; the rami apically pointed, pectinate on the edges, the inner ramus with four, the shorter outer with three marginal spines; the peduncles of the third pair about equal in length to the ramus, carrying stout marginal spines; the single ramus with two spines at the apex of the broad proximal portion, the tapering nail not forming quite half of the ramus.

Telson twice as long as broad, each lateral margin at the upper part carrying four stout spines, the two margins curving to an almost pointed apex with a small cilium on either side of it, the surface carrying two large cilia midway between the apex and the lowest marginal spines.

Length.—The specimen, in the position figured, measured, from the front of the head to the back of the third pleon-segment, less than one-fifth of an inch. A second specimen, with numerous eggs, was slightly smaller.

Locality.—Station 142, off Cape Agulhas, December 18, 1873; lat. $35^{\circ} 4'$ S., long. $18^{\circ} 37'$ E.; surface temperature, $65^{\circ}\cdot 5$. Two specimens, both females.

Remarks.—The specific name refers to the capture of the specimens while adhering to the screw of the vessel.

Almost every part of the animal showed a number of little packets of cells, crystalline in appearance, embedded in brown matter, which I suppose to be pigment-cells; it is to these that figure *p* refers. The general effect produced was a series of transverse, somewhat broken, lines of colouring, increasing in breadth towards the lower margins of the large side-plates.

For the original definition, see Note on Boeck, 1870 (p. 400). Boeck only gives two characters to distinguish this genus from *Stenothoe*, the three-jointed mandibular palp and the one-jointed palp of the first maxillæ; of these the latter must be withdrawn, since some species of the genus clearly have the palp of the first maxillæ two-jointed. Boeck apparently depends on Krøyer for the description both of *Leucothoë clypeata*, Krøyer, which he makes the type of the genus *Metopa*, and of *Leucothoë glacialis*, Krøyer, which he calls *Metopa glacialis*. Though Krøyer assigns a one-jointed palp to the first maxillæ

of the former, to the latter, as Boeck recognises, he attributes a two-jointed palp. Boeck unfortunately leaves the first maxillæ undescribed in all the other seven species which he places in the genus *Metopa*.

Metopa nasutigenes, n. sp. (Pl. XL.).

Rostrum wanting, lateral lobes of the head very inconspicuous; the postero-lateral angles of the first three pleon-segments not rounded, but not very acute.

Eyes round and bright, placed rather high up on the head; the ocelli not numerous, bright.

Upper Antennæ.—The first joint nearly twice as long as the two following united, excavate beneath and distally prolonged to a point forming a cap over the second and two-thirds of the third joint; the second joint thicker and longer than the third; the flagellum scarcely longer than the peduncle, consisting of ten slender joints, which have some apical cilia and long cylinders.

Lower Antennæ.—First joint a little inflated, gland-cone broad-pointed, third joint short and curved, fourth joint scarcely as long as the fifth, both slender; the flagellum of eight slender joints, not quite so long as the peduncle, nor yet so long as the flagellum of the upper antennæ.

Mandibles.—The cutting edge broad, with a denticle at the top, below this a smooth rim, and below this an angled piece cut into six or seven teeth or denticles; the secondary plate short, with a rather broad edge, finely denticleate; the spine-row of nine short curved spines in two detachments of three and six; a small process rises close to the base of the palp; the first joint of the palp longer than the third; the second more than twice as long as the first, with two slender spines or setæ on the inner margin and a longer one at its apex; the very short and narrow third joint is tipped with a spine more than twice its own length. The mandible here described, and figured in the Plate on the left, is the right mandible, the secondary plate and spines showing through the outer surface.

First Maxillæ.—Inner plate very small; outer plate short, with six spines on the trunecate apex, one very short, of the rest the outermost almost setiform, the innermost finely pectinate, the intermediate ones with more or fewer lateral denticles; the palp broad, two-jointed, with three small spine-teeth on the distal part of the inner margin, two on the apical margin with some intermediate spinules, and two submarginal setæ.

Second Maxillæ.—The inner plate shorter than the outer, with three setules at intervals on the inner margin, and three slender spines on the almost pointed apex; the outer plate widest distally, with nine long and three short spines round the serrate apical margin, those on the outer slope being the shortest.

Maxillipeds.—The inner plates short and rather broad, with convex outer margins,
(ZOOLOGICAL EXP.—PART LXVII.—1887.)

not reaching halfway up the second joint, the inner margin ending in a small apical tooth, on the outer side of which, not projecting beyond it, is a small spine-tooth, and beyond this at the outer corner a slender seta; the large second joint is produced into a small almost conical plate about halfway along the first joint of the palp, with a spine at its apex, and a series of six or seven smaller spines along the inner margin of the joint; the first three joints of the palp are together but little longer than this joint; the first is rather longer than the second, and equal in length to the third; the spines on these joints are few; the finger is nearly as long as the third joint, broad at the base and narrow towards the end, with the inner margin pectinate like the corresponding finger in *Stenothoe adhærens*.

First Gnathopods.—Side-plates very small, convex in front, not quite concealed by the following pair. First joint attached at the lower end of the side-plate, not quite so long as the third, fourth, and fifth joints united, with two setæ about the middle of the front margin, and some apical cilia on the hind margin; the second joint short; the third as long as the wrist, with no free front margin, the hinder furred, the apex carrying a group of spines, of which one is much more conspicuous than the rest in size and pectination; the wrist is much shorter than the hand, distally squared, rather eup-like, with a spine on the hind margin like that at the apex of the preceding joint, besides two or three others not showing the same pectination; the hand is long and narrow, with a bend near the base of the front margin, which below the bend carries four spines and some apical setæ; the shorter hind margin is nearly straight, the proximal half naked, below which are four setæ, at the fourth of which begins a series of palmar spines, a single one followed by two pairs; the finger closing over the very oblique convex palm reaches with its tip the base of the second pair of spines; the palm shows very fine pectination, and is bordered by a few submarginal setæ and setules.

Second Gnathopods.—Side-plates more than twice as long as broad, the hind margin nearly straight, with some small spines in the serrations of the lower end, the front margin meeting the hinder with a continuous curve. Branchial vesicles so short and narrow as to seem rudimentary, unless accidentally aborted in the present specimen. The marsupial plates narrow, with ten or twelve setæ around the distal part. The first joint of the limb not reaching the end of the side-plate, equal in length to the third, fourth, and fifth joints together, with several setæ at the lower end of the front margin; the second joint with a small apical group of spines on the hind margin; the third joint shorter than the wrist, with a group of spines at the apex of the hind margin, and one spine higher up; the wrist much shorter than the hand, distally eup-like though narrow, both margins convex, the hind part produced beyond the front, furred, with an apical group of spines; the hand three times as long as broad, almost parallel-sided, a little widened at the palm, which is defined by one pair of spines, and along its margin has a second pair, together with a seta and some setules, all submarginal at their origin, the actual

palm-rib being almost smooth; the hind margin carries two or three setæ, the front two apical cilia; the finger with its point scarcely reaches the defining palmar spines; the dorsal cilium is near the base.

First Peræopods.—Side-plates nearly three times as long as broad, carrying spinules at the lower part of the hind margin. Branchial vesicles shorter than the first joint, much narrower than the side-plates. Marsupial plates longer but narrower than the branchial vesicles, with a few setæ round the lower part. The limbs like all the other peræopods, very slender; the first joint not reaching the end of the side-plate, the lower part of the front margin fringed with setæ; the third joint longer than the fourth or fifth, with setules at five points of the hinder, and two of the convex, slightly decurrent, front margin; the fourth joint shorter than the fifth; the finger more than half the length of the fifth joint, a little curved towards the acute tip; a dorsal cilium very near the base.

Second Peræopods.—Side-plates very deep, but broader than deep, forming as it were a triangle with the sides curved and the apex rounded off, reaching back to the pleon; the limb nearly as in the preceding pair; part of the third joint covered by the side-plate.

Third Peræopods.—Side-plates very small, not bilobed. Branchial vesicles scarcely longer than the side-plate, twice as long as broad. Marsupial plates a little longer than the branchial vesicles. The first joint not expanded, a little narrowed in the middle, with an apical spine on the apex of the front margin; the second joint with three spines along the front margin; the third joint with five in front and two behind; the fourth joint shorter than the third or fifth, with spines at two points in front and one at the apex behind; the fifth joint shorter than the third, with spines at three points in front, and setules at two points behind; the finger much more than half the length of the fifth joint.

Fourth Peræopods similar to the preceding, the first and second joints rather shorter, the remaining rather longer, the second and third with a spine or two less.

Fifth Peræopods.—The side-plates less deep; the limb similar to the preceding pair, but with the first four joints rather shorter.

Pleopods.—Coupling spines very short, straight, the apex forming a pair of teeth, with a lateral pair below; there appears to be only one cleft spine, long, with long unequal arms, placed at about the centre of the long first joint of the inner ramus; the joints of the rami numbering from eight to nine.

Uropods.—Peduncles of the first pair longer than the rami, the upper margin pectinate, carrying an apical spine; the rami (on one side of the specimen) equal (on the other with the inner shorter, less slender), acute, with pectinate margins, the outer with three, the inner with two, spinules; the peduncles of the second pair longer than the rami, with marginal spines on one of the upper edges, the rami similar to the preceding pair but shorter, the inner ramus with only one marginal spinule; the peduncles of the

third pair not much longer than the proximal division of the ramus, which carries three marginal spines, and is itself not much larger than the second joint or nail; these uropods reach back a little beyond the telson, but not so far as either the second or third pairs.

Telson long, more than twice as long as broad, with an acute apex.

Length.—The specimen, in the position figured, measured, from the front of the head to the apex of the first uropods, less than one-fifth of an inch.

Locality.—Station 149H, Cumberland Bay, Kerguelen, January 29, 1874; depth, 127 fathoms; bottom, volcanic mud. Three specimens.

Remarks.—The specimen described is a female.

The species is very like *Metopa nasuta*, Boeck, which also has the large beak or nose formed by the first joint of the upper antennæ. Hence the specific name is a hybrid, to express "of the lineage of *nasuta*." In Boeck's species, the beak of the upper antennæ does not quite reach the end of the second joint; the maxillipeds have the second joint only as long as the two following joints, and the finger much shorter than the preceding joint; the first gnathopods have the hand narrow and not subchelate; the second gnathopods and the peræopods have not the same proportions as in the Challenger species; for instance, in *Metopa nasuta* the fifth joint of the fifth peræopods is described as equalling in length the two preceding joints.

Metopa magellanica, n. sp. (Pl. XLI.).

Rostrum and lateral angles of the head inconspicuous; first three segments of the pleon with the points of the postero-lateral angles not produced; the fourth segment with a slight dorsal depression.

Eyes round.

Upper Antennæ.—First joint thicker but not much longer than the second; the third rather more than half as long as the second; the flagellum slender, tapering, rather longer than the peduncle, consisting of thirteen joints; there is a rudimentary two-jointed secondary flagellum, but it must not be supposed that this is as obvious in the specimen as it appears in the figure, where it is isolated from the numerous markings that are visible on and beneath the surface.

Lower Antennæ longer than the upper; first three joints very short, gland-cone very small; fourth joint long and slender, rather thicker and a little shorter than the fifth; the flagellum of eight joints rather shorter than the fifth joint of the peduncle; but perhaps one or two joints of the flagellum may be missing.

Upper Lip with the distal margin unsymmetrically bilobed.

Mandibles.—The cutting edge rather broad and angular, divided into ten denticles,

the upper five very small, the lower rather larger, the lowest but one flat-topped, perhaps accidentally; the secondary plate similar with fewer teeth, but neither were these nor the spine-row well made out; the palp with the first joint short, yet nearly as long as the third, the second joint long, with setæ on the upper part; the conical third joint with two apical setæ. The opposite mandible probably with the usual differences.

Lower Lip.—Mandibular processes apically rounded.

First Maxillæ.—Inner plate small, elliptical; outer plate strongly ciliated on the inner edge, the truncate distal margin carrying five spines, the two innermost long and slender, with a very short one submarginal by their side, the third slender, the fourth much stouter, the fifth the slenderest of all, these latter three being shorter than the first two; the palp, which is certainly two-jointed, has five spinules on the dentate oblique apical margin, and two setæ on the surface, of the second joint.

Second Maxillæ.—The inner plate shorter than the outer, with five or six slender spinules and spines distributed upon the inner and apical margins; the outer plate having about nine spines, chiefly on the rounded apex.

Maxillipeds.—The inner plates reaching halfway along the inner margin of the following joint, the apical margin sloping a little outwards and carrying two setules, the inner shorter than the outer; the second joint produced on the inner side into a small rudimentary plate with a seta at its apex; five or six more small setæ are distributed on or near the rest of the margin; the first and second joints of the palp are subequal, together scarcely longer than the preceding joint; the third joint rather longer than the second, armed like the two preceding joints with a few slender setæ or spines, and having the distal margin ciliated and produced over the base of the finger; the finger long, rather broad at the base, but rapidly narrowing, strongly ciliated or spined on the inner margin.

First Gnathopods.—The side-plates small, almost concealed by the following pair, the hind margin longer than the front, the lower oblique. The first joint attached at the lower extremity of the side-plate, subequal in length to the hand and wrist united, the front margin fringed with setæ, of which there are also a very few on the hind margin; the second joint has two apical spines behind; the third joint much longer than broad, narrowing to the blunt apex, which carries a group of spines, much of the hind margin furred; the wrist not quite so long as the hand, distally squared, the hind margin much shorter than the front, fringed with a few bent spines; some spines also on the surfaces, especially the inner; the front margin of the hand much longer than the hinder, the long, very oblique, finely pectinate palm defined by a pair of spines at the widest part of the hand; these are reached by the point of the long finger, which closes over a series of spinules and a second pair of spines; there are a couple of setæ on the hind margin, four or five crossing the inner surface diagonally, and others near the front margin, of which one pair are long; the dorsal cilium of the finger is near the base.

Second Gnathopods.—Side-plates almost semicircular. Branchial vesicles very small, much shorter than the first joint. Marsupial plates very broad, rounded, much shorter than the side-plates, very much broader than the first joint, with several long marginal setæ. The first joint reaching beyond the side-plate, about equal in length to the wrist and hand, carrying setæ on both margins; the second joint with some apical setæ behind; the third joint as long as the wrist, produced behind to a sharp apex, with a group of setæ above it and a row of three setæ higher up on the hind margin; the wrist much shorter than the hand, triangular, distally cup-like, the hind margin furred, the blunt apex carrying seven or eight spines; the front margin of the hand more than twice the length of the hind margin; the hand widest at the commencement of the very long and very oblique convex palm, along the commencement of which runs a row of spines set closely together, the remainder of the palm being fringed with some setules of various sizes; the curved finger, besides the dorsal cilium near the base, and one or two at the base of the nail, has four or five hairs along the otherwise smooth inner margin.

First Peraopods.—Side-plates broader above than below, both front and hind margins nearly straight. Branchial vesicles small, pear-shaped, not so long as the first joint of the limb. Marsupial plates very broad, not very long. First joint reaching below the side-plates; many setæ, some of them long ones, on the front margin, chiefly on the lower half; the third joint curved, longer than the fourth, equal to the fifth, a little decurrent in front; these joints have a few small spines and spinules on the margins; the finger long, thin, pointed and curved, more than half the length of the fifth joint.

Second Peraopods.—The side-plates of about equal depth and width, rounded behind. The branchial vesicles rather larger than the preceding pair; neither first nor second joint of the limb reaching below the side-plate; the third joint longer than either the fourth or fifth; the fifth longer than the fourth, each with four pairs of spines on the hind margin; the finger, like the rest of the limb, stouter than in the preceding pair, more curved; the inner margin smooth.

Third Peraopods.—Side-plates small, lobed behind. Marsupial plates very small. First joint not expanded, with a few spinules on the margins; third joint longer than fourth or fifth, with small spines at seven points of the front, and six of the slightly decurrent hind margin; fourth joint shorter than the fifth, with three groups of spines on the front margin; fifth joint with four groups; finger much more than half the length of the fifth joint.

Fourth Peraopods.—Side-plates similar to the preceding pair, but smaller. First joint of the limb ovoid, not much narrowed at either end, the sides almost entirely smooth; the rest of the limb scarcely differing from the preceding; the fourth joint has four groups of spines on the front margin.

Fifth Peraopods.—Side-plates small. First joint more dilated than in the preceding pair, with six or seven spinules on the front margin, the rounded lower margin behind overlapping the second joint; the rest of the limb as in the preceding pair.

Pleopods.—Coupling-spines very short and small, with an apical pair of teeth and a lateral pair; a single cleft spine below the centre of the first joint of the inner ramus; joints of the rami numbering from seven to nine.

Uropods.—Peduncles of the first pair not quite so long as the rami; the rami equal, the inner with two, the outer with three marginal spines; peduncles of the second pair shorter than the inner ramus; the outer ramus much shorter than the inner, each with pectinate upper edge, and two marginal spines; the peduncle of the third pair equal in length to the basal portion of the ramus, which is considerably longer than the apical portion or nail, and carries three marginal spines.

Telson not quite reaching the end of the peduncle of the third uropods, twice as long as broad, flat at the base, the sides almost parallel to below the centre, armed each with three spines, the lowest of which is the largest, then converging rapidly to an almost acute apex.

Length.—The specimen, in the position figured, measured, from the front of the head to the back of the third pleon-segment, three-twentieths of an inch.

Locality.—Station 313, off Cape Virgins, Patagonia, January 20, 1876; lat. $52^{\circ} 20' S.$, long. $67^{\circ} 39' W.$; depth, 55 fathoms; bottom, sand; bottom temperature, $47^{\circ} 8$. One specimen; female. Trawled.

Remark.—The specific name alludes to the place of capture, the neighbourhood of the Strait of Magellan seeming to be particularly prolific in small species of Amphipoda.

Metopa crenatipalmata, n. sp. (Pl. XLII.).

Rostrum and lateral angles of the head inconspicuous; the first three segments of the pleon with the points of the postero-lateral angles not produced; the fourth segment with a slight dorsal depression.

Eyes round.

Upper Antennæ.—First joint thicker than the second but scarcely as long; third joint not half as long as the second; the flagellum of about twelve joints, the first as long as the third joint of the peduncle; apparently a rudimentary secondary flagellum is present.

Lower Antennæ longer than the upper. First three joints very short, gland-cone very small; fourth joint rather thicker and a little shorter than the fifth; the flagellum of eight joints longer than the fifth joint of the peduncle; the first joint of the flagellum

considerably longer than any of the others; one or two of the terminal joints apparently missing.

Upper Lip with the distal margin unsymmetrically bilobed.

Mandibles.—The cutting edge in one of the mandibles with four small denticles at the top and five larger ones below, in the other mandible with four small denticles above and four below, and three larger in the centre; the secondary plate and spine-row not clearly made out; the palp as in *Metopa magellanica*.

Lower Lip, *Maxillæ*, and *Maxillipeds* similar to those of *Metopa magellanica*, but in the present species, the first joint of the maxillipeds is much larger in proportion to the second joint than in the species just mentioned.

First Gnathopods.—Side-plates small, almost concealed by the following pair, broader above than below, with two spinules on the lower part of the front margin. The first joint attached at the lower end of the side-plate, fringed with setæ on both margins, a little widened distally, not equal in length to the hand and wrist united; the second, third, and fourth joints much as in *Metopa magellanica*, but the third joint, of which the lower part is furred, is broader in proportion to its length, while the wrist is narrower; the apical spines of the third joint are six in number, of which one is short, two are much longer, slender, geniculate, with accessory threads, and the other three are of unequal size but all feathered; there is similar variety in the spines on the hind margin and apex of the wrist, which is almost as long as the hand and rather broader, and has several spines on the surface; the hand resembles in armature that in *Metopa magellanica*, except that its palm-margin is finely crenulate instead of pectinate, the hind margin is longer and the palm proportionately shorter than in that species; the finger is finely pectinate on the inner margin, which forms a small denticle at the base of the nail, where there are two cilia, of which three more are spaced along the margin.

Second Gnathopods.—Side-plates tending to a semicircular form, but with the lower part much broader than the upper. Branchial vesicles as in *Metopa magellanica*. The marsupial plates long and broad. The first joint reaching beyond the side-plate, as long as the wrist and hand united, with setæ on the margins; the second joint short, with setæ at two points of the hind margin; the third joint as long as the short wrist, with setules at one or two points of the hind margin and a group of slender spines at its blunt apex; the wrist as in the preceding species; the hand broad, the front margin not twice as long as the hinder, which has setules at four points and is apically produced into a sharp tooth defining the palm; within this process are set two palmar spines, between which the nail of the very broad finger closes down against the process; the palm-border is crenulate in two divisions and fringed with spinules or setules; the inner margin of the finger is smooth, and much less convex than the outer; it has a dorsal cilium near the hinge and cilia at the base of the nail.

First Peræopods.—Side-plates broader below than above, front and hind margins

nearly straight. Branchial vesicles pear-shaped, much broader below than above, not as long as the first joint. Marsupial plates broad and long. First joint reaching a little beyond the side-plate, with setae and setules along the margins; third joint longer than the fourth, shorter than the fifth, a little decurrent in front; there are a few setules and spinules on the margins and apices of these joints; the finger long, thin, pointed and curved, more than half the length of the fifth joint.

Second Peræopods.—Side-plates rather deeper than broad. Branchial vesicles pear-shaped, bent, as long as the first joint. Marsupial plates broad, not as long as the side-plates. Neither first nor second joint reaching the end of the side-plate; the third joint longer than either the fourth or the fifth; the fourth shorter than the fifth, each with four groups of spines on the hind margin; the finger broad, shorter than in the preceding pair, much curved at the tip, with the inner margin a little serrate.

Third Peræopods.—Side-plates deeper than broad. Branchial vesicles short, widest just below the neck. First joint of the limb not expanded above, but forming a rounded lobe below and behind which partially overlaps the second joint, with nine spinules on the hind margin, and five or six on the lower half of the front; second joint with spines at two points in front; third joint much broader as well as longer than the fourth or fifth, with spines at six points in front, and spinules at as many on the convex decurrent hind margin; the fourth joint shorter than the fifth, each with spines at four points of the front margin; the finger much more than half the length of the fifth joint, curved at the tip, the inner margin smooth.

Fourth Peræopods.—Side-plates similar to the preceding pair, but smaller. First joint evenly expanded or a little wider above than below, with a few spines along the front margin, the hinder almost completely smooth, the rounded lower margin partially overlapping the second joint behind; the third and fifth joints rather larger than in the third peræopods.

Fifth Peræopods.—The side-plates smaller than the preceding pair. The first joint wider than in the preceding pair, and behind quite overlapping the second joint; the third joint shorter in front than in the fourth pereopods; the finger with serrate inner margin.

Pleopods.—Coupling-spines seemingly minute; a single cleft spine on the inner ramus; joints of the rami seven to nine in number.

Uropods.—Peduncles of the first pair rather longer than the rami, with spines on the pectinate upper edges; inner ramus a little shorter than the outer, with two marginal spines, the outer with three, both with the upper edges pectinate; peduncles of the second pair subequal in length to the inner ramus; the outer ramus much shorter than the inner, with one marginal spine, the inner with two, both with pectinate upper edges; peduncles of the third pair a little shorter than the ramus, with four spines along the margin; the basal portion of the ramus shorter than the nail, carrying two spines on the upper margin, the upper edge of the nail pectinate.

Telson long oval, not nearly reaching the end of the peduncles of the third uropods, flattened at the top, with a rounded point at the apex, with three spines on each margin, the largest and lowest of which is a little below the centre.

Length.—The specimen, in the position figured, measured in a straight line from the front of the head to the back of the third pleon-segment, one-fifth of an inch.

Locality.—Station 313, off Cape Virgins, Patagonia, January 20, 1876; lat. $52^{\circ} 20'$ S., long. $67^{\circ} 39'$ W.; depth, 55 fathoms; bottom, sand; bottom temperature $47^{\circ} 8$. One specimen, female. Trawled.

Station 135c, off Nightingale Island, Tristan da Cunha, October 17, 1873; depth, 100–150 fathoms. One specimen, female, smaller than that from Station 313.

Remarks.—The careful comparison of the specimen from Station 313, point by point, with *Metopa magellanica*, from the same station, makes it clear that, in spite of some general resemblance, the two forms are specifically distinct.

The specific name alludes to the palm-margin of the second gnathopods.

Metopa parallelocheir, n. sp. (Pl. XLIII.).

Rostrum obsolete, lateral lobes of the head not very prominent; postero-lateral angles of the first three pleon-segments not acutely produced.

Eyes round, rather high up on the sides of the head.

Upper Antennæ.—First joint longer and thicker than the second; third joint about half the length of the second; flagellum of eight joints, together shorter than the peduncle, but one or two joints are probably missing; accessory flagellum rudimentary, very thin, two-jointed, tipped with setules, scarcely half as long as the first joint of the primary flagellum.

Lower Antennæ longer than the upper. First two joints very short, the third longer; the fourth and fifth elongate, the fifth more so than the fourth, both with several marginal setules; the flagellum of nine joints, together scarcely as long as the fifth joint of the flagellum, the first joint as long as the four following and much broader, its width irregular, one margin serrate and carrying setules at four points.

Upper Lip with the distal margin unsymmetrically bilobed.

Mandibles, so far as observed, agreeing with those of *Metopa crenatipalmata*.

Lower Lip.—The mandibular processes rather narrow.

First and *Second Maxillæ* not materially different from those of the two preceding species.

Maxillipeds like those of *Metopa crenatipalmata*, but with the inner plates shorter, and with two setæ close together on the apex of the rudimentary outer plate.

First Gnathopods.—Side-plates small, almost concealed. First joint shorter than the

hand and wrist united, narrow at the point of attachment, then evenly wide, with one seta at the middle of the front margin, and a few minute setules; the rest of the limb almost as in *Metopa erenatipalmata*, but with fewer spines on the inner surface of the wrist and hand, and the palm of the hand almost smooth.

Second Gnathopods.—Side-plates broad, the hind margin a little sinuous, the lower margin convex. Branchial vesicles very small, pear-shaped, much broader below than above. First joint of the limb nearly as broad, but scarcely longer than the hand, with small setules on the front margin, the hind margin having only an apical spinule; the second joint armed only at the hinder apex; the third joint having one or two spines or spinules on the hind margin and a small group on the bluntly-pointed apex; the wrist not longer than the third joint, distally cup-like, but narrow, furred behind, and carrying a couple of spines on the apex; the hand long and narrow, almost parallel-sided, with four setules on the hind margin, which is produced into a tooth at the palm, near to which is a group of palmar spines, among which the tip of the finger closes down, not reaching the process of the hind margin; the palm margin comparatively short, but oblique, set with numerous spinules, apparently quite smooth; the finger much curved, not very long, its inner margin seeming to be quite smooth; the dorsal cilium near the base.

First Peraopods.—Side-plates evenly oblong, not broader than the preceding pair. Branchial vesicles larger than the preceding pair, of more even width throughout, bent near the base. First joint reaching beyond the side-plate, the limb in general scarcely differing from the corresponding limb in *Metopa erenatipalmata*.

Second Peraopods.—These are similar to those in the species just named, with trifling differences of detail; the inner margin of the finger is smooth, not serrate.

The Third, Fourth, and Fifth Peraopods closely resemble those pairs in *Metopa erenatipalmata*; there is, however, more crenulation of the hind margin of the first joint of the fourth and fifth pairs in the present species, and the finger of the fifth pair has a smooth inner margin.

The Pleopods appear to agree with those of the preceding species, or to have a joint or two less in the rami.

Uropods.—Peduncles of the first pair longer than the rami; the rami of equal length, the outer with two marginal spines, the inner with one, both with the upper edges pectinate; peduncles of the second pair not quite so long as the inner ramus; the outer ramus much shorter than the inner, without spines, the inner ramus with one spine, both with pectinate upper edges; the peduncles of the third pair not so long as the ramus, the proximal portion of which is longer than the apical, and carries a small spine on the inner margin and two spines at its apex; the upper edge of both portions pectinate.

Telson similar to that of the preceding species, rather narrower, with two spines on the upper half of each lateral margin.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the back of the third pleon-segment, scarcely more than one-tenth of an inch.

Locality.—Station 313, off Cape Virgins, Patagonia, January 20, 1876; lat. $52^{\circ} 20' S.$, long. $67^{\circ} 39' W.$; depth, 55 fathoms; bottom, sand; bottom temperature, $47^{\circ} 8$. The specimen was obtained, with perhaps one or two more, associated with *Metopa erenatipalmata*.

Remarks.—This species in many respects closely resembles *Metopa erenatipalmata*. Had the latter been the male, and the present specimen a female, the differences might have been regarded as merely sexual, but the species named *Metopa erenatipalmata* has the hand of the second gnathopod both stronger and more ornate than that found in *Metopa parallellocheir*.

The specific name alludes to the almost parallel sides of the hand in the second gnathopods, which give it a peculiarly straight and stiff appearance that is characteristic.

Metopa ovata, n. sp. (Pl. XLIV.).

Rostrum inconspicuous, lateral lobes of the head little prominent; the postero-lateral angles of the first three pleon-segments not acutely produced, but not rounded; the sixth segment of the pleon dorsally two-edged, as is probably the case in the other species.

Eyes round, near the front of the head.

Upper Antennæ.—First joint longer than broad, equal in length to the second and third united, the third not much shorter than the second, the flagellum longer than the peduncle, of ten joints, with cylinders rather longer than the joints; the secondary flagellum as usual rudimentary, two-jointed.

Lower Antennæ scarcely so long as the upper; first three joints very short, the first a little inflated, the gland-cone small, the fourth joint about equal to the first three united, broader than the fifth but not longer; the flagellum longer than the peduncle, ten- or eleven-jointed, shorter than the flagellum of the upper antennæ.

Upper Lip with the distal margin unsymmetrically bilobed.

Mandibles.—The cutting edge on the left mandible obtusely angled, divided into eight denticles, three small ones at the top followed by three larger in the middle, the next being rather flat-topped, and the lowest acute, as large as those in the centre; the secondary plate on the left mandible not so broad as the principal plate, with a slightly convex edge, cut into seven or eight denticles; the principal plate on the right mandible resembling that on the left, but with only seven denticles, the lowest but one very broad, the secondary plate scarcely denticulate, but with a separate tooth at the lower end; the

spine-row of six short denticulate spines, the first three pointing forwards; the palp very small, the first joint very short, the third joint probably occupying the short space between the apical seta and the seta on the inner margin below it, but I could not perceive any dividing line to mark off this from the second joint.

Lower Lip.—Mandibular processes short, apically narrow, divergent.

First Maxillæ.—The inner plate rather flat-topped, with one seta at the inner end of this margin; the outer plate as usual strongly ciliated on the inner margin, and with six spines in the usual arrangement and proportions on the distal margin, the innermost being finely pectinate, while the second and third are denticulate for a short space; the palp is two-jointed, as in the other species here described.

Second Maxillæ.—The inner plate shorter than the outer, with very fine setæ or spines on the apical margin.

Maxillipeds.—Inner plates reaching halfway along the inner margin of the second joint, the distal margin sloping a little outwards, with a small spine-tooth just within the inner apex, and a spinule near the outer corner; the second joint much longer than the first, with fine spinules along the inner margin, not spaced alike on the two members of the pair in the specimen examined, the rudimentary plate rather narrow; the first two joints of the palp short and broad, not longer than their breadth, the third joint a little longer, with adpressed cilia on the back, the outer margin very convex; the finger of the usual structure, but the narrow terminal part not elongated.

First Gnathopods.—Side-plates very small, completely covered by the following pair. First joint rather longer than wrist and hand united, narrowed at the base and distally, the front margin carrying a few setules, the hind margin of this and the following joint carrying an apical seta and setule; the third joint short, but as long as the wrist, the lower part behind strongly furred, the truncate apex armed with two spinules and two spines, one of which is distally serrate; the wrist triangular, distally cup-like, as broad as long, with a few spines on the hinder apex; the hand much longer than the wrist, tending to oblong, the longer and more convex front margin carrying three long spines at intervals, and on the apex a group of small setæ, the almost straight hind margin having one seta; the palm convex, not very oblique, very minutely pectinate, defined by a minute tooth at the apex of the hind margin, within which are two stout palmar spines and a long seta, followed by a few submarginal setules; the finger, with a dorsal cilium near the base, fits closely over the palm, the tip closing down between the two palmar spines.

Second Gnathopods.—Side-plates nearly semicircular, but rather more than twice as long as broad. Branchial vesicles very small, not half the length of the first joint, twice as long as broad. The marsupial plates considerably longer than the first joint, more than three times as long as broad, fringed with setæ. The first joint as long as the wrist and hand united, scarcely reaching the end of the side-plate, the margins fringed with

setules; the second, third, and fourth joints almost as in the first gnathopods, but the distal margin of the third joint wider, and the hind margin of the wrist a little longer; the hand two and a half times as long as broad, the front margin nearly straight, with one or two apical setules, the hind margin not much shorter than the front, carrying two small setæ, apically produced into a small tooth bending a little outwards so as a little to increase the width of the hand at this point; within this tooth is planted a palmar spine, with two larger spines of the same kind just beyond it, between which the tip of the finger closes; the palm-margin smooth, convex, scarcely oblique, fringed with setules; the finger smooth-edged.

First Peræopods.—Side-plates oblong, more than twice as long as broad. Branchial vesicles larger than the preceding pair, not so long as the first joint of the limb. Marsupial plates similar to the preceding pair. First joint not reaching to the end of the side-plate, fringed with setules; second joint longer than broad; third joint a little longer than the fourth, subequal to the fifth, with setules at four points behind, and at two in front, where it is slightly decurrent; the straight fourth joint with setules at two points of the hind margin; the fifth joint slightly curved, armed at three points of the hind margin; the finger curved, more than half as long as the fifth joint, having part of the inner margin peeltinate.

Second Peræopods.—Side-plates deep, but much broader than deep, reaching back to the pleon-segments and completely covering the three following pairs of side-plates. The branchial vesicles and marsupial plates similar to those of the preceding segment. The first and second joints of the limb not reaching the lower rim of the side-plate; the third joint armed at five points, and the fourth at three points of the hind margin; the limb otherwise similar to that of the first peræopods.

Third Peræopods.—Side-plates very small, not bilobed. Branchial vesicles and marsupial plates very small, but deeper than the side-plates. First joint of the limb long and narrow, the margins fringed with setules, the upper part a little wider than the distal, and ciliated on the edges; the second joint with setules at two points of the front margin; the third joint longer than the fourth, rather shorter than the fifth, armed at three points in front and two behind, the fourth and fifth each at three points in front; the finger much curved, much more than half the length of the fifth joint, having part of the inner margin peeltinate.

Fourth Peræopods.—Side-plates a little less deep than in the preceding pair. Branchial vesicles very small. The limbs very like the preceding peræopods, but with the four terminal joints longer, the second armed only at one point, the third and fourth at two points, of the front margin.

Fifth Peræopods.—Side-plates small, broader than deep. The first joint not wider above than below, shorter than in the two preceding pairs, the third joint also shorter, so as to be subequal in length to the fourth; the fifth joint rather longer than in the preceding pair.

Pleopods.—Coupling spines as usual minute, seemingly shaped as in the other species; a single long cleft spine at the middle of the long first joint of the inner ramus; in the third pair the inner ramus had but four joints, the outer ramus five.

Uropods.—Peduncles of the first pair rather longer than the rami, the upper edge pectinate, carrying one or two small spines; the inner ramus rather shorter than the outer, both with pectinate edges, and without spines; the second pair like the first, but stouter and shorter, the rami equal; the peduncles of the third pair scarcely longer than the proximal part of the ramus, carrying an apical spine; the ramus pectinate, with an apical spine to the proximal part, which is rather longer than the nail.

Telson not clearly made out, but probably equal in length to the peduncles of the third uropods, narrow at the apex, the length not equal to twice the greatest breadth.

Length.—The specimen, in the position figured, measured from the front of the head to the back of the second pleon-segment, one-tenth of an inch.

Locality.—Station 313, off Cape Virgins, Patagonia, January 20, 1876; lat. $52^{\circ} 20'$ S., long. $69^{\circ} 39'$ W.; depth, 55 fathoms; bottom, sand; bottom temperature, $47^{\circ}.8$. One specimen; female.

Remarks.—The specific name refers to the shape of the animal with the pleon folded as in the figure, which is probably its ordinary position when at rest. By the narrowness of the first joint in the fourth and fifth peraeopods this species is allied to *Metopa nasuta*, Boeck, *Metopa longimana*, Boeck, and *Metopa nasutigenes* of this Report.

Metopa compacta, n. sp. (Pl. XLV.).

Lateral lobes of the head a little prominent, postero-lateral angles of the first three pleon-segments rounded or blunt.

Eyes round.

Upper Antennæ.—First joint longer than broad, longer than the second; third joint longer than half the second; flagellum of ten joints, together shorter than the peduncle, several of them with cylinders longer than the joints; secondary flagellum minute, two-jointed, about half as long as the short first joint of the primary flagellum, tipped with two setules.

Lower Antennæ very little longer than the upper; first three joints very short; fourth joint about as long as the first of the upper antennæ, rather longer than the joint which follows, both with several setæ upon the surface; the flagellum short, tapering, consisting of eight joints, together shorter than the flagellum of the upper antennæ, longer than the fifth joint of their own peduncle.

Upper Lip broadly and unsymmetrically bilobed.

Mandibles.—Cutting plate of the left mandible with the edge forming an obtuse angle, cut into eleven denticles, the six uppermost being the smallest, the three following the largest; the secondary plate nearly, if not quite, as broad as the principal, its edge gently convex, cut into about eighteen minute equal denticles; the principal plate on the right mandible scarcely differing from that on the left, the secondary plate with a straight edge and smaller denticles; spine-row of three short serrate spines and a group of five, that seem to be smooth and not in line with the others; the first joint of the palp shorter than the short third joint; the second joint broad, with a small spine near the middle of the inner margin, and a longer one near its apex, the distal margin flat, slightly oblique; the third joint abruptly narrower, rather more than a third of the length of the second joint, with two long apieal spines.

Lower Lip very broad, principal lobes with the distal margin well ciliated; mandibular proeesses apically rounded.

First Maxillæ.—Inner plate with one seta on the narrowly rounded apex; outer plate with the usual spines a little elongate; the two-jointed palp as in other species.

Second Maxillæ with the plates rather broad, the longer outer one having many spines on the distal margin.

Maxillipeds.—The inner plates broad, reaehing more than halfway along the inner margin of the second joint, carrying a short spine and one somewhat longer on the slightly curved distal margin; the broad second joint has some six spines on the inner margin, the longest being on the rounded apex of the rudimentary plate; the joints of the palp are about equal in length, the first two broader than the third, with some rather strong spines; the third joint has many adpressed cilia on the outer distal part, and four spines at and near the inner apex, of which one is long, with the distal half pectinate; the finger is of the usual type.

First Gnathopods.—Side-plates small, nearly coneealed by the following pair, the front margin considerably shorter than the hinder, the oblique lower margin having two or three small spines. The first joint attaeed as usual, about equal in length to wrist and hand united, broad, fringed on both margins with long setæ, those behind being spine-like; the short second joint with a group of long and short spines; third joint shorter than the wrist, the front margin eonvex, the hind margin straight, furred below, the distal margin set with a row of seven or eight strong spines, which have the distal half pectinate; the wrist as long as the hand, with about a dozen strong pectinate spines round the hinder and part of the distal margin, and some long slender spines on the surfacee; the hand widest at the commencement of the palm, the hind margin unarmed, the palm convex, rather oblique, finely pectinate and denticulate, fringed with setules, and having a long seta at the eentre and another at the commencement, where there are a row of palmar spines, three pairs and a single one; the front margin has a spinule near the middle and at a little distance from the apex three strong spines on the surfacee, this

part of the hand seeming to have armature in all the species; the outer margin of the finger forms a very regular curve, and has a long dorsal cilium near the base, the inner margin is less convex, pectinate, and carries six cilia or setules, the two longest at the base of the nail.

Second Gnathopods.—Side-plates very broad, especially below, the front margin forming a continuous curve with the broad lower margin. The branchial vesicles not so small as in some of the species, pear-shaped, broader than the first joint but not so long. Marsupial plates almost circular, as broad as the side-plates, the distal half fringed with setæ. The first joint of the limb just reaching below the side-plate, fringed as in the first gnathopods; the second joint having a spine on the hind margin above the apical group; the third joint having the front margin short, with a blunt apex, the hind margin longer, with spines at two points, and a group across the almost acute apex; the wrist shorter than the hand, broader than long, not as in the first pair longer than broad, distally cup-like, furred behind, and having at the apex eight pectinate spines; the hand strong, broadest at the palm, there exceeding the breadth of the wrist; the hind margin produced into a small tooth which defines the broad, finely denticulate palm; within the process of the hind margin is a group of seven palmar spines, the palm being also fringed with setæ and setules, some of the former being moreover studded about the surface of the hand; the finger as in the first gnathopods, except that the inner margin is not pectinate.

First Peraopods.—Side-plates large, oblong, with the front and lower margins a little convex, and the upper a little oblique. Branchial vesicles like those of the preceding segment, but larger. Marsupial plates similar to the preceding pair. First joint of the limb just reaching below the side-plate, the front margin carrying setæ, the hinder a few setules; the third joint longer than the fourth or fifth, with four setules on the straight hind margin, a spine near the top and another on the slightly decurrent apex of the front margin; the fourth joint with a couple of spinules on the hind margin, and a long spine at its apex; the fifth joint longer than the fourth, nearly as long as the third, narrowing distally, with spinules at three or four points of the straight hind margin; the finger short, much curved, about half the length of the fifth joint. The peraeopods in this species are of stouter build than in the others that have been described.

Second Peraopods.—Side-plates large, broader than deep, of almost uniform depth for the first half, broadly rounded behind. The limb similar to that of the preceding pair.

Third Peraopods.—The side-plates rather deeply lobed behind. The branchial vesicles and marsupial plates deeper and broader than the lobe of the side-plate. The first joint of the limb not winged, distally a little widened, fringed on both margins with spinules, behind with a small distal lobe partially overlapping the short second joint; the third joint longer than the fourth or fifth, with spines at three points of the convex hind margin, and a group on the decurrent apex; the fourth joint short, with an apical group

of spines in front; the fifth joint and finger much as in the preceding peræopods, but the joint rather shorter, the finger a little longer.

Fourth Peræopods.—The side-plates similar to the preceding pair, but less broad. The first joint broadly and evenly expanded, the front margin not very convex, fringed with spinules, the hinder convex, almost smooth; the rest of the limb like the third pair, the third joint rather more decurrent, the fifth rather larger in both length and breadth.

Fifth Peræopods.—The side-plates small, but as usual rather deeper behind than in front. The first joint larger than in the preceding pair, the front margin more convex, the lower margin behind completely instead of partially overlapping the second joint; the remainder of the limb not materially different, but the fifth joint and finger rather smaller; in one member of the pair the fourth and fifth joints and finger were much smaller than in the fellow limb, the fourth joint being completely overlapped by the apex of the third.

Pleopods.—Coupling spines slender, curved, with the usual hooks; a single cleft spine on the inner ramus; six joints to the inner, and eight joints to the outer, ramus of the third pair.

Uropods.—Peduncles of the first pair much longer than the rami, fringed with spines; the rami equal, pectinate on the upper edges, the inner carrying two spines, the outer one; peduncles of the second pair about as long as the longer ramus; both rami with pectinate edges, the shorter with a marginal spine; the peduncles of the third pair as long as the proximal portion of the ramus, with an apical spine, and a second higher up; the proximal portion of the ramus much longer than the nail, carrying an apical spine, and a smaller one on the surface.

Telson very broad, longer than broad, apically converging to a rounded point; near each lateral margin there are three small spines, the middle one being at about the centre of the margin.

Length.—The specimen, in the position figured, measured, from the front of the head to the back of the second pleon-segment, a little under one-fifth of an inch.

Locality.—Station 313, off Cape Virgins, Patagonia, January 20, 1876; lat. $52^{\circ} 20'$ S., long. $67^{\circ} 39'$ W.; depth, 55 fathoms; bottom, sand; bottom temperature, $47^{\circ} 8$. One specimen, female.

Remarks.—A total of five species of *Metopa* were obtained at this one station, the rest of the voyage yielding but one other.

The specific name refers to the compactness and comparative solidity of this species, both in the parts of the animal and its whole figure.

The figure lettered *par.* represents a parasite which infests this specimen, especially about the telson and uropods.

Family LEUCOTHOIDÆ.

In 1852 Dana¹ established the Leucothoinæ as subfamily 3 of the family Gammaridæ. In it he includes the genera *Stenothoe* and *Leueothoe*, of which the former was placed by Spence Bate in the subfamily Stegocephalides, the latter in the subfamily Ganimarides. Lilljeborg in 1865 adopts Dana's subfamily, writing the name Leucothoina, and adding the genera *Pleustes*, Spence Bate, and *Montagua*, Spence Bate. In 1874 Boeck adopted the name "Leucothoinæ, Dana," as the name of the ninth subfamily of the Gammaridæ, and in 1876 as the sixth subfamily of the Leucothoidæ. In it he placed the genera *Liljeborgia*, Spence Bate, *Eusirus*, Krøyer, *Leucothoë*, Leach, *Tritropis*, Boeck, and *Pleustes*, Spence Bate.² The last of these genera was transferred to this subfamily by an after-thought, and Boeck's own account of the first side-plates, the third uropods, and the telson in species of *Pleustes* does not agree with his definition of the subfamily. In 1882 Sars adopted the name Leucothoidæ for a family containing the genera *Leueothoë*, *Tritropis*, *Eusirus*, "*Lilljeborgia*," presumably therefore corresponding with Boeck's Leucothoinæ, minus the genus *Pleustes*, which Sars places in the family Paramphithoidæ. Why Spence Bate and Boeck and Sars have removed *Leueothoë* from its proximity to *Stenothoe* I do not understand. In *Leueothoë* the third uropods are biramous, in the Stenothoidæ uniramous, but the mouth-organs bring the former near to the latter, as Dana and Lilljeborg have evidently felt. Gerstaecker in 1886 places *Leueothoë* next to *Stenothoe*. Costa in 1857 assigns to the Leucotoini only the genus *Leueothoë*, and I am so far in agreement with him that I have not seen reason to place in this family the other genera assigned to it by Boeck. It must be remembered that the loosely defined family, Leucothoidæ, Boeck, in which there is scarcely a single fixed character (almost everything mentioned being either large or small, present or absent), is quite distinct from the subfamily Leucothoinæ here changed into the family Leucothoidæ in accordance with the precedent set by G. O. Sars.

For the original definition see Note on Leach, 1813 (p. 84). Boeck's definition is as follows :—

- “ *Mandibles* apieally much dilated and dentate ; molar tubercle wanting.
- “ *First Maxillæ* with the inner plate very small.
- “ *Maxillipeds* with the outer plate almost obsolete.
- “ *Upper Antennæ* without an accessory flagellum.
- “ *First Gnathopods* with wrist ovate, at the lower hinder angle produced into a long, slender, curved, acuminate process ; the hand elongate, linear, armed with spines on the hind margin.
- “ *Second Gnathopods* having a long heel to the wrist ; the hand very large, sub-chelate.
- “ *The Peræopods* slender.
- “ *Third Uropods* with a tolerably long peduncle.
- “ *Telson* not cleft.”

A rudimentary secondary flagellum is present on the upper antennæ, at least in some species of the genus.

Leucothoë miersi, n. sp. (Pl. XLVI.).

Rostrum minute, lateral lobes of the head prominent ; the postero-lateral angles of the first three pleon-segments scarcely acute.

Eyes oval, situated near the lateral lobes of the head, light-coloured in the specimen preserved in spirit, the ocelli small.

Upper Antennæ.—First and second joints long, subequal in length, the first with a small apical tooth, the second fringed with a few setules ; the third narrow, about one-fourth the length of the second ; the flagellum slender, shorter than the peduncle, with seventeen joints on one antenna, and twenty-one on the other in the specimen here described, the distal joints much longer than those at the base ; the secondary flagellum a small rudiment, consisting of a single joint, much shorter than the short first joint of the primary.

Lower Antennæ.—First joint a little dilated, the gland-cone of the second short and broad, decurrent, the canal within the cone wider than usual, appearing to be surrounded with sphincter muscles; the third joint much longer than broad, a little curved, armed with spines; the fourth joint much longer than the fifth, longer than the first joint of the upper antennæ, its upper margin fringed with setules and having some spines at the upper part; the fifth joint shorter than the first joint of the upper antennæ, the straight margins fringed with setules; the flagellum slender, shorter than the fifth joint of the peduncle, consisting of twelve joints.

Epistome very sharply pointed.

Upper Lip with the front margin very unsymmetrically bilobed, the longer and narrower lobe smooth, the rest of the margin fringed with long wiry cilia.

Mandibles.—The cutting plate widening at the cutting edge, divided into five strong teeth, the two uppermost on the left mandible being flattened and to some extent subdivided; the secondary plate on the left mandible has its widened edge divided into ten teeth, of which the sixth from the top and the lowest are the most prominent; the uppermost tooth on the principal plate of the right mandible is divided into five denticles, the secondary plate is very small, almost triangular, placed near and not exceeding in width the uppermost tooth of the principal plate, its distal border cut into twenty denticles, the lower part having also two rows of submarginal denticles; the spine-row consists of many large curved spines, the largest nearest the cutting edge; twenty-nine were counted on the left and thirty-four on the right mandible; no trace of molar tubercle; palp slender, first joint very short, much broader than the second; second very long, carrying numerous long spines which seem to be almost but not quite smooth; the third short and thin, about a quarter the length of the second, tipped with a couple of spines.

Lower Lip not well observed; the texture very thin.

First Maxillæ.—Inner plate small, oval, with a seta on the inner margin just below the apex; outer plate with a row of setæ at the top of the inner margin, the apical spines seven in number, two of them short, several (perhaps all except the outermost) having a single lateral denticle, which in one or two is large; the first joint of the palp fully half as long as the second; the second reaching beyond the outer plate, its inner margin straight, the outer convex, the narrowed apex carrying four rather long spines, two of which are apically curved.

Second Maxillæ.—Inner plates much broader than the outer, with three spines on the inner margin, and six on the broad distal margin, together with two that are submarginal, one very small and one very large; the spines are spaced, stiff, not setiform; the outer plate does not reach beyond the inner, it has three strong spines on the narrow apex, and the convex outer margin strongly ciliated.

Maxillipeds.—The inner plates almost as broad as long, reaching halfway up the

second joint of the maxillipeds, carrying two spines on a fold of the inner surface, one on the middle of the fold's distal margin, the other below its inner apex; the distal margin of the plate broad, a little sculptured for three spine-teeth, of which two are near the inner and one near the outer apex; the second joint dilated on the distal part of the outer side, where it carries many spines on the apical border, and one or two on the outer border below the apex; on the inside the joint is produced into a quite rudimentary plate, almost conical, with two spine-teeth on the inner margin, one at, the other just below, the apex; the first joint of the palp longer than the second, with many spines along both margins and on the outer apex; the second joint with spines along the inner margin and the inner surface near this margin, and with one spine on the outer apex; the third joint as long as the second, the outer apex forming a slight cap over the hinge of the finger; there are spines about the apex both at front and back; the finger is nearly as long as the third joint, with a small dorsal cilium not far from the base, a short curved nail, and the inner margin closely furred with cilia.

First Gnathopods.—Side-plates wider below than above, the lower corner in front produced over the base of the upper antennæ. The first joint long, reaching far below the side-plates, distally narrowing a little, the margins more or less fringed with setules; the second joint longer than broad, with setules on or near the hind margin; the third joint very inconspicuous, much smaller than the second, the apex pointed, lying on the wrist; the wrist much longer than the hand, longer than the first joint, the basal part forming a great bulb, from which the long narrow heel is produced behind, apically curving over the outer margin of the finger (when closed) almost to its base; the inner edge set with small hairs at intervals, rounded and lined with innumerable scale-like minute tubercles recalling to mind the palate of a dog-fish; the hand is narrowly oblong, about as long as the calx or produced portion of the wrist, the hind margin very finely serrate with a beaded appearance, set with small hairs, and the distal half having eight small spines, to the seventh of which the tip of the slender curved finger reaches, the hand margin being at this part gently curved for what may be considered as the palm, though it is continuous with the straight portion of the hind margin; the finger half the length of the hand.

Second Gnathopods.—Side-plates squared, but with the corners rounded, the breadth rather greater than the depth. The branchial vesicles rather longer than the first joint and of about the same breadth. The marsupial plates as long as the first joint, much narrower, fringed with long setæ. The first joint broad, reaching much below the side-plates, much shorter and narrower than the hand, with some spinules on the margins, and setæ on the inner side of the apex; the second, third and fourth joints are all channelled in front, and combine to form a sort of irregular cup for the hand; the second joint has the hind margin smooth, and a pointed apex in front on the outer side; the third, which is not longer than the second, has a pointed apex in front on the inner side; the wrist is produced along the hind margin of the hand as far as the palm, this long heel or process

being the chief part of the joint, its distal margin truncate and at the corners serrate, its hinder surfaces thickly set with groups of spines; the margins serrate; the hand very large, its long convex front margin smooth, ending in a sharp apex to which several setæ are attached; the hind margin apart from the palm scarcely more than a third the length of the front; the long convex palm is serrate, more and more deeply as it approaches the hinge of the finger, which is strong, curved, closing over the palm and reaching a small pocket on the inner surface of the hand just above the palm margin; a row of setæ traverses the hand's inner surface from the base across to the hinge of the finger.

First Peræopods.—Side-plates deeper than broad, less broad than the preceding pair, hind margin longer than the front, both convex, lower margin straight (see fig. *pr. segm. 3*). Branchial vesicles as long as the first joint but much broader, widening distally. The marsupial plates a little longer than the first joint, of the same width with it, fringed with long setæ. The limb narrow, the first joint reaching much beyond the side-plate, almost unarmed; second joint short; third joint longer than the fourth or fifth, with the apex in front sharp, decurrent, armed with a spine, toothed on the inner side; the fourth joint shorter than the fifth, with some minute marginal spines; the fifth joint with a row of fourteen very small spines on the straight hind margin; the finger sharply pointed, not half the length of the fifth joint.

Second Peræopods.—The side-plates broader than the preceding at the point where the hind margin forms its rounded angle, the upper part of the margin being very slightly concave, and the longer lower part as slightly convex. The branchial vesicles broader than in the preceding pair; the marsupial plates and the limb in agreement with that pair.

Third Peræopods.—The side-plates broader than the preceding pair, the hind lobe rather deeper and less broad than the front. The branchial vesicles very broad distally, larger than the first joint of the limb. The marsupial plates rather shorter than the preceding pair. The first joint of the limb oval, much narrower below than above, with much of the front margin flattened, fringed with about a dozen very small spines, the convex hind margin almost imperceptibly serrate; the second joint short; the third joint subequal in length to the fifth, the apex behind sharp, minutely bidentate, with two little apical spines; there are one or two little spines high up on the hind margin, and four or five on the front; the fourth joint, which is much shorter than the fifth, has spines at five points of the front margin; the fifth joint has spines at twelve points; the finger is curved, sharply pointed, about half the length of the fifth joint.

Fourth Peræopods.—Side-plates less broad than the preceding pair, the hind lobe a good deal deeper than the front, the front margin straight. The branchial vesicles at the centre nearly as broad as long. The first three joints of the limb similar to those of the preceding pair but larger, the front margin of the first joint more, and the hind margin less, convex than in that pair. The remainder of the limb missing.

Fifth Peraopods.—The side-plates small, straight above, otherwise tending to circular in shape. The first three joints of the limb as in the preceding pair, but rather longer, the first joint also rather wider in the upper part. The rest of the limb missing.

Pleopods.—The coupling spines are small but strong, stout at the base, the shaft having on each side in one spine two or three, in the other three or four, retroverted teeth, besides the two formed by the apex; there is but a single cleft spine, the arms of which are long; the first joint of the inner ramus carries plumose setæ below the cleft spine; fifteen joints were counted on the inner ramus, and seventeen on the outer.

Uropods.—The peduncles of the first pair reaching beyond those of the second, but not nearly so far as those of the third, subequal in length to the rami; the rami long, subequal, reaching back nearly to the end of the rami of the third pair, the outer slightly shorter than the inner, not spined along the inner margin, but with fifteen or more spines on the outer; the inner ramus spined along both margins; both rami apically acute; the peduncles of the second pair as long as the inner ramus, which is considerably longer than the outer, spined on both margins, while the outer, which is equally acute, has only a few spines on the outer margin; the peduncles of the third pair much longer than the rami, carinate above, with a few spines along the upper margin; the rami subequal, lanceolate, the adjacent margins in each pair a little convex, with spines only on the lower part, the remote margins straight and spined all along.

Telson very long and narrow, reaching just beyond the peduncles of the first uropods, armed just above its acute tip with two microscopic cilia or setules.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the dorsal apex of the third pleon-segment, a little over two-fifths of an inch.

Locality.—Station 142, off Cape Agulhas, December 18, 1873; lat. $35^{\circ} 4'$ S., long. $18^{\circ} 37'$ E.; depth, 150 fathoms; bottom, green sand; bottom temperature, $47^{\circ}\cdot 0$. One specimen, female. Dredged.

Remarks.—The specific name is given in compliment to Mr. E. J. Miers, whose meritorious labours as a carcinologist are well known.

With *Leucothoë commensalis*, Haswell, from Port Jackson, the present species has many points of resemblance. Mr. Haswell accepts the suggestion of Mr. Miers that his species is only a well-marked variety of the European *Leucothoë spinicarpa* of Abildgaard. A specimen for which I am indebted to Mr. Haswell's kindness shows the following points of difference from *Leucothoë miersi*; in the mandibles the secondary plate on the left mandible has its edge divided into eight broad teeth, the spines of the spine-row seem to be less numerous, the third joint of the palp is longer and curved; the first joint of the palp in the first maxillæ has greater width; in the maxillipeds the relative sizes of the various joints are different, the inner plates are differently shaped, their texture

and spines stronger, the rudimentary outer plates are smaller; in the second gnathopods the hand is longer in proportion to its breadth, and the first joint of the limb longer in proportion to the other joints; the peduncles of the third uropods are less elongate in comparison with the rami, and the long narrow telson is far less sharply pointed, or rather has the narrow apex rounded. There are other points of difference which a minute description of the whole animal would display.

Leucothoë tridens, n. sp. (Pl. XLVII.). .

The first three segments of the pleon with the postero-lateral angles scarcely acute; those of the second segment in this, as in the preceding species, perhaps having a little produced point.

Eyes between round and oval in shape, dark in the specimen preserved in spirits.

Upper Antennæ.—The first joint not longer than the second, having a very small apical tooth; the second joint with a small spine near the middle of the upper margin, and a feathered eilium or seta at the apex of the lower; the third joint nearly half the length of the second; the flagellum very short, with five joints remaining, probably not more than one or two missing, the first the shortest, and the minute narrow secondary flagellum shorter than this.

Lower Antennæ.—Similar in proportions to those of *Leucothoë miersi*; the flagellum consisting of only six slender joints.

Upper Lip narrow, very unequally bilobed, finely fringed with eilia except at the apex of the longer lobe.

Mandibles.—The cutting-plates nearly as in *Leucothoë miersi*; the spines of the spine-row much less numerous; the second joint of the palp with two pairs of spines near the middle of the front margin and one at its apex, the third joint a little more than half the length of the second, with two spines or setæ on its narrow apex.

Lower Lip of very thin texture, the eilia few on the rounded distal margins of the principal lobes.

First Maxillæ.—Inner plates small, oval, with a very small apical seta; the seven spines on the distal margin of the outer plate similar to those in *Leucothoë miersi*, the lateral denticle not large on any of them, the setæ at the apex of the inner margin not large; the palp as in the other species.

Second Maxillæ.—The inner plate broader than the outer, with two small spines on the apex and one on the inner margin just below the apex; the outer plate reaching a little beyond the inner, with two apical spines, and a seta on the outer margin just below the apex.

Maxillipeds.—The rudimentary plate of the second joint appears to be extremely small; the joint has spines on the outer apex, and two on the margin below; the first

joint of the palp is short and broad, with spines on the inner margin and outer apex, the second joint is a little longer, similarly armed; the third joint is as long as the second, with apical spines, not produced at the outer apex; the finger is as long as the third joint, with a short sharp nail, and the inner margin ciliated.

The triturating organ of the stomach has half of its oval fringed with seventeen unequal spinules, each of which has two rows of spinules.

First Gnathopods.—Side-plates broader below than above, the front lower corner produced, but not reaching the antennæ, the flat lower margin forming more of an angle with the front margin than in the preceding species, the serrations at the lower part of the front margin more marked. The first joint much shorter than the wrist, the margins smooth, the front nearly straight, the hind gently convex; the second and third joints as in *Leucothoë miersi*, the third with two setæ at the apex; the process of the wrist prolonged quite round to the hinge of the finger, thin on both margins, which have a few hairs at intervals; the hand with four to six spines on the distal half of the finely serrate inner margin; the finger short, about one third the length of the hand, not reaching the two uppermost spines.

Second Gnathopods.—These do not differ very strikingly from those of *Leucothoë miersi*. The straight hind margin of the side-plate is a little serrate. The hind margin of the second joint has some groups of setules; the distal margin of the wrist is cut into five distinct denticles, and one of its inner margins is without any serration, the hand has two or three rows of spinules not very closely set on each surface near the palm border, but is without the transverse row of setæ on the inner surface, although there are some groups towards the hinge of the finger; the apex of the front margin is not sharply pointed.

First Peræopods.—Side-plates nearly square, a little deeper than broad. The branchial vesicles narrowly oval, not so long as the first joint, the marsupial plates about as long as the branchial vesicles, narrower, fringed with long setæ. The first joint widening a little distally, with the front margin concave, the hinder convex, both fringed with spinules; the relative proportions of the third, fourth, and fifth joints as in *Leucothoë miersi*, the third joint with a spine at the upper, another at the lower part of the hind margin, and a third at the apex, the fourth joint with three, and the fifth with four, little spines on the hind margin; the finger more than half the length of the fifth joint.

Second Peræopods.—The side-plates four-sided, the hind margin shorter than the front; the lower margin has two little notches indicating the portion perhaps which technically should be reckoned as hind margin. The branchial vesicles rather larger than the preceding pair, the marsupial plates and the joints of the limb not showing any material difference.

Third Peræopods.—Side-plates with the front lobe wider and rather deeper than the hinder one. The branchial vesicles rather longer than the first joint, but not so broad.

The marsupial plates as long as the branchial vesicles, but much narrower. The first joint not very wide, oblong-oval, with about a dozen small spines along the nearly straight front margin, and seven or eight minute serrations on the hinder; the third joint is longer than the fourth, apically decurrent behind, and with a spine on the hind margin; the fourth joint has two small spines on the front margin; the fifth joint subequal in length to the third, has five small spines along the front margin; the finger is more than half its length.

Fourth Peræopods.—The side-plates much narrower than the preceding pair, the hind lobe rather deeper than the front. The branchial vesicles and the limb similar to those of the third peræopods, but with the first, third and fifth joints larger.

Fifth Peræopods.—Side-plates small, broader than deep, not bilobed. The limb as in the preceding pair, but with all the joints, except the second, longer, and the first joint more oval.

Pleopods.—The coupling spines are similar in structure to those of the preceding species, but with the lateral teeth numbering only from two to three; the eleventh spine single; the joints of the rami about eight or nine in number.

Uropods.—Peduncles of the first pair subequal in length to the long narrow rami, which have a few spines on the outer margin; the outer ramus a little shorter than the inner; peduncles of the second pair not reaching so far as those of the first, about as long as the inner ramus; the outer ramus a good deal shorter than the inner; the peduncles of the third pair longer than the rami, the inner margin apically pointed and carrying a few marginal spines, the longer ramus with five marginal spines, the shorter and narrower with only three.

Telson reaching beyond the peduncles of the first uropods, not so long in proportion to its breadth at the base as in *Leucothoë miersi*, the minute apex microscopically tridentate.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the apex of the third uropods, one-fifth of an inch.

Locality.—Station 168, off New Zealand, July 8, 1874; lat. $40^{\circ} 28' S.$, long. $177^{\circ} 43' E.$; depth, 1100 fathoms; bottom, blue mud; bottom temperature, $37^{\circ} 2$. One specimen, female. Trawled.

Remark.—The specific name refers to the tridentate apex of the telson, but this is a character difficult to observe and not one on which much stress can be laid.

Leucothoë flindersi, n. sp. (Pl. XLVIII.).

The first pleon-segment with the postero-lateral angles minutely pointed, but with the hind margin bulging out beyond the points; the second pleon-segment with the angles pointed, not produced beyond the hind margins.

Eyes oval.

Upper Antennæ.—The first joint about equal in length to the next two united, not twice as long as broad; the third joint much more than half the length of the second; the flagellum tapering, of five joints, together shorter than the first joint of the peduncle; the third joint of the peduncle and the first four of the flagellum carrying long cylinders; the secondary flagellum minute, not longer than broad.

Lower Antennæ.—First three joints short, the first dilated, the fourth as long as the three preceding united, the fifth rather shorter; the flagellum tapering, of four joints, together equalling the length of the fifth joint of the peduncle.

Upper Lip comparatively broad, the narrow lobe not produced much beyond the other.

Mandibles.—The cutting edge divided into nine or ten denticles, on the left mandible the two in the centre projecting beyond the rest; the secondary plate on the left mandible nearly as large as the principal, with a straight row of eight denticles; on the right mandible the secondary plate is very small, its distal margin not clearly observed; the spine-row of about ten not very long spines; the palp broad, the second joint with three or four spines near the apex on the inner side; the third joint much narrower than the second, more than half its length, with two apical spines or setæ exceeding its own length.

First Maxillæ.—So far as observed, the spines of the outer plate were slender, in general structure like those of *Leucothoë tridens*, the second joint of the palp long and broad, with three short spines on the apex, and some rather long cilia on the outer margin.

Second Maxillæ.—The inner plate scarcely broader than the outer, with a few spines on the apex; the outer plate not reaching quite so far as the inner, the narrow apex tipped with three spines, the convex outer margin ciliated.

Maxillipeds.—The inner plates seem to be slender, nearly as long as the second joint of the maxillipeds; this has a very small rudimentary plate, a spine on the outer apex, but none on the margin below; the first joint of the palp is broad, rather longer than the second or third; the first and second joints have three or four spines on the inner margin, the third has a group of three or four near the inner apex, and one on the outer apex; the finger is longer than the third joint, with a short sharp nail, and a ciliated inner margin.

In the *tritirating organs* of the stomach the lower margin has six unequal spines.

First Gnathopods.—Side-plates broader below than above, but with the front lower corner little produced. The first joint as long as the hand, reaching much below the side-plate, the hind margin gently convex, with an apical seta, the front margin sinuous, fringed with ten long setæ; the second joint scarcely longer than broad; the third rather longer than the second, more squared than in the preceding species, carrying two setæ at

the apex, one of them very long ; the wrist longer than the hand, scarcely bulbous at the base, the heel broadly tapering, curved at the tip, which reaches, or even reaches beyond, the apex of the hand, the hind margin fringed with eleven long setæ, the front or inner margin having only a few hairs ; the hand a sort of elongate oval, narrow at the base, with a few spinules on the hinder or inner margin and one at the apex of the outer ; the finger very small and short, apparently not adapted for closing down between the hand and the process of the wrist.

Second Gnathopods.—Side-plates with the front margin convex, forming a little tooth below, the lower margin also convex. The branchial vesicles of narrow oval shape, longer than the first joint. The limb shaped nearly as in the preceding species ; the first joint with two or three setules near the front apex, and two on the hinder, the margins otherwise smooth ; the second joint not longer than broad, with two spinules on the apex of the hind margin ; the third joint with five setiform spines along its distal border ; the process of the wrist not quite reaching the beginning of the palm, its edges not serrate ; the front margin of the hand nearly straight, not apically produced into a point either sharp or blunt, with a group of setæ a little below the apex ; the hind margin half as long as the front, the smooth very convex palm margin and the finger being proportionately shorter than in the other species ; there are a few spinules on the surface within the palm-margin.

First Peræopods.—Side-plates more or less oblong, with a small tooth at the bottom of the front margin. The branchial vesicles widening below, a little shorter and broader than the first joint. The first joint lageniform, with three or four spinules on the front margin, the hind margin smooth ; the third joint carrying a spinule on the decurrent front apex, and another higher up the margin ; the fifth joint is longer than the fourth, as long as the third, the hind margin straight, unarmed, except with a couple of setules or hairs ; the finger curved, sharply pointed, more than half the length of the fifth joint.

Second Peræopods.—The short front and hind margins of the side-plates diverge, and are connected the one with the other by a very long convex lower margin ; the front margin ends in a little notch. The limb does not materially differ from that of the first peræopods.

Third Peræopods.—The side-plates with the front lobe broader and deeper than the hinder one. The first joint oval, with three or four little spines on the front margin, the hinder absolutely smooth ; the third joint very decurrent behind, the apex a little rounded, and the convex hind margin having a spinule near the centre. The rest of the limb missing.

Fourth Peræopods.—The hinder lobe of the side-plates deeper and longer than the front one. The first joint of the limb larger and much broader than in the preceding pair, with five spines on the front margin, the hinder perceptibly serrate ; the third joint as in the third peræopods, but larger. The remainder of the limb missing.

Fifth Peraopods missing.

Pleopods.—Coupling spines not observed, cleft spine single; joints of the rami numbering about five or six.

Uropods.—The relative dimensions of the first and second pairs much as in the two preceding species. The third pair missing.

The Telson appeared to be rather shorter in proportion to its length than in the preceding species.

Length.—The specimen, in the (curled) position figured, measured, in a straight line from the rostrum to the back of the third pleon-segment, one-tenth of an inch.

Locality.—Station 186, in Flinders Passage; lat. $10^{\circ} 30' S.$, long. $142^{\circ} 18' E.$; depth, 7 to 8 fathoms; bottom, coral mud. One specimen.

Remarks.—The specific name refers to the place of capture.

Between this species and *Leueothoë brevidigitata*, Miers,¹ the following differences may be noticed. Mr. Miers' specimen, obtained at Thursday Island, was very much larger, "length about $7\frac{1}{2}$ lines (16 millim.)"; the flagellum of the upper antennæ was thirteen or fourteen jointed; the first gnathopods "have their basus joints moderately dilated, with the posterior margins thin-edged and hairy;" the front margin of the wrist is much longer, to judge by the figure, than in the Challenger species; in the second gnathopods the carpus is said to be "very short, and produced along the posterior margin of the propus for less than half its length," while the figure shows the palm of the hand very long and concave instead of convex; nothing is said of the fringe of setæ on the front margin of the first joint and hind margin of the wrist of the first gnathopods, which are very noticeable features in *Leueothoë flindersi*, nor is mention made of the long cylinders on the flagellum of the upper antennæ. Nevertheless the possibility remains that the specimen here described may be only the young form of *Leucothoë brevidigitata*.

Genus *Seba*, Costa.

(?) *Seba*, Costa (?).

- 1862. " Spence Bate, Brit. Mus. Catal. Amph. Crust., p. 159.
- 1875. " Stebbing, Ann. and Mag. Nat. Hist., ser. 4, vol. xv. p. 2.
- 1884. *Teraticum*, Chilton, Trans. New Zealand Inst., vol. xvi. p. 257.
- 1885. *Seba*, Chilton, New Zealand Journ. Sci., vol. ii. p. 320.

The original authority for this genus has thus far eluded my researches. For a definition, apparently translated from a memoir by A. Costa, see Note on Spence Bate, 1862 (p. 334). For a second, independent definition, see Note on Chilton, 1884 (p. 550). The genus makes some approach to *Leueothoë* in the proportions of the mandibular

¹ "Alert" Report, p. 313, pl. xxxiv. fig A, 1884.

palm, the plates of the first maxillæ, the small inner plates of the maxillipeds, but on the other hand the palp of the first maxillæ is one-jointed, and the outer plates of the maxillipeds, though small, are not rudimentary. The telson is undivided as in *Leucothoë*, but the third uropods are uniramous as in the Stenothoinæ. In the gnathopods of *Seba* it is not the wrist, as in *Leucothoë*, but the hand which sends out the chela-forming process. In the British Museum Catalogue, Spence Bate places *Pardalisca* immediately before *Seba*, and *Leucothoë* before *Pardalisca*. Thomson and Chilton in their New Zealand Catalogue place *Seba* immediately after *Leucothoë*. Gerstaecker, with a note of interrogation prefixed, makes *Seba* a synonym of *Leucothoë*, but in the definition of the latter genus he describes the wrist of the gnathopods as "stark fingerförmig ausgezogen," both this character and the account given of the uropods precluding the union of the two genera which he suggests. Boeck's definition of the Leucothoinæ would require to be considerably modified for the inclusion of *Seba*, which for the present I am content to place rather on the confines of the family Leucothoidæ (Sars) than within it.

Seba saundersii, Stebbing, 1875 (Pl. XLIX.).

 ? 1885. *Seba typica*, Chilton, New Zealand Journ. Sci., vol. ii. p. 320.
 1886. " " Thomson and Chilton, Trans. New Zealand Inst., vol. xviii. p. 148.

The lateral lobes of the head narrow, not very prominent, the first two segments of the pleon postero-laterally almost right-angled, the hind margin of the second segment faintly serrate upwards, the third segment with the postero-lateral angles somewhat produced, rounded.

Eyes not observed.

Upper Antennæ.—The first joint shorter but broader than the second, the third scarcely half the length of the second, the flagellum of five joints, together equal to the second joint of the peduncle, the first equal to the third joint of the peduncle, the first four armed with cylinders; the accessory flagellum not quite so long as the first joint of the primary, its first joint narrow and tapering, its second rudimentary, cylindrical, tipped with two setules.

Lower Antennæ rather shorter than the upper. The first joint a little dilated, the second as long as the third, with the gland-cone inconspicuous; the fourth joint longer than the three preceding joints united; the fifth shorter and narrower than the fourth, tapering slightly; the flagellum of three joints tipped with setules, the first joint longer than the second, and the second than the third, the three together shorter than the fifth joint of the peduncle.

Upper Lip with the distal border slightly emarginate.

Mandibles with the trunk broad, the cutting edge slightly angled and divided into about seven teeth; the secondary plate on the left mandible with six teeth, its breadth almost as great as that of the principal plate; the secondary plate on the right mandible less broad and much less strong than the principal plate, its distal edge minutely dentieulate; the spine-row begins with three short spines, of which the first is laminar, with a widened dentieulate distal edge, a short ciliated space is followed by a fourth spine pointing backwards and ending in two unequal teeth; of molar tubercles there appears to be no trace; the palp is broad, set well forward, the first joint longer than broad, the second joint broad and long, with a couple of setules near the apex of the inner margin, the third joint much shorter and narrower than the second, apically pointed, with two spines or setæ on the inner side of the apex.

Lower Lip broad, the somewhat narrowed and lightly ciliated apices of the principal lobes standing wide apart, their inner margins sinuous; the mandibular processes short, apically narrowed and rounded.

First Maxillæ.—Inner plates small, oval, with one or two hairs observed on the apex; the outer plates broad at the base, the obliquely truncate distal margin carrying seven spines, the innermost with five lateral teeth, followed by two other slender spines apparently with fewer lateral teeth; in the parallel row the two innermost spines are falcate, the inner branch or tooth being the longer, the other two spines have a single denticle on the inner side; the palp is one-jointed, tapering, reaching beyond the outer plate, having two small spines on the apex.

Second Maxillæ.—The inner plates much shorter and a little broader than the outer, with two spines on the apex; the outer plates with three spines on the apex.

Maxillipeds.—Inner plates small, scarcely reaching the base of the palp, carrying a spine on the upper part of the inner margin, a spine-tooth at the inner apex, with a slender curved spine on the outer curve of the distal margin; the outer plates narrowed, reaching as far as the distal end of the first joint of the palp, with a small not pointed spine near the middle of the inner margin, a spine-tooth in an indent just below the apex, accompanied by a slender spine, and a second spine-tooth at the apex; the first joint of the palp is broad, with one or two spinules on the inner margin; the second joint is rather broader and longer, with eight marginal or sub-marginal spinules; the third joint is shorter and narrower than the first, the outer margin produced into a pointed cap over the base of the finger, the apex and part of the inner surface carrying some finely pectinate spines; the finger is curved, longer than the third joint, with a small dorsal cilium near the hinge, and a cilium at the base of the short sharp nail.

The *triturating organ* of the stomach shows a group of some eight broad spines, distally thorny.

First Gnathopods.—The side-plates broader below than above, the rounded lower

front corner produced to the base of the lower antennæ. The first joint reaching beyond the side-plates, distally widening, the front margin smooth, rather sinuous; the second joint with one peetinate spine low down on the hind margin; the third joint a little longer than the second, narrowed distally, with three peetinate spines on the apical border, the uppermost the longest; the wrist triangular, longer than broad, distally somewhat cup-like, the hind margin near the apex having a fringe of eight gradnated spines, the lowest and longest less conspicuously peetinate than the others; the hand much longer than the wrist, the basal part longer than broad, fringed on the hinder side with thirteen finely plumose setæ, and on this side carrying a long thumb, tapering to an abruptly curved tip, which is set about with four short curved spines, against which the equally long and almost similarly formed finger antagonizes, making the hand completely chelate; the thumb and finger are shorter than the basal portion of the hand; the finger has one or two setules or elia on the outer margin near the base, and the thumb has a series along the margin which adjoins the finger.

Second Gnathopods.—Side-plates with the front margin convex, the width of the plates nearly even throughout. The first joint rather longer than in the preceding pair, not distally widened; the second joint narrow, as long as the wrist, the hind margin almost straight; the third joint a narrow oval, much shorter than the second, like it armed only with a cilium near the apex; the wrist narrowly triangular, longer than that of the first gnathopods, but not so broad distally, with an apieal cilium; the hand similar in general structure to that of the first gnathopods, but longer and narrower, the front and hind margins alike unarmed, except for a cilium on the thumb at some distance from the curved apex, and two spines at the apex; the border adjoining the finger is armed as in the preceding pair; the finger, which here as there is narrower than the thumb, has similarly placed cilia. In the Plate the more highly magnified figure of the apex of this limb has been left without the line of dots which should have connected it with the smaller figure.

First Peræopods.—Side-plates squared, with the front and lower margins convex, separated by a notch or tooth, the hind margin sinuous, rather longer than the front. The branchial vesicles narrowly oval, very small, little more than half the length of the first joint. The marsupial plates rather longer than the branchial vesicles, apically fringed with long broad setæ. The first joint reaching beyond the side-plates, with a few spinules at distant intervals on the margins, whieh are nearly straight; the second joint short, with an apical spinule behind; the third joint with two spinules on the straight hind margin, one on the convex front margin at the eentre, and another on its deurrent apex; the fourth joint shorter than the third, with spines at three points of the straight hind margin; the fifth joint longer than the fourth, subequal to the third, with spines at four points of the hind margin; the finger more than half the length of the fifth joint, with a small dorsal cilium near the base, the nail short, sharp, slightly curved.

Second Peræopods.—These, with the side-plates, branchial vesicles, and marsupial plates, closely resemble the preceding pair.

Third Peræopods.—Side-plates broader than deep, the lobes nearly equal. The branchial vesicles and marsupial plates nearly as in the two preceding segments. The first joint of the limb oval, with spines at five points of the flattened front margin, and three or four slight serratures on the hinder one; the second joint short, with two little spines on the front margin; the third joint with spines at three points on the front margin, and three on the very deurrent hind margin, the third being just behind the rather blunt apex; the fourth joint shorter than the fifth, with spines at three points in front; the fifth joint a little shorter than the third, with spines at four points of the straight front margin, and two setules or cilia on the slightly convex hind margin; the finger as in the preceding pair of limbs.

Fourth Peræopods.—These differ very slightly indeed from the third; they are rather larger, and the fourth joint has spines at four points of the front margin.

Fifth Peræopods.—These are very similar to the two preceding pairs, but the first joint is considerably larger, the front margin nearly straight, the hind margin very convex; the remaining joints are not longer than those that correspond in the fourth pair; the fourth joint has spines at three points in front.

Pleopods.—The coupling spines, so far as could be made out, are filiform, with backward serratures at the upper part; there is but one cleft spine; the joints of the inner ramus are four, of the outer five, in number.

Uropods.—The peduncles of the first pair are shorter than those of the second, shorter than the rami, with one or two spinules on the outer, and an apical spinule on the inner, margin; the rami are slender, tapering, without spines, the inner longer than the outer, tipped with a minute nail; the peduncles of the second pair longer than those of the first or third, a little shorter than the rami, which are subequal, curved at the tips, with a small spine at about the centre, the inner ramus a little longer than the outer; the peduncles of the third pair are shorter than the broad, lanceolate, single ramus, which reaches back not quite so far as the rami of the second pair, has strongly pectinate edges, one or two setules on the surface, and a broad apical nail accompanied by a cilium.

The Telson triangular, much longer than broad, the sides slightly convex, the smoothness of each a little interrupted at the point where a submarginal cilium is inserted not far from the rounded point of the apex, the margin here being almost impereetibly serrate.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the apex of the second uropods, three-twentieths of an inch.

Locality.—Station 313, off Cape Virgins, Patagonia, January 20, 1876; lat. $52^{\circ} 20'$ S., long. $67^{\circ} 39'$ W.; depth, 55 fathoms; bottom, sand; bottom temperature, $47^{\circ}.8$. One specimen, female.

Remarks.—The specific name was given in honour of the late W. Wilson Saunders Esq., F.R.S.

There seems little reason to doubt that this is the same species as that described in the Annals and Magazine of Natural History for March 1875. The specimen originally figured was obtained from a collection of sponges and other marine objects which had been gathered partly in Algoa Bay, South Africa, and partly from the neighbourhood of Swan River, West Australia. As the various objects had been packed together, small specimens might easily have been shaken out of one into another, and therefore the proper habitat to assign to such small specimens would become a matter of uncertainty. *Teraticum typicum*, described by Mr. Charles Chilton in 1884, must, I think, be identical with the present species, and from his figures it may be inferred, as he suggests, that the first gnathopods of the two sexes differ greatly, if we may presume that his figures 1b, 1c represent the first gnathopod of the male. In his account of the antennæ, Mr. Chilton gives “first joint of upper antenna equal in length to the second, but stouter,” whereas in the specimen described in 1875 the second joint is a little the longer, and in the specimen here described decidedly longer.

Family SYRRHOIDÆ, G. O. Sars, 1882.

In 1870 Boeck established the Syrrhoïnæ as seventh subfamily of the Gammaridæ; in 1876 he made it the fourth subfamily of the Leucothoidæ; in 1882 Sars changed the subfamily into a family without alteration except in the form of the name. The genera assigned to the group alike by Boeck and Sars are *Syrrhoë*, Goës, *Tiron*, Lilljeborg, and *Bruzelia*, Boeck. Boeck gives the following definition:—

“ *Upper Lip* broad, apically insinuate.

“ *Mandibles* very strong, broad; the pair not uniform; the left mandible furnished with an inner accessory process; the palp three-jointed, with the last joint very short.

“ *Lower Lip* broad.

“ *First Maxillæ* with the inner plate broad, setose; the palp two-jointed, narrow, generally furnished apically with few setæ.

“ *Second Maxillæ* with broad plates.

“ *Maxillipeds* with the outer plates very large, armed with strong teeth on the inner margin; the inner plates broad, long; the palp broad, short, or more elongate.

“ The body more or less sub-depressed; the head large; the side-plates of moderate size.

“ The *Eyes* often approximate and coalesced.

“ *Upper Antennæ* with an accessory flagellum.

"First and Second Gnathopods alike in form, thin, narrow; the hand subcheliform.

"Last three pairs of Peræopods successively longer; the first joint more or less dilated behind.

"Uropods biramous; the first and second pairs with the outer ramus shorter than the inner; the third pair with the two rami of almost the same length, laminar, setose on the margin.

"Telson long, cleft." In *Tiron*, however, the hand of the gnathopods is not subcheliform.

Genus *Syrrhoë*, Goës, 1865.

1865. *Syrrhoë*, Goës, Crust. Amph. Maris Spetsh., p. 12.

1870. " Boeck, Crust. Amph. bor. et arct., p. 67.

1876. " Boeck, De Skand. og Arkt. Amph., p. 471.

For the brief original definition of the genus, see Note on Goës, 1865 (p. 357). The following more expanded definition was given by Boeck in 1870:—

"Mandibles very thick, robust, apically little dentate; molar tubercle prominent, not robust.

"Eyes confluent.

"Side-plates of moderate size.

"First and Second Gnathopods with the hand short, subcheliform; the second gnathopods longer than the first.

"The last three pairs of Peræopods elongate, narrow; first joint more or less dilated behind.

"First and Second Uropods with the outer ramus much shorter than the inner.

"Third Uropods with the rami foliaceous, subequal.

"Telson cleft."

In the description of the subfamily, Boeck states that the lip is insinuate at the apex, which does not appear to be the case with the Challenger species, *Syrrhoë papyraea*. In the generic definition Boeck speaks of the mandibles as with "tuberculo molari prominenti, non robusto," while in the specific description of *Syrrhoë crenulata*, he says "Tyggeknuden er bred, men kun lidet fremstaaende"; in the Challenger species the molar tubercle is both robust and prominent. Norman in 1869 gives a definition of *Syrrhoë*, including the character, "Gnathopods not subchelate," but this evidently has reference to the species *Syrrhoë hamatipes*, Norman, which, as well on account of the gnathopods as of the short fifth peræopods, ought to be transferred to the genus *Tiron*, Lilljeborg. Gerstaecker in 1886 makes *Syrrhoë* a synonym of *Tiron*, which he says differs from *Urothoë* "durch das nicht in eine Greifhand endigende erste und zweite Beinpaar." Yet in this particular character *Tiron* is as much separated from *Syrrhoë* as it is from *Urothoë*.

Syrrhoë papyracea, n. sp. (Pl. L.).

The Head bent down, with a rounded corner over the first joint of the upper antennæ, forming a depressed rostrum, sharp-edged, and acute at the apex, at right angles with the top of the head; the first five segments of the peraeon very short; the first three of the pleon very long, the postero-lateral angles a little produced and very acute in the second and third, not produced in the first; the last segment of the peraeon and the first four of the pleon-segment are provided with a sharp dorsal tooth on the hind margin, small in the first of these segments, with about eleven denticles on either side, larger in the next, with thirteen denticles on either side, a little longer still in the next, with as many or more attendant denticles, very small in the two following segments, with a diminished number of denticles; the fourth segment of the pleon is long at the upper part, longer than the two following united. The integument dotted with small round spots in various parts, elsewhere presenting the appearance of finely ribbed silk; the first joints of the last peraeopods showing prismatic colours.

No Eyes perceived.

Upper Antennæ.—The first joint rather thick, a little bent, twice as long as broad, with several setules on the upper margin and the apex of the lower; the second joint thinner and a little shorter, the third three-quarters the length of the second; fifteen joints of the flagellum remaining, together longer than the peduncle, the first joint much longer than the rest, shorter than the third joint of the peduncle, smooth; the secondary flagellum three-jointed, the first joint longer than the first of the primary, the second nearly as long, reaching to the end of the fourth joint of the primary, the third very small, tipped with long setæ.

Lower Antennæ.—First joint a little expanded, second with a well-developed gland-cone, third not longer than the second; fourth narrow, elongate; fifth as long as the third and fourth united; flagellum of eighteen unequal joints, more or less alternately long and short, with some long setæ at the apices of some, the joints together not so long as the peduncle.

Upper Lip with the distal margin not in the least insinuate, forming a rounded apex to an equilateral triangle, the apical border furred very finely, the hairs as usual on the right and left pointing towards the centre.

Mandibles.—Cutting plate with a long scarcely indented edge ending in two strong teeth below; the secondary plate narrow, cut into four teeth, stronger on the left than on the right mandible; spine-row of six spines, the first three stronger than the others; the molar tubercle strong and prominent, the front edge sinuous, with one or two teeth stronger than the crowd of denticles, the hind margin nearly straight, with a comparatively small seta; the first joint of the palp short, the second very long, narrowing a little distally, fringed with setæ, the third joint short, almost rudimentary, tipped with four or five very long setæ.

Lower Lip.—The principal lobes distally rather narrow, little dehiscent, much ciliated, on the inner margin each carrying two spines, which are short, not tapering, but ending in a small double tip; the inner plates inflated; the mandibular processes divergent, apically rounded and narrow.

First Maxillæ.—The inner plate fringed on the inner side with fifteen plumose setæ, the two at the apex being the shortest; the outer plate having on the trunecate distal margin eleven strong spines in two rows of four and seven; in the latter the two innermost are plumose, the next three dentieulate with from fourteen to eighteen denticles, the other two with two or three denticles; in the other row the outermost spine is broad, simple, the other three are fureate, with the inner arm of the fork shorter than the outer, these spines as well as some in the other row being finely plumose on the upper part of the outer side; the palp is long and slender, reaching much beyond the outer plate, its first joint a good deal longer than broad, but not nearly half as long as the second, which has on the apex four finely dentieulate or serrate spines, followed by six more along the inner margin.

Second Maxillæ.—The plates differing but little from one another in length and breadth, the inner plate having a series of about eighteen long plumose setæ, beginning near the base of the inner margin and passing nearly to the distal outer corner; further from the base begins a series of shorter plumose setæ, which keep to the margin till they approach the apex and become submarginal, the apex itself being fringed with plumose spines not passing down the outer margin; the apex of the outer plate is fringed with long curved spines, showing some plumosity below and peetination above; shorter spines pass a little way down the outer margin.

Maxillipeds.—Inner plates broad, reaching beyond the distal end of the first joint of the palp; nine strong plumose spines pass along the upper part of the inner margin round to the outer corner, the three along the distal margin being much shorter than the others; near to these are two curved more slender spines on the distal margin, which is broad, irregularly sculptured, sloping a little inwards, and armed with two strong tapering spine-teeth; on the outer surface at a little distance from the inner margin there is a row of three spines, as shown in the more highly magnified portion of the figure *mxp*, the uppermost of these spines being broad and curved, the next longer and thinner, and the lowest still longer; the outer plates not reaching the distal end of the second joint of the palp, fringed with a row of some sixteen teeth or spines, eight or nine being regular spine-teeth on the inner margin, the remainder with increased length passing gradually into plumose setæ round the distal margin; there are also several groups of slender spines on the surface within the inner margin; the first joint of the palp short, the second long, fringed with long spines or setæ on the inner margin, the third joint longer than the first, fringed with spines on both margins and round the apex; the finger long and tapering, the dorsal cilium set near the base of the nail, which is as long as or longer

than the proximal part of the finger, and has at its base, on the inner side, two cilia or setules, one nearly as long as the nail, the other half as long as the former.

Triturating Organ.—Twelve or more strong spines are set close together at the bases, the apices being very divergent; these spines are of unusual breadth, narrowing with abruptness apically, denticulate on the inner margin; they are surrounded by a forest of slender spines.

First Gnathopods.—The front margin of the side-plates curved to correspond with the under margin of the head, forming an acute angle with the lower margin, which is produced as far as the base of the lower antennæ; these and the next pair of side-plates, though deeper than broad, have a shallow appearance through being so much bent forwards. The first joint of the limb reaching beyond the side-plate, as long as the wrist and hand united, a little dilated at the upper part behind, at the lower part in front, fringed on both margins with setæ more or less plumose; the second joint short, with an apical group of setæ behind; third joint triangular, with a very short free margin in front, the lower half of the somewhat convex hind margin fringed with plumose setæ, some passing across the acute apex; the wrist long and narrow, more than twice the length of the hand, slightly narrowing distally, with seven setæ along the nearly straight front margin, and an apical group, the hind margin crowded with plumose spines of various lengths, the inner surface carrying some nine spines not far from the hind margin, some of these spines being abruptly narrower in the pectinate distal half; the central part of the distal half of the inner surface and the outer surface near the hinder margin is covered with rows of microscopic spinules, which are continued on the centre of the inner surface of the hand but not reaching the palm; the hand widens a little distally; its front margin has an apical group of long setæ, with a similar group a little higher up, followed by one or two isolated setæ; the hind margin is pectinate almost to the palm, near which it has a group of four spines with long accessory threads, the spines themselves graduated in thickness, the first being scarcely more than a seta; the palm is a little oblique, wavy in outline, fringed with long setæ, at its commencement having two edges, between which rises a monster palmar spine, on the sinuous inner side of which are from six to seven stout outstanding denticles, and a still larger decurrent tooth; the finger is long, reaching beyond the palm, the dorsal cilium near the base of the nail, which is much curved, abruptly narrower, but not much shorter than the proximal part of the finger, and having at its base on the inner side some long cilia or setules; on the inner surface of the hand there are four spines and two long setæ.

Second Gnathopods.—Side-plates very similar to the preceding pair, but wider above and less sharply produced below. Branchial vesicles elongate, oval, longer than the first joint of the limb. Marsupial plates narrower than the branchial vesicles but rather longer, distally narrowed, fringed on both margins with setæ, of which some at least are lightly feathered. The first joint similar to that of the first gnathopods but longer and

narrower, and not bulging near the base; the third joint narrower than in the preceding pair, carrying only four or five setæ; the wrist narrow, elongate, almost as long as the first joint, distally scarcely widened, with five small setæ on the gently curved front margin, and an apical group, the hind margin carrying twelve spaced groups of spines on the outer surface, and a smaller number on the inner surface, besides rows of spinules; the hand, though not half the length of the wrist, is much longer than in the preceding pair, more slender, very little widened distally, in the armature closely agreeing with the other gnathopods, the great palmar spine on one of the hands having seven marginal teeth, on the other only five.

First Peraopods.—The side-plates much broader than deep, the front margin sloping forwards, making an acute angle with the long and nearly straight lower margin; behind the plates are very broadly excavate so as to entirely overlap the following side-plates; the hind margin below the excavation is straight, serrate, making almost a right angle with the lower margin. Marsupial plates long and slender, with very long apical setæ. The limb, like the rest of the pereopods, is long and slender; the first joint reaching much beyond the side-plate, equal in length to the fourth and fifth joints united, the margins carrying some long plumose setæ; the second joint short, the third shorter than the fourth or fifth, scarcely decurrent, with a curved slender spine at the hinder apex and two smaller spines on the hind margin, and two on the front; the fourth joint rather longer than the fifth, with seven spines on the hind margin, of which the apical one is very long and curved; the fifth joint straight, with mixed spines on the hind margin, the apical one close to the finger, strong and long, with serrate edges; at the front apex is a fan of eight or nine curved spines; the finger is slender, more than half the length of the fifth joint, the proximal part not so long as the adjacent apical spine of the fifth joint, with a strong dorsal cilium near the base; the nail almost as long as the proximal part of the finger, with two small cilia at its base on the inner margin.

Second Peraopods.—Side-plates very small, excavate behind, with a short straight margin below the excavation, while the remaining margin, which is perhaps front and lower combined, is convex. The marsupial plates and the limb as in the preceding pair.

Third Peraopods.—First joint of the limb almost circular, with five stout spines on the lower half of the front margin, the hinder margin except at the upper part deeply serrate, the hind margin of the inner surface within the wing is straight and distinct; the second joint short; the third much shorter than the fourth, with four spines on the front margin and an apical group, three on the hind margin and a group on its slightly decurrent apex; the fourth joint has spines at seven points in front and at six behind. The rest of the limb missing.

Fourth Peraopods.—The first joint similar in general character and armature to that of the third pereopods, but much larger, longer than broad, the hind margin more overlapping the second joint; the third and fourth joints also much longer than in the

preceding pair, the third with the same number of spines, the very much longer fourth joint with spines at nine points in front, and seven behind; the fifth joint slender, straight, broken.

Fifth Peræopods.—Side-plates much broader than deep. Branchial vesicles very small, not half the length of the first joint. The first joint as broad as the preceding but much longer, similarly armed, the lower margin produced below the second joint; the third joint longer than in the preceding pair, with spines at five points in front and four behind, besides the apical groups; the fourth joint similar to that of the preceding pair; the rest of the limb missing.

Pleopods.—The coupling spines large, broad at the base, with two or three large lateral hooks and some smaller ones, besides a small apical hook; there is a small interlocking process at the apex of the peduncle on the outer side; the cleft spines are four in number; the joints of the rami numbering from seventeen to nineteen.

Uropods.—The peduncles of the first pair longer than the outer ramus, with five spines on the upper margin; the narrow outer ramus with three spines on the lower part of the upper margin and two at the apex; the inner ramus broken, but evidently longer than the outer; the peduncles of the second pair reaching a little beyond those of the first, and those of the third a little beyond the second, but the rami of both broken.

Telson reaching much beyond the peduncles of the third uropods, cleft rather beyond the centre, much longer than broad, the sides of the cleft curving a very little outward to the sharp forked apices, which have the outer peak shorter than the inner, and a cilium inserted at the fork.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the rostrum to the apex of the telson, almost half an inch.

Locality.—Station 24, off Culebra Island, West Indies, March 25, 1873; lat. $18^{\circ} 38' 30''$ N., long. $65^{\circ} 5' 30''$ W.; depth, 390 fathoms; bottom, Pteropod ooze; surface temperature, 76° . One specimen, female. Dredged.

Remarks.—The specific name refers to the thin paper-like consistence of the integument.

Syrrhoë semiserrata, n. sp. (Pl. LI.).

Rostrum depressed, acute, earinate; first six segments of the peræon short, first three of the pleon long, postero-lateral angles of the first rounded, of the second produced to a sharp point, in the third the hind margin makes an obtuse angle with the lower, and its lower part is cut into eight slightly upturned denticles; dorsally this segment rather shows a tendency to form a tooth than forms one; the fourth segment is longer than the two following united. Besides the ribbed appearance of the integument, this species

has rounded spots of a darker colour than the rest of the surface, numerous on the lower part of the first three pleon-segments, the third side-plates of the peræon and the first joints of the last three peræopods, but scattered also elsewhere.

Eyes meeting at the top of the head, roundish oval, the ocelli numerous.

Upper Antennæ.—First joint thick, bent, longer than broad, longer than the next two united; second much thinner than the first, nearly twice as long as the third; only nine joints of the flagellum remaining, the first much broader than the rest, narrowing distally, as long as the six following together, fringed with about four and twenty cross rows of broad filaments; the remaining joints carrying small filaments and setæ at different points of the margin; the slender secondary flagellum almost hidden in the bushy fringe of the first joint of the primary, serrate-edged, its first joint much longer than the second, fringed on the one side with setæ, on the other with spines, the narrower second joint reaching the end of the first joint of the primary; a small third joint is broken.

Lower Antennæ.—First joint a little expanded, second very short, third rather longer, bent, fourth twice as long as the third, closely fringed above with setæ; fifth considerably more than twice as long as the fourth, thicker near the base than distally, fringed like the fourth joint; twenty slender joints of the flagellum remaining, fringed with setules.

Upper Lip with the distal margin slightly convex, not incised.

Mandibles.—The cutting edge as in *Syrrhoë papyracea*; the secondary plate of the left mandible with six teeth; the spine-row showing three curved denticulate spines; the molar tubercle prominent, wedge-like, strongly denticleate, with a small seta at the back; the first joint of the palp short, bent forwards; the second joint very long, with the hind margin concave, the front margin convex, carrying six pairs of spines; the very small third joint carrying six very long spines; the muscles of the second joint appear to run right through from the lower outer corner to the apical inner corner. The cutting edge of the right mandible is figured in the Plate, not in profile, but flat, from the outside, with the secondary plate showing through, and not very clearly discerned.

Lower Lip as in *Syrrhoë papyracea*.

First Maxillæ.—Inner plate fringed with about twelve plumose setæ; on the outer plate the two innermost spines are long, slender, finely pectinate on the outer convex edge, the three following are denticulate with from six to eight denticles, the three furcate spines alongside of them have one arm of the fork much shorter than the other, the remaining three are as in the preceding species; the second joint of the palp is twice as long as the first, and has three curved pectinate spines set round the apex and six similarly ornamented setæ on the inner margin.

Second Maxillæ appearing to be very similar to those of *Syrrhoë papyracea*, the inner plate, however, broader than the outer.

Maxillipeds compact, differing but little in general structure from those of the preceding species; the outer plate with six strong and long spine-teeth on the inner margin, followed by four longer on the indented apieal margin, and one on the outer margin, rather shorter and more slender than those on the apex, but still more of a spine than a seta.

First Gnathopods.—Side-plates small and slender, directed forwards but not reaehing the base of the upper antennæ, the front margin little curved, its lower corner rounded and but slightly produced. The first joint not as long as the wrist and hand united, a little widened distally, the front margin a little concave, with a few setules, the hind margin convex or a little sinuous, with some long setæ; the second joint longer than broad; the third joint short, with the hind margin eonvex, furred below and carrying three setæ and a row of fine graduated geniculate spines, that nearest the apex the longest; the wrist nearly twice as long as the hand, narrow at both ends, widest near the base, the front margin carrying a few setules, the hind margin fringed with numerous spines of various lengths and some long setæ, many of the spines abruptly narrowing at about the middle and having the distal part pectinate; on the surface of this joint and of the hand there are numbers of adpressed cilia; the hand is narrow, widening a little distally, more than twiee as long as broad, with groups of long setæ at and near the apex of the front margin; the straight hind margin fringed with a row of short spines, and having a group of setæ at the apex; the palm is short, at right angles to the hind margin, of irregular outline, fringed with long setæ and defined by a great palmar spine, which on its inner margin has a prominent tooth at right angles, followed by some six slender denticles more oblique, and a rather stouter one that is decurrent; the short sturdy finger reaches beyond the palm-margin with its much curved nail, which equals or exceeds the proximal part of the finger; the dorsal eilium is close to the base of the nail, which has one or two cilia or setules at its base on the inner margin. As in the previous species the palmar spine is of such a character, that were it a process of the hand instead of inserted in it, the limb might be considered chelate rather than subchelate.

Second Gnathopods.—Side-plates not unlike the first pair, also directed forwards, the front margin nearly straight, considerably longer than the hinder margin. Branchial vesicles elongate oval. First joint thinner than in the first pair, but of about the same length, equal in length to the wrist; the seeond joint much longer than broad, longer than the third joint, channelled in front; the third joint shaped as in the first pair, but armed only with a seta and a setule near the apex; the wrist long and narrow, slightly bent, with some setules on the front margin and a group of setæ at its apex, the hinder margin having some long spines and setæ near the apex; the hand long and narrow, scarcely widened distally, about half as long as the wrist, with a large group of long setæ at, and another close to, the apex of the front margin; the hind margin

pectinate, the upper half fringed with small spines; the palm and finger as in the first pair, but smaller, the palmar spine not having the tooth at right angles to its inner margin.

First Peræopods.—The side-plates narrow above, the oblique front margin forming an acute angle with the long almost straight lower margin, the plate deeply excavate behind, so as to receive in the hollow nearly the whole of the following side-plate. The branchial vesicles like the preceding pair or rather longer, much longer than the first joint of the limb. The first joint slender, reaching much beyond the side-plate, with spinules or setules along the front margin, and a long feathered spine at the hinder apex; the second joint short, with a very small distal lobe in front, such as there is also on the first joint; the third joint shorter than the fourth, with three very slender geniculate spines standing out from the hind margin, the lowest much the longest; the fourth joint about as long as the fifth, narrowing distally, with slender spines at two or three points of the front margin, and five or six of the hinder, the lowest here being of great length; the fifth joint with very slender spines at three points of the front margin, and spines at ten points of the hind margin, the lowest much stronger than the rest and apically hooked; the finger with a small dorsal cilium near the base, a short nail, and a small decurrent tooth-spine at the base of it on the inner margin.

Second Peræopods.—Side-plates small, excavate behind, the hind margin below the excavation straight, the continuous curve of the front and lower margins scarcely extending beyond the preceding side-plate. The branchial vesicles like the preceding pair. The limb very little different from that of the preceding pair, with two or three long slender spines on the margins of the first joint, perhaps only accidentally missing in the first peræopods; the fourth joint with spines of various sizes at eight points of the hind margin, the front margin of this and the following joint pectinately furred.

Third Peræopods.—Side-plates very much broader than deep, bilobed. The branchial vesicles as in the preceding pairs, but smaller. The first joint longer than broad, the front margin descending lower than the hinder, which rises higher than the front, the lower part of the front margin carrying five short stout spines, the central part of the hind margin having five rather deep incisions, each with the usual cilium; the second joint is very short, with one spine at the front apex; the third joint is much shorter than the fourth, with nine long plumose setæ on the hind margin, and at its slightly decurrent apex a short spine and a long one with a very long accessory thread; it has short spines at six points in front; the fourth joint is long, the margins serrate, the front with spines at nine points, the hinder with eleven plumose setæ interspersed with long spines at five points, the spines stiff at first, but where the accessory thread arises becoming setæ-like and very finely pectinate; the fifth joint a little shorter than the fourth, spined at seven points in front and nine behind; the finger slender, a little

curved, scarcely half the length of the fifth joint, having a short nail, with a spinule on the inner margin at its base, and another at some distance from the base.

Fourth Peræopods.—Side-plates shallow, oblong behind. The limb similar to that of the preceding pair, but longer. The first joint nearly as broad as long, with six spines on the front margin, and six deep slits and one shallow one on the hind margin; the third joint with fourteen setæ on the hind margin; the finger much less than half the length of the fifth joint.

Fifth Peræopods.—Side-plates shallow, not lobed. The first joint not large, but larger than that of the preceding pair, longer than broad, produced behind beyond the short second joint; the third, fourth, and fifth joints longer than those which correspond in the preceding pair; the finger a third the length of the fifth joint.

Pleopods.—Coupling spines rather long and slender, with a row of three or four lateral teeth; below the coupling spines there are some acute spines; the eleventh spines are four in number on the comparatively very short first joint of the inner ramus; the joints of the rami vary in number on the different pairs from fifteen to eighteen.

Uropods.—Peduncles of the first pair longer than the rami; the outer ramus much shorter than the inner, with two or three spines on the margin and two at the apex, the inner ramus shorter than the outer of the second pair, spined along the margins and at the apex; peduncles of the second pair reaching beyond those of the first, much shorter than the inner ramus; the outer ramus spined along both margins and at the apex, much shorter and more slender than the broad and long inner ramus, which reaches even beyond the rami of the third pair, is spined along both margins, and apically pointed; the rami of the third pair are long, lanceolate, the outer rather shorter than the inner, with spines on the margins, a nail at the apex, and long densely plumose setæ on the inner margin; the inner ramus likewise fringed with marginal spines and plumose setæ on the inner margin.

The Telson reaching beyond the peduncles of the third uropods, much longer than broad, cleft much beyond the middle, the apices probably acute, but in our specimen broken, hence in the figure appearing trunate.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the apices of the third uropods, three-tenths of an inch.

Locality.—Station 161, off Melbourne, April 1, 1874; lat. $38^{\circ} 22' 30''$ S., long. $144^{\circ} 36' 30''$ E.; depth, 33 fathoms; bottom, sand. One specimen, male. Trawled.

Remark.—The specific name refers to the partial serration of the hind margin of the third pleon-segment, which among other things distinguishes this species from *Syrrhoë crenulata*, Goës.

Family SYNOPIDÆ, Bovallius, 1886.

In Dana's classification, 1852, the Synopinæ are the third subfamily of the Hyperidæ; Spence Bate, in 1862, made the Synopiades the first subfamily of the Oxycephalidæ; Kossmann, in 1880, places the family Synopiadæ in the tribe Hyperina; Bovallius, in 1886, named the family Synopidæ, with the following diagnosis:—

- “The head is triangular, not tumid.
- “The eyes occupy the upper median part of the head, and are distinctly faceted.
- “The mandibles are well-developed, with a three-jointed palp.
- “The maxillipeds, coalesced at the base, carry strong four-jointed palps.
- “The antennæ are fixed on the under side of the head. The second pair are like those of the Gammarids.
- “The seventh pair of pereiopoda are not transformed.
- “The uropoda are like those of the Gammarids.
- “The telson is eleft to the middle.”

According to Bovallius the Synopidæ are the first family of a new tribe which he names Amphipoda Synopidea, and in which he places two other families, named respectively, Trischizostomatidæ, Sars, and Hyperiopsidæ. In my opinion the resemblance of *Trischizostoma* (or rather *Guerinia*) to such genera of the Lysianassidæ as *Aeidostoma* and *Aeontiostoma* is far too close to permit of its separation from the Amphipoda Gammarina (Gammaridea, Bovallius). I have already (p. 576) expressed a similar opinion with regard to the Synopidæ, and think that Claus was quite right when, in 1871, he incidentally remarked that the genus *Synopia* belonged to the Gammarids. If the tribe Synopidea be set aside, much of the diagnosis above given becomes superfluous, since what is said of the maxillipeds, the second pair of antennæ, the seventh (our fifth) pair of peræopods, and the uropods, does not require mention for an accepted family of the Amphipoda Gammarina. On the other hand, the remnant of the diagnosis would not suffice to distinguish this family from the nearly related Syrrhoidæ and Pontoporeiidæ; I propose therefore to add the following characters:—

Upper Lip apically bilobed.

Mandibles with the second joint of the palp broad, the third minute.

First Maxillæ with the inner plate small.

Second Gnathopods not subchelate.

First and Second Peræopods with the third and fourth joints dilated.

Whether the eyes are in reality faceted I am unable to say.

Genus *Synopia*, Dana, 1852.

1852. *Synopia*, Dana, Amer. Journ. Science and Art, ser. 2, vol. xiv.
 1852. " Dana, U. S. Explor. Exped., vol. xiii. pt. 2, pp. 981, 994.
 1862. " Spence Bate, Brit. Mus. Catal. Amph. Crust., p. 341.
 1880. " Kossman, Zool. Ergeb. Küst. des rothen Meeres, p. 137.
 1886. " Bovallius, Amph. Synopidea, p. 4.

For the original definition of the genus, see Notes on Dana, 1852 (pp. 259 and 268).
 Bovallius defines the genus thus:—

- “ The *body* is compressed.
 - “ The *head* is narrow, triangular.
 - “ The *eyes* are very large, coalesced into one in the middle of the head, with distinct large ocelli.
 - “ The first pair of *antennæ* with a multiarticulate flagellum; the first joint of the flagellum very long, beset with long hairs.
 - “ The first four pairs of *pereiopoda* [first and second gnathopods and first and second peraeopods] are unequal, setose, the three last ones subequal, elongate, with long dastyli.
 - “ The last pair of *uropoda* with the outer rami biarticulate.
 - “ The *telson* is very large.”
- The size of the telson, however, seems scarcely suited for a generic character, since in *Synopia schéeleana*, Bovallius, the telson is of no great comparative size, and in *Synopia gracilis*, Dana, Bovallius himself describes the telson as “ obsolete.”

Synopia schéeleana, Bovallius, 1886 (Pl. LII.).

1886. *Synopia Schéeleana*, Bovallius, Amphipoda Synopidea, p. 16, pl. ii. figs. 22–29.

Head as long as the first three segments of the *pereion*, rostrum or front of the head bent down at a right angle to the dorsal line, both this front and the whole dorsal line of the animal being sharp-edged; the segments of the *pereion* short, the first three of the *pleon* long and large, the fourth as long as the fifth and sixth united; the first three segments of the *pleon* postero-laterally angled, but not sharply.

Eyes large, oval, meeting at the top of the head, set diagonally across the top front corner of the head. The colour dark in the preserved specimens. Underneath the large eyes, in more or less close proximity, but externally quite distinct, there are two small ones of a few (seemingly four) ocelli.

Upper Antennæ.—First joint bulbous, as broad as long; second much shorter and narrower than the first, and the third than the second; flagellum with ten joints

remaining, the first longer than the first of the peduncle or the three following of the flagellum, rapidly tapering, fringed with a brush of long filaments; the next joint short and narrow, with a little apical spine and some marginal setules, the other joints longer, not much thinner, similarly furnished. The secondary flagellum narrow, about as long as the first joint of the primary, two-jointed, the terminal joint minute, missing in the present specimen.

Lower Antennæ.—First joint little expanded, gland-cone very small, third joint longer than broad, apically pointed, fourth joint considerably longer than fifth, broader at the base than distally; fifth joint longer than the third, narrowest at the base; flagellum with fourteen slender joints remaining, at the base abruptly narrower than the peduncle.

Upper Lip unsymmetrically bilobed, both lobes ciliated, the smaller also very finely denticulate, and carrying some minute spine-teeth.

Mandibles.—The cutting plate not very broad, with four or five teeth; the secondary plate on the left mandible with four teeth, that on the right mandible more slender, with two slender distal teeth and possibly some unobserved denticles; the spine-row of six curved dentieulate spines; the molar tubercle tolerably massive, with a strong tuft of cilia at the front corner of its multidentate crown, and a small seta behind; the palp shorter than the body of the mandible, the first joint very small, the second abruptly broader, nearly three times as long as broad, with two long plumose setæ on the inner margin; the third joint minute, but tipped with two plumose setæ, still longer than those on the second joint. In the Plate the mandibles are figured from the outer side, so that the right mandible is on the left, the left on the right, of the Plate.

Lower Lip.—The principal lobes closely ciliated on the distal and inner margins; the mandibular processes short and narrow.

First Maxillæ.—The inner plate with five long plumose setæ on the inner margin and two short setæ at the apex; the outer plate appears to have eight small spines on the truncale distal margin, of which the outermost is denticulate, three are distally furcate, and the rest smooth; the second joint of the palp is strongly ciliated on the outer margin, and has five spine-teeth on its distal border, the outermost being longer than the rest, and pectinate.

Second Maxillæ.—The inner plate with a row along the inner margin of about eighteen long setæ slightly widened near the base; the apical border of each plate furnished with several plumose seta-like spines.

Maxillipeds.—The inner plates short, not reaching the distal end of the first joint of the palp, with about ten ciliated spines or setæ on the sloping distal margin and upper part of the inner edge, which below is strongly ciliated; the outer plate narrow, not quite reaching the apex of the second joint of the palp, strongly ciliated on the outer margin, which has at the top two long plumose setæ; there is also a long row of plumose setæ

down the inner margin; the first joint of the palp is short, the second very long, fringed on the inner margin with long plumose setæ, whieh, like those of the outer plate, might equally well be designated as spines; the third joint a little bent, with two plumose setæ on the convex outer margin, and three on the truncate distal border; the finger very small, the long spine-like nail being about twice as long as the base.

The *triturating organs* appear to have very many slender spines, but not stout strong ones.

First Gnathopods.—Outline of side-plates not clearly made out. First joint reaehing much beyond the side-plate, as long as the wrist, widening distally, near the front apex having two long plumose setæ; the second joint with a plumose seta on the hinder apex; the third joint with the hind margin almost semicircular, earrying a setule at the centre, two plumose setæ near the apex; the wrist a very elongate oval, narrow at both ends, much longer than the hand, the front margin convex, unarmed, except that at the apex there are two geniculate spines which have their lower half peetinate; the hind margin more convex, fringed with eighteen long plumose setæ, near which there are five or six smaller setæ on the surfacee; the hand narrow at the base, thenee rapidly widening, tending to oval, the front margin with two apical spines, one apparently smooth, the other feathered with six or seven long branches; the convex hind margin carries nineteen long plumose spines or setæ, and close to the finger a geniculate spine mueh longer than the rest, and mueh longer than the finger; the surface has many adpressed cilia near the front, and five plumose spines near the hind margin; the finger is nearly as long as the hand, slender, slightly geniculate, the tip curved.

Second Gnathopods.—Side-plates doubtful, seemingly with the front and lower margin forming a continuous convex curve. Branehial vesicles longer than the first joint of the limb. In a female specimen the marsupial plates were very narrow, but nearly as long as the branchial vesicles, and having long setæ. The first joint of the limb slenderer than in the preeeding pair, about as long as the wrist, but narrower; the second and third joints small as in the preeeding pair, the third with two setules but seemingly without long apieal setæ; the wrist elongate, as long as in the preeeding pair, but mueh narrower, narrowest distally, the hind margin carrying about fourteen pairs of long setæ, strongly rather than densely plumose, most of them geniculate, and on a blunt apex having a little point with two long arms, diverging one on either side; the hand longer and narrower than in the preeeding pair, about three-quarters the length of the wrist, narrow at both ends, with seven of the furcate and six of the unfurcate setæ along the hinder margin, the apex having two of mueh greater length than the rest, longer than the hand itself; between the two latter is the minute finger, of whieh the basal portion has a tooth on the inner margin, and the nail, which is equally long but abruptly narrower, has one on the outer.

First Peræopods.—Side-plates larger than the preeeding pair, front margin similar,
(ZOOL. CHALL. EXP.—PART LXVII.—1887.)

the hind margin sloping irregularly backwards, to form an acute angle with the convex lower margin. The branchial vesicles narrow above and below, longer than the first joint of the limb, the distal end bending a little forwards. The first joint reaching beyond the side-plate, wider below than above, with three spines on each margin; the second joint with one spine at the hinder apex; third joint about as long as the wrist, and broader, the front margin eiliated, with a long spine at the apex, the hind margin very convex, with three spines on the lower part; the wrist oval, the distal end narrow, the hind margin a little erenate, with nine long plumose spines or setæ; the hand narrow, as long as the wrist, with six slender plumose setæ on the hind margin; the finger straight, not tapering, with a little curved nail, the two together not so long as the adjacent spines, which indeed exceed the length of the hand.

Second Peraopods.—Side-plates not clearly made out, but apparently much smaller than the preceding pair. Branchial vesicles like the preceding pair. First joint of the limb narrow above, much dilated below, lageniform, with a long apical spine or seta on the hind margin, and a spine above the apex on the front margin; the second joint short, with an apical seta behind; the third joint more triangular than in the first peraeopods, similarly armed, not nearly so long as the wrist; the wrist long, oval, much larger than in the first peraeopods, attached to the third joint by the top of the smooth front margin, the hind margin from apex to apex set round with twenty-two long plumose setæ, those below being the longest; the hand very much smaller than the wrist, a narrow oval, rather wider at the truncate distal end than at the base, with an apical seta in front, and eight very long ones on the serrate hinder margin; the finger is small, straight, with a little decurrent tooth or spinule on the inner margin at the base of the short curved nail.

Third Peraopods.—The side-plates appear to be small, but the extreme delicacy and transparency of these and the other side-plates make it extremely difficult to ascertain their precise boundaries, and in Dana's figures of this genus they are almost concealed under a blotch of colour.¹ The branchial vesicles reach below the second joint of the limb. The first joint is oval, the front longer than the hinder margin, with three setiform spines at intervals and a small apical spine, the hind margin of great tenuity; the

¹ By Bovallius, Amphipoda Synopidea, pp. 9, 10, a clear account is given of the side-plates of *Synopia ultramarina*, Dana, as follows:—"The epimerales of the first and second segments are as long as the segments, of an irregular shape and only half as deep as long. The epimerales of the third segment (Pl. I. fig. 13) are enormously developed. They are quadrangular, with the upper corner (the articulation with the segment) truncate, and the hinder margin excavate. At the inside of the upper corner is a tuberculous prominence, against which the upper end of the femur articulates; the epimeral is as deep as the length of the femur of the corresponding leg, quite as large as the femur of the fifth pair. The epimerales of the fourth segment are scarcely as long as the segment (Pl. I. fig. 14), deeper than long, the anterior margin rounded, the posterior straight; at the middle of the upper margin there is on the inside of the epimeral a tubercular projection for the articulation with the leg. The epimeral reaches as far down as half the length of its femur, and is partly concealed by the femur of the fifth pair of pereiopoda. The epimerales of the fifth and sixth segments are longer than the segments, rounded at both ends, more than twice longer than deep; the posterior portion is a little deeper than the anterior. The last epimerales are shorter than the segment and smaller than the preceding, but of the same form (Pl. I. fig. 17)." Of *Synopia scheeleana*, he says, "The epimerales (Pl. II. fig. 22) resemble very closely those of *S. ultramarina*."

second joint short; the third longer than the fourth, shorter than the fifth, with apical spines before and behind, and three small spines along the front margin; the fourth joint with apical spines in like manner, and two groups on the front margin; the fifth joint with spines at six points in front and three behind, one of those at the front apex being much longer than the rest; the finger almost straight, about half the length of the fifth joint, pectinate.

Fourth Peræopods.—The side-plates with the lower hinder corner apparently angled. The branchial vesicles and limb almost as in the previous pair, but all the joints larger, the first with one seta instead of three on the front margin, the third with only one small spine high up on the front, and one low down on the hind margin, besides the apical spines; the fourth joint with an extra spine on the hind margin; the fifth with spines at eight points in front and five behind; the front margins of the lower joints more conspicuously pectinate than in the preceding pair.

Fifth Peræopods.—Branchial vesicles nearly as large as the first joint. The first joint not oval, the front and hind margins nearly straight except at the top, unarmed, the hinder produced so as to form an acute angle with the lower margin much below the short second joint; the third joint not quite so long as the first or fifth, longer than the fourth, with spines at three points in front, and the apex behind; the fourth joint with spines at four points in front and two behind; the fifth with spines at seven points in front and five behind; the finger rather shorter than in the preceding pair.

Pleopods.—The peduncles of great breadth, the hinder apex rounded; the coupling spines broad for the basal two-thirds, then narrow, with two lateral teeth projecting, not retroverted; the cleft spines two in number, the outer arm not much longer than the inner, conspicuously pectinate; the joints of the rami twelve to thirteen.

Uropods.—Peduncles of the first pair subequal to the inner ramus, with four spines on the upper margin; the outer ramus shorter than the inner, with one of its upper edges finely pectinate, the other pectinate with small spines, the apex having three spines, of which the largest has the appearance of being jointed in the middle; the inner ramus is similarly furnished, but has also a spine at the middle of the finely pectinate margin; peduncles of the second pair scarcely so long as the inner ramus, not nearly reaching so far back as the peduncles of the third pair, carrying three spines on the upper margin; the outer ramus shorter than the inner, pectinate with spines along the upper margin, and tipped with a spine of jointed appearance, the inner ramus armed in like manner, with the addition of a prominent spine on the proximal part of the upper margin; the peduncles of the third pair very much shorter than the rami, which are long, broad, lanceolate, subequal, fringed on the inner margin with long plumose setæ, the outer with a spine on the outer margin not far from the apex.

Telson short, oval, reaching a little beyond the peduncles of the third uropods, cleft beyond the centre, each apex forming a double point, the outer advanced beyond the inner, the cavity containing a small spine.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the apex of the third uropods, one-fifth of an inch.

Locality.—The specimen figured was taken in the Pacific, at the surface, September 1875. The figure of the fifth pereiopods, with the adjacent ventral portion of their segment, will show that this specimen was a male. A female of the same species was taken at St. Vincent, Cape Verde, April 26, 1876. A third specimen, small and in poor condition, was taken at the surface, lat. $24^{\circ} 49' N.$, long. $138^{\circ} 34' E.$ A fourth specimen was taken in "W. Pacific, 16 Febr. 75."

Remarks.—That the species belongs to Dana's genus there can be no doubt, although he speaks of a single large compound eye, whereas to the present species one might be justified in attributing two pairs of eyes.

From Dana's *Synopia ultramarina* the present species differs in having the second joint of the mandibular palp much longer; the finger of the first gnathopods in Dana's species "applies against the rounded terminal margin" of the hand, which it scarcely seems adapted for doing in our species; of the first pereiopods Dana says that "the finger is slender, with a short claw, the whole about as long as the hand," but in our species the proportions of the joints referred to are different, the hand and finger together being considerably longer than the wrist. He says, moreover, that the branchiae in his species are oblong, sublinear, except those of the fifth pereiopods. Here the epithet sublinear would not apply. It is nevertheless still possible that both this and Dana's own *Synopia angustifrons* may be synonyms of his *Synopia ultramarina*, the resemblances between the three having a tendency to outweigh the differences.

The figures and description given by Bovallius of his new species so closely agree with those prepared for the Challenger specimens, that I have little hesitation in accepting his specific name, to supersede that which I had myself chosen. But here also there are some slight points of difference: Bovallius figures a lageniform eye; he states that in the second pair of uropods the outer ramus is totally smooth along both margins, and he describes the telson as "bifid with rounded ends, the fissure scarcely equalling half the length of the telson," without either mentioning or figuring the small apical cavity in each half of the telson. He gives the colour of his specimens as hyaline, the length 4 to 6 mm., the habitat "the tropical parts of the Atlantic" and "some twenty miles east off Barbadoes."

Family PONTOPOREIIDÆ, G. O. Sars, 1882.

Dana in 1852 established the Pontoporeinæ as fifth subfamily of the Gammaridæ. He placed it under the heading, "Pedes 10 postici partim prehensiles," with the vague and insufficient definition, "Pedes 3tii 4tique plus minusve prehensiles; 6 postici non

prehensiles." To it he assigns the genera *Lepidaetlylis*, "Pontiporeia," *Ampelisca*, *Protomedea*, *Aora*, in one division, and *Phoxus* by itself in a second. In 1857¹ Spence Bate made the Pontoporeidae the fourth subfamily of the Gammaridæ, with the genera *Westwoodia*, *Kroyera*, *Phoxus*, *Suleator*. In the same year he changed the name of the subfamily to Phoxides, on the ground that Kroyer's *Pontoporeia* belonged to the Lysianassides. In 1862 he placed in the subfamily Phoxides the genera *Phoxus*, *Grayia*, *Westwoodilla*, *Oedieerus*, *Monoculodes*, *Kroyera*, *Amphilochus*, *Darwinia*, *Lafystius*, *Guerinia*, *Lepidaetlylis*, *Suleator*, *Urothoë*, *Liljeborgia*, *Phædra*, *Prosonniseus*, *Isæa*, *Iphimedia*, *Otus*, *Acanthonotus*. Lilljeborg in 1865 made the "Pontoporeina, Dana," the second subfamily of the Gammaridæ, with the genera *Bathyporeia*, *Stegocephalus*, *Pontoporeia*, and the "Phoxina (Phoxides, S. Bate)" the fourth subfamily, with the genera *Phoxus*, *Urothoë*, *Tiron*, by implication therefore including *Syrrhoë* also. Boeck in 1870 made the "Pontoporinæ, Dana," the second, and the "Phoxinæ, Spence Bate," the fifth subfamily of the Gammaridæ. In 1872–6 he placed the two subfamilies side by side, as respectively the second and third subfamilies of the Gammaridæ, the Pontoporinæ receiving the genera *Pontoporeia*, *Priseilla*, *Argissa* and *Bathyporeia*, the Phoxinæ containing the genera *Phoxus*, *Harpinia*, *Suleator*, *Urothoë*. Gerstæcker in 1866 places *Stegocephalus*, *Pontoporeia*, and *Bathyporeia* in the second division of the "Lysianassina (et Stegocephalina), Dana," sinking the names *Andania*, *Priseilla*, and *Argissa* as synonyms, while to the "Phoxina Sp. Bate," he gives much the same extension as Spence Bate gives to the Phoxides. Sars in 1882 established, without defining, the Pontoporeiidæ, as fourth family of the Gammarina, placing in it the eight genera which Boeck had divided between the Pontoporinæ and Phoxinæ. From the definitions given by Boeck of the two groups, the following characteristics may be taken as belonging to both:—

Upper Lip apically rounded.

Mandibles apically dentate, strong, with a powerful molar tubercle, palp triarticulate.

Upper Antennæ short, with an accessory flagellum.

Third, Fourth, and Fifth Peræopods of various forms in the different genera, especially the third pair; the fourth pair generally longer than the third or fifth, sometimes much dilated; the fifth pair with the first joint much dilated.

The *Uropods* biramous.

Telson more or less eleventh.

The first four pairs of side-plates generally large, plumose on the lower margins.

In 1885 Sars makes the Phoxidæ the second family of the tribe Gammarina, placing in it the genera *Phoxus*, *Harpinia* and *Urothoë*, but without otherwise indicating the limits of the family.

¹ See also Note on Spence Bate, 1856 (p. 290).

Genus *Cardenio*, n. gen.

Upper Antennæ shorter than the lower; the first joint not apically clubbed, the third joint not shorter than the second of the peduncle or the first of the flagellum.

Third joint of the mandibular palp short, but not rudimentary.

Maxillipeds.—The fourth joint absent or rudimentary.

The finger rudimentary in the first gnathopods, absent from the second gnathopods, the first, second, and fifth peræopods, short and blunt in the third and fourth peræopods.

Telson long, deeply cleft.

The generic name is taken from a character in Don Quixote.

The genus is allied to *Bathyporeia*, Lindström, by the character of the limbs, the gnathopods also showing a resemblance to those of *Synopia*, Dana.

Cardenio paurodactylus, n. sp. (Pl. LIII.).

The head projecting over the antennæ in what from above or from the side appears to be a rounded point, but in front appears to be trunate; the head dorsally as long as the first two segments of the pereon; the back rounded, widening to the centre of the pereon, and then narrowing; the hind rim of the pleon-segments more or less crenate or dentate across the centre of the back; the postero-lateral angles of the first two rounded, of the third acute; the fourth, fifth, and sixth segments not very short.

Eyes small, reniform, set near the front of the head, near together, forming an angle one with the other, dark in the spirit-specimen, with the ocelli numerous, more than sixty in number.

Upper Antennæ.—Peduncle of three short joints, the first a little longer than the third, both than the second, which is intermediate in thickness; flagellum four-jointed, equal in length to the second and third joints of the peduncle, with a pair of stout cylinders on each of the first and second joints; the secondary flagellum with one long joint and a minute second one, the two together not equalling the first of the primary, which itself is longer than the second of the primary, but shorter than any of the joints of the peduncle. In one specimen the accessory flagellum had an additional joint.

Lower Antennæ.—First and second joints short and small, gland-eone not produced; third joint as long as the two preceding combined, fourth joint stouter but a little shorter than the fifth; third, fourth, and fifth armed to some extent with spines; flagellum slender, five-jointed, the first joint the longest. In one specimen the flagellum was seven-jointed.

Upper Lip.—Both plates broad and thin, squarely rounded distally, the outer advanced a good deal beyond the inner, its distal margin smooth in the centre, with a group of cilia on either side.

Mandibles short and strong; cutting edge divided into four teeth; secondary plate on the left mandible with a strong upper tooth and three smaller below it, on the right mandible bidentate, but with denticles on the larger teeth; the plan of these plates is best seen in the unworn condition as it appears through the transparent integument in preparation for the next change of skin; the spine-row exhibits three curved serrate spines on the left mandible, on the right only two, but one of these two laminar; the molar tubercle very large and prominent, with strongly dentate crown; the palp set rather behind the very forward molar tubercle, its first joint very short, the second longer than the first and third united, with spines on the surface near to both margins; the short third joint, widest about the centre, has spines on the inner side of the upper half, the longest at the rounded apex.

Lower Lip short and broad, inner lobes stout.

First Maxillæ.—Inner plate broadest at the base, with twelve plumose setæ round the inner margin and apex; outer plate broadest at the base, carrying on the trunecate apical margin nine finely denticulate or pectinate spines; the long second joint of the palp overarched by the outer plate, and on its apical margin carrying six slender spine-teeth, and seven small setæ below the apex.

Second Maxillæ.—Both plates broad, with long slender spines on the broad apical margins; the inner plate also with a row of setæ passing from the inner margin across towards the outer apex, and with two spines or setæ on the inner margin just below the apex.

Maxillipeds.—Inner plates rather small, but extending considerably beyond the very short first joint of the palp, the broad apical margin irregularly dentieulate, carrying several plumose setæ; there are some long plumose setæ on the inner margin and a curved spine-tooth at its apex; outer plates nearly reaching the apex of the long second joint of the palp, inner edge almost smooth till near and at the apex, where it is serrate and armed with setæ successively increasing in length as they pass to the outer part of the apical margin; within the inner margin, at a little distance from the base, begin rows of slender spines, not very acute; the inner margin of the large second joint of the palp has abundance of long setæ; the short third joint has also several; this widens distally, and is apically set about with strong spines, some of them long, one of them finely pectinate; the fourth joint or finger seems to be absent or rudimentary.

First Gnathopods.—Side-plates quite small and inconspicuous, front margin rounded. First joint long, equal to the wrist and hand together, finely pectinate on the lower part of the almost straight hind margin, there also carrying some long plumose setæ, distally lobed in front, the lobe fringed with plumose setæ; the second joint shorter than the small oval third joint, both furred slightly on the hind margin, the third with numerous spines round the lower part of the hind and the somewhat squared apical margins; the

wrist large, twice as long as the hand, and much broader, the front margin straight and smooth, the hinder eonvex, fringed almost all round with strongly pectinate spines and setæ, with setæ also on its surfaces; the hand with a narrow neck, the convex front margin furred slightly, the hind margin straight; round the serrate distal half of the hand is set a fringe of spines; on the apex a little tubercle represents the finger, from the apex of the tubercle projects a nail or short sharp spine, and a cilium about twice the length of the nail.

Second Gnathopods.—Side-plates large and broad, narrowed a little distally, with cilia round the lower part of front and the lower margin. Branchial vesicles simple, not very large; marsupial plates small in the specimen examined, with cilia at intervals. First joint long, reaching below the side-plate, a little curved, the concavity facing forwards; the second and third joints very short and small, the third rather longer than the second, with an angular lappet on the outer side near the base; the wrist very elongate, all but as long as the first joint, narrowing distally but in no part broad, carrying on either side a series of very long, distant setæ, sparsely plumose with long distant cilia; the hand long and narrow, narrowest at either end, more than half the length of the wrist, which it resembles in armature, but with the upper part of the almost straight hinder margin free from setæ; there are four long setæ at the apex, one point of which projects beyond the rest, but there seems to be no representative of a finger; to the setæ in question lines could be traced running the whole length of the hand. The first joint, wrist, and hand are adapted to fold up closely side by side; to a more limited extent this is the case in the first gnathopods also.

First Peræopods.—Side-plates deeper and broader than the preceding pair, widest distally. Branchial vesicles and marsupial plates much as in the preceding pair. First joint not reaching to the end of the side-plate, distally in front slightly lobed, behind carrying a row of long plumose setæ; second joint short, hind margin furred, apex with setæ; third joint shorter than fourth, dilated, widest apically, scarcely decurrent, with setæ on both margins; fourth joint dilated, widest proximally, with setæ on front, hind, and apical margins; fifth joint shorter and very much narrower than the fourth, straight, narrowing distally, with spines or setæ at two points of each margin, and a group at the apex, at which a cilium marks the place where the finger is not, unless it be represented by a little triangular point near the cilium, within the apical margin.

Second Peræopods.—Side-plates scarcely deeper than the preceding but much broader, a little broader than deep, with no excavation behind worth calling such. First joint not reaching the end of the side-plates, with a longer row of plumose setæ on the hind margin than in the preceding pair; third joint longer and broader than the fourth, with spines at two points of the hind margin, and at the apex before and behind; the fourth joint not dilated, a little furred on the front margin, with a spine at the middle of the hind margin, and a group at its apex; the fifth joint straight, slender, narrowing a little

distally, rather longer than the fourth, with the margins smooth, not as in the preceding pair notched for the spines ; at the apex a group of spines of various lengths, and a small feathered cilium ; no finger apparent.

Third Peraopods.—Side-plates small, broader than deep, presenting a rounded lobe pointing forwards and upwards, and a more elongate one pointing backwards and downwards, this latter with its lower margin straight and a spine at the apex. First joint enormously larger than the side-plate, irregularly rounded, broader than deep, the hinder margin smooth, the front one with a few slender spines round the lower half ; the second joint small, without spines ; the third very large, equalling the length of the first, and at the centre more than half its breadth, with spines on both margins, but weak ones ; the fourth joint insignificant in comparison with the third, which overlaps it partially behind, but much broader and a little longer than the fifth, with spines on the front margin, and apically behind ; the fifth joint straight, with smooth margins, widening slightly towards the apex about which it carries various spines ; the sixth joint short and stout, not one-third the length of the fifth joint, with a cleanly rounded, in no way pointed apex, instead of a nail carrying three spines of very different lengths, but similar in structure, each having its distal end bent forward at an obtuse angle, while the hind margin is continued on for a small distance behind the bent part, so that the effect is that of a long Wellington boot, with a delicately-shaped foot ; there is one such spine among those on the fifth joint.

Fourth Peraopods.—Side-plates similar to those of the preceding pair, but shallower, with two spines on the straight lower hinder margin. Branchial vesicles small, bent directly forwards. The first joint longer than broad, wider above than below, the front margin convex, with spines at three or four points, the hind margin sinuous, the outer surface outdrawn below into a lobe which overlaps the short second joint ; the third joint longer than the first, of considerable width, with the sides parallel for most of the length, the spines few and slight ; the fourth joint as long as the fifth and sixth together, which closely resemble those of the preceding pair.

Fifth Peraopods.—First joint longer than wide, expanding rapidly from a narrow base, widest below ; front margin slightly convex, smooth, hinder slightly serrate ; third joint not longer than broad, much shorter than the first joint and not longer than the fourth, with spines on both margins ; the fourth joint broader but shorter than the fifth, with groups of spines on both margins ; the fifth long, straight, narrowing a little distally, with spines at three points on the front, at two on the hind margin, and a group round the apex, to which in none of the specimens was any finger attached.

Pleopods.—There are some groups of setæ on the peduncles ; the two coupling spines are small, one showing four, the other three, retroverted teeth on one of the margins ; the opposite margin appears to be serrate, but possibly the difference in the aspect of the two margins is due only to the point of view ; the joints of the rami vary in number from seven to eleven ; there is but one eleft spine to each pair.

Uropods.—Peduncles of the first pair longer than the rami, which are subequal, the outer rather the longer, each with a distal group of spines; peduncles of the second pair shorter than the longer, longer than the shorter, ramus; both rami with apical groups of spines, the longer with pectinate margin and spines at two points upon it; peduncles of the third pair much shorter than the lanceolate rami, of which the outer is a little the shorter.

Telson very long and narrow, reaching far beyond the peduncles of the third uropods, sharply tapering, cleft nearly to the base, and distally scarcely dehiscent, the apex of each half tipped with a spine.

The Length of the outstretched specimen as figured was rather over four-twentieths of an inch, of the dried specimen as figured three-twentieths.

Locality.—Betsy Cove, Kerguelen, January 10, 1874. Four specimens.

Remarks.—The details have been figured from a female specimen. The specific name, derived from *παῦροι*, few, and *δάκτυλος*, a finger, refers to the scarcity of fingers in this creature, for they seem to be wanting in the maxillipeds, the second gnathopods, the first, second, and fifth pereiopods, to be rudimentary in the first gnathopods, and very short in the third and fourth pereiopods.

From Scudder's *Nomenclator Zoologicus* it appears that the name *Phoxus* was pre-occupied among Coleoptera by Billberg in 1820; I have therefore substituted the form

Phoxocephalus in accordance with the explanatory derivation which Krøyer supplies at the institution of the genus.

For the original definition see Note on Krøyer, 1842 (p. 198). Boeck in 1870 and 1876 gives the following:—

“First Maxillæ with the palp one-jointed.

“Maxillipeds with the palp narrow, the plates small.

“Third Peraopods with the first joint dilated behind.

“Body compressed, deep; head produced into a broad rostrum, which towards the apex is acuminate or curved.

“Third Uropods with the inner ramus in the male equalling the length of the outer, in the female much shorter.”

Phoxocephalus bassi, n. sp. (*Phoxus bassi*, Pl. LIV.).

Head a large triangle, longer than the breadth at the base; the rostral portion viewed laterally looks like the nib of a quill pen; it projects as far as the outstretched peduncle of the upper antennæ, of which it completely covers the first joint; the apex is blunt; the first three segments of the pleon much longer than any of the peræon-segments; their postero-lateral angles rounded; the fourth segment with a dorsal depression; the fifth very short.

Eyes large, irregularly quadrate, very dark in the spirit-preserved specimen, with very numerous, small ocelli.

Upper Antennæ.—Peduncles nearly as long as the flagella, first joint longer than the next two united, much thicker than the second, which is longer and thicker than the third; there are feathered cilia on the first joint, and a group of setæ at the inner apex; several setæ at the outer apex of the second joint have the distal part plumose; the third joint is thicker but little longer than the first of the flagellum; the eight joints of the flagellum do not differ materially in length but successively decrease in thickness, small calceoli, cylinders, short setæ and cilia are among their appendages; the accessory flagellum of five joints does not quite equal in length the first four of the primary.

Lower Antennæ.—The first joint somewhat expanded, the gland-conc obscure, third joint broad, not long, distinguished by a furry tuft on the distal part of the upper border; the fourth joint not very much longer, but much broader than the fifth, with partially feathered setæ below, and strong flat spines (each with an accessory thread) on the surface and round the distal margin, and on the surface within the upper margin a furry brush of cilia; the fifth joint with a pair of spines about the middle of the upper margin and at its apex, a few small groups of cilia along that margin, and some setæ at the apex and on the lower margin near it; the flagellum is of great tenuity, reaching nearly back to the hinder extremity of the animal; it consists of thirty-seven joints bearing calceoli on

every other one, all the first four, however, being so armed, as well as the apex of the fifth joint of the peduncle; the caleoeli are very small; the last joint of the flagellum is tipped with a long seta, except under a high power scarcely distinguishable from the slender joint itself; a short thin seta or cilium attends the larger one.

Upper Lip.—The apical margin of the broad plate shows a central prominenee between two small depressions, the rows of very short cilia over the eentral part giving it, when highly magnified, a sort of nutmeg-grater appearance.

Mandibles.—A short massive trunk, from which in the left mandible the cutting plate projects somewhat abruptly, with a strongly sloping front edge, not so much toothed as having a small unevenness above and a larger one below, the hind margin sloping upwards from the rounded apex so as to make the whole plate a sort of massive tooth; the secondary plate not much smaller, broad, with its front margin divided into four broad teeth; close behind this the spine-row consists of three strong curved ciliated spines with the tips bent hookwise; near to the spine-row is the molar tubercle, small, but compact and strong, the oval dentate crown set round with long sharp teeth; a small plumose seta at the upper corner; just over, but a long way above, the molar tubercle, the palp is placed, having just below it a small tooth-like process, which resembles Schiødte's articular condyle in the Lysianassidæ; the first joint of the palp is very small, the second large, narrowed a little distally, with five setiform spines along the upper half of the inner margin; the third joint, almost as long as the second, from a narrow base widens a little for more than half its length, with smooth margins, then narrows to the apex, having the inner margin of the narrowing tract thickly set below with setiform spines, but above and for the most part with large flat sword-spines, the two sets together numbering fourteen. In the right mandible the secondary plate has two large teeth below, and its margin above these cut into a dozen denticles, some more prominent than others; in both mandibles it is probable that the prineipal cutting plates, when unworn, would show dentation.

Lower Lip.—The large outer and the small but tumid inner lobes apically rounded, the outer plates finely ciliated, and having an indent on the inner margin a little below the apex; the mandibular proeesses short and divergent.

First Maxillæ.—Inner plate broad, with smoothly rounded apex, elia inconspicuous; outer plate short, with nine spines on the apical margin, the innermost long, almost straight, with its upper half finely pectinate, the next shorter, with a long curved point and six lateral teeth; the next two pairs very similar to this first pair, the remaining three spines somewhat stouter; the palp one-jointed, slender, scarcely longer than the outer plate, with four long setiform spines on, and one just below, its narrow apial margin. In having nine spines on the outer plate this speeies agrees with Krøyer's account of *Phoxus (Harpinia) plumosus*.

Second Maxillæ.—The inner plate rather broader and scarcely shorter than the outer,

the rounded apex smooth, eight or nine short, more or less spine-like, plumose setæ along the upper part of the inner margin; the outer plate with ten longer spines round the upper part of the inner and the apical margins, and a short spine at the top of the outer margin.

Maxillipeds.—Inner plates broader than the outer, short, reaching a little beyond the base of the first joint of the palp, with three spine-teeth and two spines on the apical border; the outer plates narrow, not reaching quite to the end of the first joint of the palp, on the inner margin carrying a single spine, a pair of spines, five spine-teeth, successively larger towards the apex, upon which is a long spine-tooth and a plumose seta; the first joint of the palp rather longer than the third; the second joint considerably longer than either, with the convex inner margin fringed with numerous slender spines; the third joint narrow, oval, with spines along the inner margin, on the surface near the outer, and at the apex of the outer margin; the finger slender, nearly as long as the third joint, inner margin straight and smooth, a spine rather than a nail affixed to the apex, with an attendant eilium; the dorsal eilium small, near the base.

First Gnathopods.—Side-plates expanded in front below, hind margin nearly straight, lower margin fringed with some fourteen partially feathered setæ, leaving a third of the length in front unarmed except for a single eilium; the first joint reaching the end of the side-plate, with six long setæ along the central part of the convex hind margin; the second joint narrow, as long as the triangular third, of which the front margin is much longer than the hinder one; the wrist, a little shorter than the hand, to which it is attached by a narrow neck, carries a few setæ on the somewhat expanded part of the hind margin just below the third joint; the hand oblong, the front margin a little prolonged at the root of the finger, where it has two or three eilia or setules; the hind margin is a little indented for its second setule a little below the apex; the broad palm consists of a small rounded lobe in front, beyond which the strong palmar spine a little projects, while the small lobe is followed by a broad, slightly convex, margin, bordered on both sides with numerous spinules or setules; the finger is bulbous at the base, the remainder slender, curved in correspondence with the convexity of the palm-margin, the nail being protected by a projecting cap; the cap being in this, as in many other similar examples, much more delicate than the nail, has probably some sensitive function.

Second Gnathopods.—Side-plates similar to those of the preceding segment, but broader above and therefore more squared. The branchial vesicles of delicate texture, an elongate oval attached to a narrow neck. The first joint reaching beyond the side-plate, with setæ on both margins; the second joint scarcely as long as the third, which is roughly quadrate and combines with the triangular wrist to form a cap for the broad hand; the wrist forms a bent triangle, the lower apex of which is attached to the base of the front margin of the hand as in the genus *Eusirus*, Kröyer, while the base adjoins the front margin of the preceding joint, this front margin being, however, no doubt

homologically not the front but the lower margin ; the hand is constructed and armed on the same plan as in the first pair, but is of enormously greater breadth, exceeding the breadth of the side-plate as well as its own length ; it is rather wider at the palm than at the rounded base, and the incision in the palm-margin near the palmar spine is very deep ; the size of the finger matches the requirements of the increased palm.

First Peræopods.—Side-plates evenly oblong, armed as in the preceding pairs. Branchial vesicles as with the preceding pair, but rather larger. First joint reaching but little beyond the side-plate, with some very long setæ on the lower part of the convex hind margin ; the second joint short, the third long, broad, as long as the fourth and fifth together, with setæ on the hind, and apex of the front, margin ; fourth joint oval, narrower distally than at the base, shorter but broader than the fifth joint, the hind margin fringed with long setæ and carrying at the apex a long thick spine, nearly equal in length to the fifth joint ; the fifth joint slender, of nearly even width throughout, fringed with setæ on the hind margin and carrying four stout spines of different lengths near its apex ; the finger not half the length of the fifth joint, of unimportant appearance among the neighbouring spines.

Second Peræopods.—Side-plates very broad, a little deeper than broad, excavation behind descending a very small distance, lower margin carrying setæ as in the preceding segments, joining the hind margin with a gentle curve. First joint not reaching the end of the side-plate ; details of the limb similar to those of the preceding pair.

Third Peræopods.—Side-plates much broader than deep, hind lobe narrower but deeper than the front one. Branchial vesicles broadest above, forming a triangle with the neck at one corner of the base. The first joint broadest above, almost oval, but that the front margin is nearly straight ; the setæ along this are short at the upper and long at the lower part of it, the hind margin is almost entirely smooth and unarmed ; the second joint short ; the third not long, broad, with setæ along most of the front margin, spines and setæ at and near the apex behind ; the fourth equal in length to the third, a little less broad, with setæ on both margins, various groups of spines on the front and at the apex of the hind margin ; the fifth joint longer and thinner than the fourth, the armature of the same character ; the finger more than half the length of the fifth joint, more like a great spine than a joint, at the tip curved a little forward, near the somewhat thickened base carrying two dorsal cilia, one feathered in the usual way, the other peetinate with long teeth.

Fourth Peræopods much longer than the third or fifth. Side-plates very shallow, much broader than deep. First joint broadly oval, with numerous and long setæ on the convex front margin, the hinder almost unarmed ; the third joint subequal in length to the fifth, with spines and setæ on both margins ; fourth joint a little shorter, with setæ on the hind margin, spines on the front, and apex of the hind, margin ; fifth joint slender and straight, with spines and setæ on the hind, spines on the front margin, an apical

spine in front and an apical seta behind nearly as long as the slender finger; the finger is more than half the length of the fifth joint, and has two dorsal feathered cilia.

Fifth Peraopods.—Side-plates small. First joint greatly dilated, front margin smooth, with an apical spine, hind margin slightly serrate; the broad lower margin behind and below the second joint is smooth; the third joint much shorter than the fourth, with setæ on the front margin, the lower ones long and plumose, a group also on the apex behind; the fourth joint a little longer than the fifth, and much broader, with numerous feathered setæ along the front, and distally and apically on the hinder margin; the fifth joint with setæ on both margins; the finger more than half the length of the fifth joint, with one dorsal cilium.

Pleopods.—The coupling spines have an oval bulbous base, followed by a narrow shaft with three small lateral retroverted teeth and a sharply bent tip; the pair is accompanied by a plumose seta. The eleventh spines are three in number on the first joint of each inner ramus; the joints number sixteen on the outer, thirteen on the inner ramus.

Uropods.—Peduncles of the first pair a little longer than the rami, with six or seven slender spines along the upper margin; the rami subequal, with a couple of spines on the proximal half of the upper margin; peduncles of the second pair stout, equal in length to the longer ramus, with seven spines on the upper and two near the lower margin; the longer ramus with three spines on the proximal part of the upper margin, the shorter ramus smooth; peduncles of the third pair short, distally set with spines, the rami long, lanceolate, subequal, the lower with a narrow nail tipped with two setæ; plumose setæ round most of both margins of both rami, that with the nail having also short spines along the inner margin.

Telson extending beyond the peduncles of the third uropods, much longer than broad, not tapering, eleventh almost to the root, dehiscent for some distance, though not widely except where the margins curve outwards to form the rounded apices; there is a slight contraction below the centre, the outer margins being here armed with a small row of setiform spines; on the outer side of each apex a small cavity contains a spine and a cilium.

Length.—The specimen, in the position figured, measured two-fifths of an inch.

Locality.—Station 162, April 2, 1874; Bass Strait; depth, 38 fathoms; bottom, sand and shells; surface temperature, $63^{\circ}2$. One specimen, surface.

Remarks.—The specific name refers to the place of capture. That the specimen was a male may be taken for granted from the structure of the lower antennæ. From *Phoxus villosus*, Haswell, this species differs in the size and shape of the eyes, in the flagella of the upper antennæ, in the relative sizes of the gnathopods, and in the third and fourth joints of the second gnathopods; from *Phoxus batei*, Haswell, it differs in regard to the eyes, the peduncles of the upper antennæ, the gnathopods, and the rami of the third uropods.

Phoxocephalus kergueleni, n. sp. (*Phoxus kergueleni*, Pl. LV.).

The rostral part of the head projecting with a tolerably sharp apex over the peduncle of the upper antennæ; the first three segments of the pleon each longer than any segment of the pereon; their postero-lateral angles rounded, the lower border of the third long and for the most part straight.

Eyes small, distant, in the spirit-preserved specimens not dark, with few ocelli.

Upper Antennæ.—First joint considerably longer than the next two united, its breadth little less than its length, distally a little outdrawn on one side; second joint longer and broader than third, each of a length about equal to its breadth; the flagellum of five articulations; the first equalling in length the last of the peduncle and also the last of the flagellum; the secondary flagellum of three joints, the three together equalling the first two of the primary.

Lower Antennæ.—First joint not much expanded, gland-cone obscure, seemingly with a broad apex, third joint not very short, the fourth broad, with marginal setæ and apical and surface spines; the fifth half the length of the fourth in the male, more than half in the female, expanding distally, broader in the male than in the female; the flagellum in the male specimen examined had fifteen joints, moderately thick, with quite inconspicuous eilia, except two short ones on the tip of the last joint; in the female this flagellum had five slender joints.

Upper Lip.—The broad apical border slightly emarginate.

Mandibles.—Similar to those of *Phoxocephalus bassi*; the cutting plate, however, here on both mandibles showing both above, below, and on the oblique margin a certain amount of dentation, one tooth below being prominent and large, especially on the right mandible; the secondary plate of the left mandible has its margin divided into five teeth; on the right mandible it has two sharp teeth below and a row of denticles above; the spine-row of each mandible contains three curved spines; the palp, as in *Phoxocephalus bassi*, is much longer than the trunk; its third joint in the male was as long as the second, but in the female not so long; there are three or four spines along the upper part of the inner margin of the second joint, and nine on the apical part of the third joint.

Lower Lip small and compact, with the mandibular processes seemingly less divergent than in *Phoxocephalus bassi*.

First Maxillæ.—Inner plate oval, smooth; outer plate short, with seven spines on the rather oblique apical margin, the spines similar in character to those of *Phoxocephalus bassi*; the one-jointed palp narrow, but little overtopping the outer plate, with four long setæ on the apex. In having seven spines on the outer plate this species agrees with Krøyer's account of *Phoxus holbölli*.

Second Maxillæ.—The outer plate extending a very little beyond the inner, each

with few apical setæ, those of the outer plate the longer, those of the inner extending more down the inner margin.

Maxillipeds.—Inner plates not reaching much beyond the base of the first joint of the palp, with two spines on the apical, and one on the inner margin; outer plates narrow, not reaching the end of the first joint of the palp, the inner margin carrying two small setæ and three spine-teeth, the largest of these being apical; the first joint of the palp subequal in length to the third, the second joint longer than either, with seven or eight setæ on or near the inner margin; the third joint with about the same number of setæ distributed over it; the fourth joint as long as the third, finger-formed, but with the inner margin not concave; the dorsal cilium short, the nail short and sharp, spine-like, with a couple of cilia near it on the inner margin.

First Gnathopods.—Side-plates expanded below, the hinder part of the lower margin carrying five setæ and a cilium, another cilium also in advance of the setæ. The first joint not reaching below the side-plate, carrying five setæ, four of them very long, on the hind margin; second joint as long as the third; the third rather broader above than below, with a small process filling up the narrow space in front between the second and fourth joints; the wrist not quite so long as the second and third joints together, broader above than below, with a group of setæ at the top of its free hind margin, its lower apex attached to the front margin of the hand, which seems partially to rest on its free hind margin; the hand oblong, broad, muscular, the front margin longer than the hinder, which is outlined into a small tooth-process; on this is seated a strong spine, not reached by the tip of the finger when closed over the convex, ciliated palm; there are two cilia on the hind margin, one on the apex in front; a short dorsal cilium on the finger.

Second Gnathopods.—Side-plates oblong, distally less broad than those of the first segment, similarly armed. The branchial vesicle narrow, nearly as long as the first joint of the limb; the marsupial plates in the female narrower than the branchiæ, of the same length, with a few long setæ on the front margin. The joints of the limb similar to those of the first gnathopods, but larger, the third joint longer than the second and as long as the wrist, with which it forms a small cup for the broad, muscular, oblong hand, which in both sexes greatly exceeds the size of the hand of the first pair, the palm margin being also more oblique, and its tooth process stronger.

First Peræopods.—Side-plates like those of the preceding segment. Branchial vesicles oval, longer and broader than the first joint of the limb. First joint reaching fully as far down as the side-plate, with setæ on the convex hind margin; third joint subequal in length to the fourth and fifth together, with setæ on the hind margin; fourth joint rather shorter than the fifth, narrower than the third, oval, with setæ and spines on the hind margin, an apical spine longer than the fifth joint; the fifth joint narrow, with one seta at the centre, and a group of spines and setæ at the apex, of the hind

margin; the finger more than half the length of the fifth joint, with a small cap projecting little beyond its bent tip.

Second Peraopods.—Side-plates nearly as broad as long, very slightly excavated behind, with only two or three setae on the lower margin. Branchial vesicles broader than in the preceding pair. First joint not reaching the end of the side-plate; the limb not materially differing from the first peræopods.

Third Peraopods.—Side-plates broad, front lobe shallow, hinder much deeper. Branchial vesicles broader but perhaps a little shorter than those of the preceding segment. The first joint evenly expanded, longer than broad, the front margin rather sinuous, armed with some long setæ near the lower apex, the hind margin smoothly convex, with a minute elium here and there, the lower rounded behind and overlapping the short second joint; the third joint as long as the fifth; the fourth joint a little shorter than either, and in breadth intermediate; all these three have setæ or spines on the front margins and at the apiees both behind and in front; the finger slender, acute, but little shorter than the fifth joint.

Fourth Peraopods much longer than the third or fifth. Branchial vesicles small, of rounded oval shape. First joint large, wider above than below, longer than wide, front margin convex, with small cilia on the upper part, but most of it fringed with groups of long setæ, the long hind margin nearly straight, interrupted only by three or four minute cilia, the lower margin rounded and overlapping the second joint behind; the third joint exceeding the fourth in length, the fourth the fifth, and the fifth the sixth, about equally in each case, not greatly; the third armed on both margins, the fourth only on the front, the fifth on neither, but all on the apiees before and behind; the finger slender, curved at the tip, with a little eap upon it.

Fifth Peræopods.—Side-plates small. First joint of the limb greatly expanded, especially below, breadth greater than the length, lower margin behind descending far below the almost straight front margin, which has two or three setæ, three or four cilia and an apical spine; part of the hinder and of the lower margin is serrate; the third joint a little longer than the fourth, has a straight hind margin with two spines at, and one a little above, the apex; the hind margin of the fourth joint is convex with similar armature; both of these joints carry setæ or spines in front and are laid back against the wing of the first joint, not nearly reaching its hind margin; the fifth joint shorter and much narrower than the fourth, has two eonvex smooth margins, and a lower margin cap-like over the hinge of the finger with a minutely pectinate edge; the finger is as long as the fifth joint, or as its apieal spines.

Pleopods.—The peduncles have, together with a plumose seta, a pair of coupling spines with very slender stalks on small basal bulbs; these spines have three minute retroverted teeth and an apieal hook; the eleft spines are three in number, one arm of the cleft much longer than the other; the joints of the rami number from nine to eleven.

Uropods.—Peduncles of the first pair subequal to the rami; the longer of the two rami with two or three spines on the upper margin, the shorter with none; the second pair smaller than the first, the peduncles with one rather prominent apical spine; the rami without spines, equal in length to one another and to the peduncle; peduncles of the third pair shorter than the rami, carrying some apical spines; the rami lanceolate, the outer longer than the inner by almost the length of its long slender nail, which has a couple of cilia at its tip, and spines on either side of the base; there is also a small spine on the outer margin of the longer ramus, the shorter has a cilium at its tip.

Telson extending a little beyond the peduncles of the third uropods, eleft beyond the middle, the apices somewhat divergent, each armed with a long spine, and a cilium outside of the spine; the outer margins appear to be evenly convex and unarmed; the length not greatly exceeding the breadth.

The Length of the female specimen, in the position figured, was rather less than one-fifth of an inch. The details were figured from a male specimen, with the exception of the lower antennæ of the female.

Locality.—Off Cumberland Bay, Kerguelen, at a depth of 120 fathoms. Several specimens.

Remarks.—The specific name is derived from the place of capture.

A dark-coloured specimen, less than a tenth of an inch in length, from Marion Island, appears to be of this species, though presenting some differences.

The present species differs from *Phoxocephalus bassi* in many particulars, but the gnathopods alone suffice to distinguish the one species from the other.

Genus *Harpinia*, Boeck, 1876.

- 1842. *Phoxus (pars)*, Krøyer, Naturh. Tidsskr. R. i. Bd. iv. p. 150.
- 1845. " Krøyer, Naturh. Tidsskr. R. ii. Bd. i. p. 551.
- 1870. *Harpina*, Boeck, Crust. amph. bor. et arct., p. 55.
- 1876. *Harpinia*, Boeck, De Skand. og Arkt. Amph., p. 218.
- 1877. *Harpina*, Meinert, Crust. Isop. Amph. et Decap. Daniæ, p. 106.
- 1879. *Harpinia*, Sars, Crust. et Pycn. nova, p. 443.
- 1884. " Schneider, Crust. og Pycn. Kvænangsfiorden, p. 70.
- 1885. " Sars, Den norske Nordhav-Exp., p. 157.

For Boeck's definition of the genus see Note on Boeck, 1870 (p. 400). Gerstaecker in 1886 makes *Harpina*, Boeck, a synonym of *Phoxus*, Krøyer, but in the definition he includes as a character, "die drei hinteren Beinpaare mit lamellös erweitertem Schenkelglied," which is unsuitable to *Harpinia*, since there the first joint of the third peræopods is not expanded. *Phoxus plumosus*, Krøyer, is the type species of Boeck's *Harpinia*, so that the writers prior to 1870 who have mentioned *Phoxus plumosus*, as Spence Bate, Goës, &c., might be included in the above synonymy.

Harpinia obtusifrons, n. sp. (Pl. LVI.).

Rostral portion of the head broadly rounded, reaching to the apices of the peduncles of the upper antennæ. The head broad at the base, longer than broad, the sides a little sinuous, with a conical plate underneath, situate outside the base of the upper antennæ; postero-lateral angles of the third plcon-segment upturned, forming a rather long sharp tooth, the lower boundary of a deep cavity in the hind margin of the segment; the sides of the sixth segment are produced some way along the telson.

Eyes not perceived.

Upper Antennæ.—First joint of the peduncle bulky, widest at the base, the inner border smooth, convex, the other sinuous, with four broad distally feathered cilia at the apex; the second joint small, not twice as long as broad, with long setæ and a plumose cilium on the outer apex; the third joint much shorter and narrower, with setæ at the apex on both sides; the flagellum slender, of seven joints, the first the longest, a little shorter than the second of the peduncle; the secondary flagellum of five joints, nearly equal in thickness as well as length to the first five of the primary.

Lower Antennæ.—The first joint is bent round at right angles to its base, with a distally narrowed process on the outer side, the piece which appears to correspond to the coalescent second joint being rounded on the outer margin, not in any way produced either conically or otherwise; the third joint is nearly as long as the fourth, it has a group of setæ on the lower part of the outer margin; the fourth joint widens distally, round the apical border armed with rows of long setæ, setiform spines, and two stronger spines, on the inner border above having a group of three small spines; the fifth joint much narrower and a little shorter, has a straight smooth inner margin, the outer convex, armed with setæ and two spines near the apex; the flagellum shorter than the peduncle, of eight joints, of which the first is the longest.

Upper Lip widening to a broad distal margin.

Mandibles with a longer trunk than in the genus *Phoxocephalus*; the cutting edge on the left mandible showing a tooth above, then a long oblique margin without prominent dentation, ending with a bidentate apex, the whole plate being itself more or less tooth-like; the secondary plate broad, widening slightly to the front edge, which is cut into six teeth, the lowest being the longest; the spine-row is long, showing amongst some accompanying cilia nine curved denticulate spines, the last a very small one; the molar tubercle appears to be rather broad, but weak in structure, and unarmed; the cutting edge on the right mandible has a tooth above, an oblique, slightly concave, almost invisibly denticulate, margin, forming at the apex a large sharp tooth, with a little one considerably in the rear below; the secondary plate is very different from that of the left mandible and much smaller, presenting below a spine-like tooth and

above a shorter broader piece cut distally into three denticles; the spine-row appears to consist on this side of only seven spines; the palp, much longer than the body of the mandible, is attached to the front over the base of the cutting edge; the first joint is short, though not unusually so; the second is broader, but slightly shorter, than the third, carrying three or four short setæ on the outer margin; the long slender third joint has its sides unarmed, and carries ten spines of different lengths on the obliquely truncate definite apical margin. In *Phoxus plumosus* Krøyer describes the molar tubercle as insignificant, without teeth, but furnished with three or four long and strong setæ.

Lower Lip.—The plates are very broad at the base, with small and narrow mandibular processes, the forward lobes being rounded, not strongly ciliated, though some of the cilia are long, the rounded apical margin being produced on the inner side into a conical tooth traversed by a duct which apparently opens at the apex of the tooth.

First Maxillæ.—Inner plate with sinuous inner margin carrying a spiniform cilium, above which is a plumose seta, followed at a distance on the apex by a larger one; outer plate short, carrying on the truncate apex nine spines, three pairs with one spine long and multidentate attended by a short one with a single lateral tooth, and an outer group of three in which the longest and strongest is not denticulate; the long rather narrow second joint of the palp overtopping the outer plate, and carrying a double row of slender spines on its apex. The border which connects the two members of this pair of maxillæ is surmounted by a row of seven setæ.

Lower Maxillæ.—The plates are somewhat curved, the inner not much shorter than the outer, with ten or eleven plumose setæ round the upper part of the inner margin and the rounded apex, several of them being pectinate in the upper part as well as plumose; the longest are not those lowest on the inner margin, but the two placed where the inner margin passes into the apical; the outer plate has some sixteen spines or setæ passing round the apex and upper part of each lateral margin, the smallest of the spines being on the outer side.

Maxillipeds.—The inner plates not reaching nearly to the end of the first joint of the palp, the inner margin unarmed, the rounded apex carrying four plumose setæ, the outer surface having a single spine-tooth just within the inner margin and below the apex; the outer plates long and narrow, reaching to the middle of the second joint of the palp, armed on the inner margin with some fourteen spine-teeth and round the outer margin with long plumose setæ, about seven in number; the spine-teeth gradually increase in size to the apical one, which is the largest, each near its own apex being delicately pectinate on both sides for a short distance, some of the upper being also slightly plumose; the first joint of the palp is almost as long as the third, the second is nearly twice as long, armed on the inner border with numerous pairs of spines; the

third joint armed on the inner and apical margins, and on the upper part of the outer margin; the finger slender, slightly curved, in conjunction with its long spine-like nail fully equalling the length of the third joint; there are two elia at the base of the nail on the inner side.

First Gnathopods.—Side-plates broad, expanded below, with a score of cilia round the lower margin. First joint rather broad, reaching below the side-plate, with some setæ near the centre of the convex hind margin and at its apex; second joint shorter than the third, the front, or properly lower, margin of which adjoins the hind margin of the wrist; the hinder margins of the third joint and of the wrist have setæ on the lower part; the hand is broad, with the front margin continuing the curve of the wrist and then becoming almost straight, giving a length to the hand not much less than that of the first joint, the hind margin being very much shorter, ending in a very shallow tooth carrying a long palmar spine, the palm being convex, very oblique, ciliated; a few small setæ are on the surface of the hand, and one on each lateral margin, besides longer ones at the front apex; the finger is curved, reaching to the cavity between the tooth and convex margin of the palm, and carrying a short dorsal elium near the middle.

Second Gnathopods.—Side-plates oblong, the hinder margin straight, the front a little sinuous, the lower furnished with a dozen setæ. The marsupial plates narrow, as long as the side-plates, with long setæ on the front and apical margins. The first joint of the limb broad, reaching the lower border of the side-plate, with six long setæ on the central part, and a tuft at the apex, of the hind margin, the limb in general similar to that of the first gnathopods, but more massive, the wrist relatively smaller, the tooth of the palm larger, and the following palm-margin sinuous, being at first concave and then convex; the hand in front subequal in length to the first joint.

First Peræopods.—The side-plates similar to those of the preceding segment, but larger, with fifteen setæ on the lower margin. The first joint reaching the lower margin of the side-plate, carrying four long setæ at the centre, and as many in a group at the apex, of the hind margin; third joint broad and long, but not as long as the fourth and fifth together, with numerous setæ along the hind margin and a tuft at the apex in front; the fourth joint oval, shorter than the fifth, bordered behind with numerous spines, those near the apex being longer than the fifth joint; the fifth joint narrow, of even width throughout, slightly curved, bordered behind with spines; the finger slender, curved, more than half the length of the fifth joint.

Second Peræopods.—The side-plates very broad, broader than long, not deeply excavate behind, with four and twenty short setæ on the lower margin. The first joint not reaching the end of the side-plate, with half a dozen setæ on the hind margin, the lowest two very long, some short setæ on the upper part of the front margin; the limb in general similar to that of the first peræopods.

Third Peræopods.—The side-plates almost concealed under those of the preceding segment. The first joint not expanded, the margins almost parallel, seven small setæ along the front, and a tuft of longer ones at its apex; second joint short, with setæ in front; the third, fourth, and fifth subequal in length, the fourth rather shorter than the other two, intermediate in breadth, all three armed on both margins with groups of setæ and spines; the fifth joint somewhat tapering, its apical spines not so long as the slender, slightly curved finger, which is more than half the length of the fifth joint; several of the setæ on this limb are very long and plumose, especially at the back of the fourth and fifth joints.

Fourth Peræopods very much longer than the third or fifth. The first joint broadest above, armed all round the convex front margin with setæ and spines, the hinder margin smooth, lobed above, then straight or slightly concave; a pocket is marked in the surface of the integument at the upper part in front; the second joint short; the third long, straight, with spines on both margins, those at the apex strong, and the hinder ones also long; the fourth joint rather longer and narrower than the third, similarly armed, its hinder margin very slightly concave; the fifth joint slender, longer than the preceding, its hind margin rather more concave, carrying some long setæ, the front margin correspondingly convex, fringed with slender spines of different lengths, the finger very slender, long and straight; in one specimen, apparently belonging to this species, the finger is as long as the preceding joint.

Fifth Peræopods.—The first joint greatly expanded, and behind outdrawn much below the second joint; the front border comparatively short, fringed with spines, the lower part of the hind border serrate, and the lower border also serrate but in the opposite direction, spiny cilia in the serratures; the second joint comparatively large, with the front margin very convex, and having its lower half fringed with spines which at the apex are very long; the third joint longer and much stouter than either the fourth or the fifth, with long spines on much of the front, and on the lower part of the hind margin, one on the hind apex being longer than the fourth joint; the fourth joint shorter and broader than the fifth, spined at three points in front, and at two behind, one of the apical spines as long as the fifth joint, which is spined in a similar manner, and has an apical spine nearly as long as the finger; the finger slender, nearly straight, subequal in length to the fifth joint, which has some pectination on the apical margin.

Pleopods.—A row of five setæ was observed on the peduncle at about the centre, the two coupling hooks were also seen to be round-headed, bent so as to form a sharp strong hook, seemingly without other dentation; the cleft spines were three in number on the one pleopod examined; the joints of the inner ramus being twelve, those of the outer fifteen in number.

Uropods.—Peduncles of the first pair somewhat longer than the rami, fringed with spines of various lengths, the longer above, at the apex carrying one very stout spine

on either side; the longer ramus carrying spines on both margins, but none near the apex, the shorter ramus with spines only on one margin; the peduncles of the second pair shorter than the rami, with some slender spines on the margins, and a shorter, stout, somewhat curved one at the apex; the rami not very unequal in length, with a few spines near the centre of the margin; peduncles of the third pair much shorter than the rami, with several spines about the apex; the upper and inner ramus shorter than the lower, broad at the base, but tapering to a sharp point which is formed by an apical spine, its only armature; the lower and outer ramus ending in a long nail, with a spine on either side of its base; this ramus has three other spines on the outer margin and one other on the inner, not far above the base of the nail.

Telson.—Not reaching to the end of the peduncles of the third uropods; breadth at the base rather greater than the length; eleft nearly to the root, not dehiseent; sides converging to the broad apiees, each of which has a couple of cilia on the outer part whieh is not carried baek quite so far as the inner; there are two other unequal cilia on the surface near the outer margin not halfway down.

Length.—The specimen, a female, in the position figured, measured a quarter of an inch.

Locality.—Kerguelen. Four specimens, to two of which the depth assigned was 120 fathoms, and to one 30 fathoms; the depth at which the other was taken not being speefified.

Remarks.—The speefifie name, from *obtusus*, blunt, and *frons*, forehead, refers to the breadth of the rostral portion of the head.

There is a strong general resemblance between this species and *Harpinia plumosa*, Krøyer, but it differs from that species in numerous details; for example, the outer plate of the maxillipeds has many more teeth, and the telson is not eleft quite to the root.

For the original definition of the genus see Note on Dana, 1852 (p. 257). Dana placed it along with *Anonyx* in the subfamily *Lysianassinae*. Costa placed *Egidia* in the *Gammaerini*, the fourth subfamily of the *Gammaridei*. Spence Bate in 1862 placed *Urothoe* between *Sulcator* and *Liljeborgia*. The identity between *Egidia* and *Urothoe* was detected by Boeck, who in 1870 and 1876 thus defines the genus:—

- " *Mandibles* apically only a little dentate.
- " *First Maxillæ* with the palp two-jointed; the two joints of nearly equal length.
- " *Maxillipeds* with the second joint of the palp much dilated on the inner side.
- " *First and Second Gnathopods* with the hand small, subcheliform.
- " *Third Peræopods* with very broad joints.
- " *Third Uropods* with the outer ramus a trifle longer than the inner.
- " *Telson* eleft to the base.
- " Body much depressed, broad; the head in front only a little produced and rounded; the side-plates narrow."

Urothoe lachneëssa, n. sp. (Pl. LVII.).

Head broad at the base behind the upper antennæ, in front of the insertion of which it is laterally flattened, the upper surface bending down over the base of the upper antennæ in a broad rostral portion, of which the distal margin forms an obtuse angle with a rounded apex; the peræon broad and like all the rest of the back covered with a sort of bristly down; the first three segments of the pleon longer but narrower than those of the peræon; the postero-lateral angles of the third segment presenting a slightly outdrawn rounded point, with a deep re-entering angle above it.

No *Eyes* perceived.

Upper Antennæ.—First joint a little longer and a good deal thicker than the second, the second longer and thicker than the third, the third not as long as the first three joints of the flagellum; the flagellum of five joints, of which the third is the longest; one or two short cylinders were seen on these joints; the secondary flagellum of two joints, the first nearly as long as the first two of the primary, the second shorter and much thinner.

Lower Antennæ.—Gland-cone not very prominent, third joint shorter than the fifth, somewhat curved; fourth joint longer than fifth, with the lower part thickened, the lower distal margin carrying setæ and an oblique row of four strong slightly bent spines, alternately long and short; the fifth joint with the upper margin straight, the lower apical oblique, armed like that of the preceding joint; the flagellum two-jointed, the first not longer and not a great deal broader than the longest of the spines on the apex of the peduncle, the second joint much shorter, tipped with two cilia and the rudiment of a third joint. In a second specimen the flagellum was definitely three-jointed.

Upper Lip.—The broad distally widened plate seems to be without cilia on the foremost edge, which has a small incision on each side.

Mandibles.—The part in front of the palp and molar tubercle presents the appearance of a large, bent, blunt tooth; the apical part of this is found to show a line marking off the cutting plate, which shows the traces of a tooth above and below with a rounded edge between; there is also a squared secondary plate, rather broader at the base than at the distal edge; it would be natural to expect to find this secondary plate on the left mandible, but it certainly appears to me to be on the right mandible, and the figure of the mandible containing it will be found on the right hand in the Plate, although that on the left hand, both from the absence of a secondary plate and the shape of the molar tubercle, looks far more like a right mandible. The preparatory growth seen within the transparent skin shows on both mandibles an edging to the cutting plate of numerous small teeth turned backwards, while the secondary plate above mentioned shows a border cut into four teeth. The enlarged figure, *m.A.*, is from the second specimen already alluded to. The molar tubercle is prominent and powerful, but apparently set with but few teeth and many cilia. The palp is very slight in structure, fixed a little above the molar tubercle, the first joint as long as the third or nearly so, the second only slightly longer than the third, and on one side in the second specimen actually shorter; the third joint is apically tipped with two unequal setæ.

Lower Lip of delicate structure, the forward lobes very broadly rounded, with a lozenge-shaped interval between them, which is to a great extent covered by the inner lobes, also broadly rounded but not dehiscent; the mandibular processes divergent, with rounded ends.

First Maxillæ.—Inner plate small, without setæ on the narrow apex; outer plate having the truncate apical margin occupied by nine spines of no great stoutness, two of them apically bifurcate; the palp, reaching little beyond the outer plate, and not beyond its spines, consists of two joints, the second scarcely exceeding the first in length, tipped with three or four setæ.

Second Maxillæ.—The outer plate longer and broader than the inner, both with slender spines on the rounded apices, the inner plate having also one or two on the inner margin below the apex.

Maxillipeds.—Inner plates not reaching quite the end of the first joint of the palp, carrying on the apical margin two or three slender spine-teeth and some small setæ; the outer plates not equalling in breadth the second joint of the palp, nor reaching so far forward, the inner margin armed with setæ and six or seven curved spines, increasing in size successively to the apex; the first joint of the palp short, with a seta at the inner apex, the second joint long and broad, especially at the distal end, which forms a produced lobe on the inner side; much of its inner margin is bordered with bristles directed backwards, and from its surface start some very long ones, the whole apparatus of setæ and spines in this pair of appendages making a very close network; the third joint longer than the first, expanded distally; the finger narrow, curved, ending in a little peak, from beneath which issue a thin spine and a cilium.

The *triturating organs* of the stomach exhibit on the inner margin four or five serrate teeth, more or less curved, and succeeded below by a tuft of long cilia.

First Gnathopods.—Side-plates small, expanded below, the front part downy like the back of the animal. The first joint reaching much beyond the side-plate, slender, equal in length to the four following joints together, with some long setæ on the hind margin; second joint very short; third not much longer, distally pointed; the wrist longer and broader than the hand, its hind margin fringed with bristles of various lengths, a row of these also on the surface, the lower margin making a sharp angle with the hinder; the cross-banding of the principal muscles in this joint very conspicuous; the hand oval, narrow at both ends, more bowed behind than in front, some setæ or seta-like spines on the hind margin and surface; the finger thin, and long enough with a slight inclination of the hand to touch the wrist, while what may be considered the palm-margin is defined by a minute emargination and a spine with a long accessory thread at about the middle of the hand's hinder margin. In the second specimen the finger was longer and more curved than in that figured.

Second Gnathopods.—Side-plates narrow, distally rounded, with a pocket in the integument near the upper front border; the front half of the surface very hairy. The branchial vesicle long and narrow. The first joint reaching much beyond the side-plate, longer than the branchial vesicle, but not so long as the four following joints united, with some long setæ on the hind margin; the second and third joints like those of the preceding limb, the wrist more slender, with fewer setæ, but both margins, as also those of the hand and the upper margin of the finger, are lined with adpressed scale-like cilia; the hand shorter than the wrist, the hind margin not out-bowed, but forming a definite angle at the beginning of the palm, occupied by two palmar spines, against which the small finger closes down over the ciliated palm; both about the base and about the tip of the finger the hand has several seta-like spines.

First Peræopods.—The side-plates with convex front border, rounded below. The first joint reaching below the side-plate, the second short, the third longer than the fourth

or fifth, with groups of long setæ on the lower part of the hind margin and apex in front; the fourth joint equal to the fifth in length, but much broader, with setæ near the middle of the hind margin and low down on the front margin, and behind, near the juncture with the fifth joint, four broad spines, the lower pair as long as the fifth joint, which is straight, armed in front below with six strong spines; the finger is nearly as long as the preceding joint, minutely pectinate on the inner margin, which runs out into a little tooth before reaching the nail.

Second Peræopods.—Side-plates little longer, though considerably broader than those of the preceding segment, the hinder margin concave. The branchial vesicle very long, not broad. The first joint reaching below the side-plate, but it must not be supposed that the figures in the Plate, drawn from flattened dissections, represent the relations of limb and side-plate in this broad-backed animal when whole. This limb has the joints somewhat longer than those that correspond in the first peræopods, to which it is in general similar.

Third Peræopods.—Side-plates with the hind lobe rather broader and longer than the front. Branchial vesicles long-oval as in the preceding pairs, but shorter. The marsupial plates in the specimen figured were short and narrow, with a few long setæ round the apex and part of the front margin. The first joint not so broad as the side-plate, slightly longer than broad, the breadth almost uniform, the hinder surface hairy, the front margin fringed with setæ, especially below, with one spine at the apex; the second joint overlapped by the first behind; the third joint short but broad, widening distally, with one apical spine behind, in front four groups; the fourth joint short, broad, squared, a little narrowed distally, with two groups of spines behind, and three in front, the apical groups almost encircling the joint; the fifth joint narrow, straight, shorter than the fourth, with two groups of spines in front and one behind; the finger narrow, acute, as long as the preceding joint.

Fourth Peræopods.—The side-plates and branchial vesicles small. The first joint, like most of the limb, larger than in the preceding pair, the hind margin concave, ciliated, the front a little sinuous but chiefly convex, armed with numerous groups of long setæ as well as with spines, behind broadly overlapping the second joint, which in front carries two groups of spines; the third joint armed as in the preceding limbs, but much larger, greatly expanded below, the front margin straight, the hinder much curved; the fourth joint not much longer than its width at the base, with two groups of spines on the straight front margin, and one at the apex of the hinder one; the fifth and sixth joints as in the preceding pair.

Fifth Peræopods.—The first joint greatly dilated, especially below, so that the three following joints turned backwards do not reach the serrate hinder border; the front border is convex, with some small setæ and spines, at the apex a large and a small spine; the interior of this broad joint is largely occupied with packets of gland-cells

in several rows, giving a darkened appearance to the centre part in spirit-preserved specimens; the second and third joints each have a long and a short spine at the apex in front, the third joint is broader and a little longer than the fourth, and has a spine on the apex behind; the fourth joint, a little longer and broader than the fifth, has two groups of spines in front and an apical group behind, the hind margin tending to concave; the fifth joint has the hind margin straight, forming a small finely fringed cap over the base of the finger, and has two seta-like spines at this apex, and spines at two points of the front margin; the finger is almost straight, slender, with some fine pectination on two edges.

The descriptions of the peræopods apply to the specimen figured, a female; in the other specimen which has been alluded to, these limbs showed in many parts a diminished breadth in comparison with the length.

Pleopods.—Peduncles short, not longer than broad; the pair of coupling spines slightly sinuous, tapering, apically hooked, with five minute serratures on the margin below the hook; with these spines there is a plumose seta; the outer rami with eight to ten joints, the inner with six or seven, the first joint not very long, and carrying two cleft spines on its upper part.

Uropods.—Peduncles of the first pair rather longer than the rami, with a strong apical spine, besides two or three marginal spines and a row of marginal spinules; the rami stiliform, subequal, that which is rather the longer having one marginal spine; the second pair reaching little beyond the peduncles of the first, the peduncles armed with two or three spines, not longer than the slender, smooth, subequal rami; the third pair reaching much beyond the second, the peduncles shorter than the outer ramus, darkened by a large packet of gland-cells, apically bordered with spinules; the outer ramus as if two-jointed, the nail apart from its apical seta being as long as the stem, which has spines on either side of the base of the nail, the inner branch rather resembling a broad tapering spine, not reaching the base of the nail of the outer branch, carrying a small cilium near the top.

Telson reaching a little beyond the peduncles of the third uropods, rather longer than the breadth at the base, cleft nearly to the root, the halves not in the least dehiscent, unless a little near the sharp apices; each half has a pair of cilia on the outer margin near the apex, another a little higher up, and a single cilium on the surface high up.

Length.—The specimen figured measured, in its bent position, less than three-twentieths of an inch.

Locality.—Off Cumberland Bay, Kerguelen; from a depth of 120 fathoms. Five specimens.

Remarks.—The specific name is derived from the Greek word *λαχνήεσσα*, woolly, shaggy, and refers to the hairiness of the integument. The rostral prolongation of the

head in this species favours the view taken by Gerstaecker in placing the genus among the Phoxina, Sp. Bate (see p. 582).

Genus *Platyischnopus*, n. gen.

Mandibles with denticulate molar tubercle, third joint of the slender palp elongate.

First Maxillæ with one-jointed palp, apical spines of the outer plate almost smooth.

Second Maxillæ with the plates broad, especially the outer.

Maxillipeds with the outer plate reaching beyond the second joint of the palp, and having long teeth on the inner margin.

Both pairs of *Gnathopods* long and slender, with the first, second, and fourth joints long, and the hands chelate.

The *Fourth* and *Fifth Peraopods* with the third and fourth joints of great breadth, and carrying numerous spines.

The *Telson* emarginate.

The head long, irregularly-shaped, produced over both pairs of antennæ to a rostral tip; none of the side-plates deep.

The generic name is derived from the Greek words, πλατύς, broad, ὅσχυός, narrow, πούς, a foot, and refers to the union in the animal of very narrow with very broad feet.

The general structure brings the genus into alliance with the subfamily Phoxinæ, Spence Bate, as defined by Boeck, while the peraeopods show a relationship to those of *Urothoë* and *Haustorius* (*Lepidactylis*), so that it may stand for the present in the family Pontoporeiidæ, although the combined characters of its peculiar head, the chelate gnathopods, and the emarginate telson, give it a more or less isolated position among the Amphipoda at present known.

Platyischnopus mirabilis, n. sp. (Pl. LVIII.).

Head long and remarkable, the short rostral peak in our specimen pucker'd perhaps accidentally, behind this the head widens rather abruptly, and continuing to widen forms a tract included in the back of which are the first joints of the peduncles of the upper or front antennæ; close behind these the head becomes quite abruptly shallower and then again deepens gradually to the base, the eyes occupying the shallow part between the places of insertion of the upper and lower antennæ; the dorsal line of the head is nearly straight, longer than the first three segments of the peraeon united; of the peraeon-segments the sixth and seventh are the longest, and the seventh has the postero-lateral angles acutely produced to a small extent; of the pleon-segments the first has the postero-lateral angles rounded, the second has these angles acute, the third acute and

upturned ; the fourth has a transverse dorsal depression and a cilium near the end of the convex part which follows the depression.

Eyes small, round, dark, with about twenty-five rather long ocelli.

Upper Antennæ subequal in length to the lower, the peduncles being shorter but the flagella longer, first joint of the peduncle short, embedded in the head ; the second much longer than the first or third, with some deep serrations on the lower margin, and various groups of strong spines on the surface and margins ; the third joint not much longer than the first of the flagellum, with one large group of spines near the base ; the flagellum of six joints, of which the first is the longest ; the secondary flagellum of three, of which the first is nearly as long as the first of the primary, but more slender, the third is minute.

Lower Antennæ.—These are separated by a wide interval from the upper antennæ, and in the natural position of the head may be described rather as being set behind than below the other pair ; the basal part of the first and second joints somewhat expanded, the gland-cone small but distinct; the third small, scarcely reaching beyond the gland-cone at its side, the fourth and fifth long, armed on the margins with spines and long setæ, the fifth joint shorter than the fourth, but longer than the slender three-jointed flagellum, which is outstripped by the apical setæ of the fifth joint.

Upper Lip.—Distal margin rounded, but with the centre flattened and a little roughened with projecting points.

Mandibles.—Cutting plate with a small apical margin showing one or two little denticles, seemingly folded over a small secondary plate, the part of the mandible in front of the palp and molar tubercle forming a long bent tongue or tooth, without, so far as could be perceived, any spine-row ; molar tubercle prominent, with small denticles ; the slender palp set just over the molar tubercle, the first joint short, the second curved, with the front margin convex, the third straight, nearly as long as the second, tipped with four or five short setæ. Whether a secondary plate belongs to either, both, or neither of the mandibles I have not been able to determine.

Lower Lip of delicate structure, principal lobes broadly rounded, little dehiscent.

First Maxillæ.—Inner plates small, slender, not very distinctly made out ; outer plates broad, with eight or nine spines on the apical border, the innermost straight, pointing away from the rest, the remainder more or less curved, some with a single lateral tooth, the outermost simple, broad-tipped ; the palp one-jointed, slender, not reaching so far as the outer plate, tipped with three setæ, two of which are long, reaching beyond the spines of the outer plate.

Second Maxillæ.—The inner plate broad at the base, round the apical and upper part of the inner margin carrying several setæ ; the outer plate very much broader than the inner, the broad oblique apical margin carrying numerous setæ or seta-like spines ; there is a single cilium near the apex on the convex outer margin.

Maxillipeds.—Inner plates reaching nearly to the apex of the first joint of the palp, the apical border sloping back towards the outer, and occupied by five long plumose setæ; the inner plates long and narrow, reaching slightly beyond the second joint of the palp, having on the straight inner margin five setæ, followed by nine rather long spine-teeth in a series which does not quite reach the apex; there is also on the surface a row of eight setæ beginning a little lower than the row of spine-teeth; the first joint of the palp is short, the second much longer, its inner margin bordered with long setæ except close to the base and for a space distally; the third joint longer than the first, with setæ or spines only on the apical part; the finger short, with a long slender nail accompanied by some cilia.

First Gnathopods.—Side-plates very small, directed forwards. The narrow first joint extending much beyond the side-plate, with some long setæ at a few points on each margin, the lower half of the joint a little expanded; the second joint narrow, longer than the third, as long as the hand; the third joint not long, bent, the hind margin being much longer than the front, and carrying a single cilium near the apex; the wrist long and slender, but not equal in length to the two preceding joints united, with a group of setæ near the apex behind; the hand with the closed finger forming a long oval, the front margin of the hand being much shorter than the hinder, the extremities of the two being joined by a very oblique palm, in antagonism with which the finger and nail form a complete chela, capable of gaping widely; at the apex of the front margin there is a group of setæ, some of which are longer than the finger; there are two groups of setæ on the hind margin not far from the apex, a small spine at the apex, and setules along part of the palm-border; the finger shows some cilia about the base of the nail. The skin is extremely transparent.

Second Gnathopods.—Side-plates small, with an excavation behind, not at the top but above the middle, the first joint of the limb being attached at this point, a long seta and two elia being set in the margin lower down. Branchial vesicles of slight structure, larger than the side-plates, tapering below. The limb constructed on the same plan as in the first gnathopod, but all the joints except the finger longer, the slender wrist being longer than the two preceding joints and as long as the first joint, the hand longer in proportion to its breadth, and with less difference between the lengths of the front and hind margins, so that the finger antagonises with a shorter palm, and is itself shorter to correspond.

First Peræopods.—Side-plates not large, with a long seta at the lower front angle. Branchial vesicles longer and larger than the side-plates; marsupial plates narrow, longer than the first joint of the limb, with half a dozen long setæ on the hinder margin and apex. First joint of the limb reaching much beyond the side-plate, with three long setæ on the lower part of its hinder margin; second joint short; third longer and broader than any of those which follow, expanded downwards, not decurrent, with setæ along much of

the hind margin, some of them very long, and a group at the apex in front; the fourth joint subequal in length to the fifth, a little expanded downwards, with spine-like setæ near the apex behind; the fifth joint similarly armed, of almost even width throughout; the finger shorter than the fifth joint, slender, tapering.

Second Peræopods.—Side-plates broad, squared, scarcely deeper than broad, the excavation behind not deep. Branchial vesicles longer than the side-plates. Marsupial plates as in the preceding pair. The first joint of the limb not quite reaching the end of the side-plate, the setæ at the end of the fourth joint exceeding the length of the fifth and sixth joints combined; the limb in general not differing from the preceding.

Third Peræopods.—The front lobe of the side-plate with the front margin flattened, the convex lower margin somewhat serrate, carrying setæ. The marsupial plates a little widened distally, there carrying four long setæ and one short one. The first joint longer than broad, widened below, the hind margin nearly straight and almost naked, the front convex, with two long setæ near the centre and two spines lower down, at the apex a seta and two long spines; the second joint short, with one spine; the third broad at the centre, decurrent behind, carrying groups of strong spines in two deep serrations of the front margin, and two of the hind margin, the apex of which is truncate, and bordered with five unequal spines attended by two small setæ, an additional group of spines being placed on the surface at the base of the decurrent part; the fourth joint is longer and narrower than the third, and carries groups of spines, one on the margin and one on the apex before and behind, many of the spines here and elsewhere being notched at the tip besides carrying an accessory thread; the fifth joint short and slender, with spines at the apex; the finger missing, evidently broken off.

Fourth Peræopods.—Side-plates broader than deep, with some setæ on the lower margin behind, this margin curving upwards to an angle. The first joint oval, with some setæ on the upper part of the front margin and spines at its apex; the hind margin smooth; the second joint small, with a spine in front; the third joint greatly expanded, so as distally to exceed the width of the first joint; it has four groups of spines and setæ on the hind margin, one on the front, and three distal groups as in the preceding pair; the fourth joint is also of great breadth, narrowing distally, carrying three groups of spines and setæ in the deep serrations of the front, and two in those of the hind margin, besides two large groups at the apex; the fifth joint is narrow, as long as the third, rather shorter than the fourth, with two sets of spines in the serrations of each margin, and two apical groups; the finger is straight, slender, tapering, more than half the length of the fifth joint, with pectinate edges. In many of the groups of spines there is one with the upper part tapering, pectinate on both edges, while others have the notched end without pectination, and some are slightly plumose.

Fifth Peræopods.—Side-plates small, the segment with its postero-lateral angle acute, carrying a cilium in a little notch below the angle. The first joint appears to be

partially coalesced with the side-plate; it is very broad, twice as broad as long, with three long setæ near the top of the front border, and a spine at its apex, the hinder border sinuous, the lower border behind also sinuous, meeting the other in a sharply outdrawn angle; the second joint short, but broader than usual, overlapped behind by the inner part of the first joint; the third joint of great breadth, distally exceeding the breadth of the first joint, with spines at six points of the hinder margin, at the top a single spine, the rest in groups; small spines at five points of the front margin; seven rows of spines along the distal border, the longest being that nearest to the front apex; the fourth joint broad, narrowing a little distally, not quite so long as the third, with two groups of spines on the hind margin, four on the front, four on the distal. The rest of the limb broken off.

Pleopods.—Some setæ on the sides of the peduncles; the coupling spines two in number, rather swollen at the base, otherwise slender, flat-topped, with one lateral hook a little way below the apical one; the cleft spines four in number on the first and second pairs, seemingly only three on the third pair; the joints of the rami numbering from twelve to fourteen; the rami not powerful.

Uropods.—Peduncles of the first pair not longer than the outer ramus, with two or three spines on the upper margin, and a long tooth at the apex of the lower; the rami slender, the outer rather longer than the inner, bordered with five spines at intervals on the upper margin, and a group of long ones at the apex by the side of a small tooth or nail; the inner ramus has three spines on the margin and the apical group; the edges are pectinate; peduncles of the second pair shorter than the outer ramus, carrying some strong spines on the edges; the outer ramus considerably longer than the inner, each with spines at two points of the margin, and a group at the apex; as in the preceding pair, the rami are nearly parallel-sided. The third uropods were unfortunately missing.

Telson small, longer than broad, narrowing slightly to the strongly emarginate termination, forming a sharp point at each side of the emargination which reaches up for not quite a quarter of the telson's length; there are four spines on each of the nearly straight lateral margins, and two long setiform spines arise on the surface just over the emargination.

Length.—The specimen, in the position figured, measured, from the rostrum to the end of the peræon, one-fifth of an inch.

Locality.—Port Jackson, Australia, from a depth of between 2 and 10 fathoms. Two specimens.

Remarks.—Unfortunately both specimens were defective; the one from which the head and peræon have been figured was without the pleon, this, as shown by the marsupial plates, being a female; the other, from which the pleon has been figured and

described, had lost the head and the third uropod; in both specimens the third and fifth pairs of peræopods were imperfect.

The specific name alludes to the bizarre configuration of the head and the odd combination of the long and slender gnathopods with the broad hinder peræopods.

Family OEDICERIDÆ, G. O. Sars, 1882.

In 1865 Lilljeborg established the Oedicerina as sixth subfamily of the Gammaridæ, distinguishing it from the other subfamilies as having, "Antennæ superiores flagello appendiculari carentes. Oculi compositi. Pedes trunei (thoraciei) 7:mi paris antecedentibus multo longiores, segmento ultimo (uunque) longo, recto et stiliformi." To it he assigned the new genus *Oediceropsis*, together with *Oedicerus*, Kröyer, *Monoculodes*, Stimpson, and *Kröyera*, Spence Bate. In 1870 Boeck made the Oedicerinæ the tenth subfamily of the Gammaridæ, placing in it *Oediceros*, *Acanthostephia*, *Monoculodes*, *Halimedon*, *Pontocrates*, *Accros*, *Halicrcion*, *Oediceropsis*, *Paramphithoë*. In 1872–6 he still placed this subfamily among the Gammaridæ,¹ with the same definition as before, but excluding the genus *Paramphithoë* as having been previously enrolled by a mistake. Nevertheless *Pleustes*, Spence Bate, which Boeck here adopts in preference to *Paramphithoë*, Bruzelius, took its place as the ninth genus of the Oedicerinæ (p. 299). But later on (p. 496) Boeck explains that this was only an error passed on from the earlier to the later work. In 1882 Sars changed the subfamily into a family, with the name Oediceridæ, placing in it the same genera as Boeck had done, with the exception of *Acanthostephia*, which did not happen to be included in the Norwegian fauna. In J. S. Schneider's preliminary revision of the Norwegian Oediceridæ, the same limits are adopted for the family, though Schneider suggests that a new genus should be formed for some specimens which he refers with much hesitation to *Halimedon saussurei*, Boeck. All the genera above named, with the exception of *Aceros*, are included along with several others in the subfamily Phoxina, Spence Bate, by Gerstaecker in 1886, *Halimedon* being made a synonym of *Monoculodes*, and *Acanthostephia* of *Oedicerus*.

Boeck gave the following definition of the Oedicerinæ:—

"Upper Lip apically insinuate.

"Mandibles very robust, apically broad, more or less dentate; the accessory plate also more or less dentate; the spine-row with the spines simple but strong; the molar tubercle not very large; the palp long, three-jointed.

"The Lower Lip broad; the inner lobes large.

¹ On page 74 of Boeck's great work the Oedicerinæ are the fourth subfamily of the Gammaridæ, in front of the Epimerinæ; on p. 254 they follow the Epimerinæ as fifth subfamily, being numbered as "Subfamilia VI," owing to the accidental interposition of the Iphimedinæ in front of them.

“*First Maxillæ* with the inner plate tolerably large, apically furnished with two setæ, sometimes plumose; the palp two-jointed, carrying narrow spines on the apex.

“*Second Maxillæ* with the plates very short and broad, the inner broader than the outer.

“*Maxillipeds* with the inner plates small; the outer plates sometimes longer, sometimes shorter, never very large, armed on the inner margin with strong spines increasing as they approach the apex; the palp broad and robust; its last joint strong, unguiform.

“The body little compressed. The back round, rarely carinate or armed with teeth. The side-plates of moderate size, setose on the lower margin. The first side-plate apically dilated. The head generally produced in front into a broad rostrum, on which the eyes are placed. For the rostrum to be absent and the eyes placed on the sides of the head is rare.

“*Upper Antennæ* without accessory flagellum.

“*First and Second Gnathopods* with the hand more or less strong, either subcheliform or cheliform; the *Second Gnathopods* rarely without a subcheliform hand; in each pair the wrist generally strongly produced into a process (calx) on the lower hinder angle.

“*Third and Fourth Peræopods* almost alike in size and shape.

“*Fifth Peræopods* elongate, very often twice as long as either of the two preceding pairs.

“*Uropods* elongate, biramous; the third pair with the rami narrow; the peduncle seldom elongate.

“*Telson* short, undivided.”

Schneider, in his valuable review of the characteristics of the family Oediceridæ, lays especial stress on the last joint of the *Fifth Peræopods*, which is not nail-like but quite straight, cylindrical, about as long as the preceding joint, armed with spinules and sometimes with plumose setæ. He notices that owing to its extreme fragility it is often met with in a damaged condition. The inner plate of the *First Maxillæ*, he says, is large, broadly oval, apically furnished with two short setæ, of which the upper is always plumose, the lower simple, except in *Oediceros saginatus*, which has both plumose, and in *Aceros phyllonyx*, which has three setæ, all plumose; in some species of *Halimedon* he finds only a single simple seta. In the genus *Oediceroïdes* of this Report the number of these setæ varies from three to eight. Of the *Second Maxillæ* Schneider says that in most species the two plates are of about equal breadth, in one the outer is the broader, and in two the inner, while the outer is uniformly the longer, and in all genera except *Halimedon* (to which *Oediceroïdes* may now be added) there is a thicker plumose seta on the middle of the inner margin of the inner plate.

 1886. *Oedicerus*, Gerstaecker, Brönn's Klassen und Ordnungen, Bd. v. Abth. ii. p. 503.

For the original definition of this genus, see Note on Krøyer, 1842 (p. 199). J. S. Schneider, in 1883, defines it as follows:—

" Head produced into a frontal rostrum, which is sometimes geniculate, acuminate, sometimes extended forwards and obtuse; the eyes either flat or prominent, coaleseed.

" Antennæ furnished with feathered cilia (plumulis instruetæ), the flagellum of the lower antennæ of the adult male not elongated.

" Mandibles with the molar tubercle rather small, of irregular shape.

" Gnathopods with the wrist short, the hand very large, subcheliform."

Œdiceros lynceus, M. Sars (Pl. CXXXVII. B).

 1870. *Oediceros lynceus*, Boeck, Crust. amph. bor. et arct., p. 82.
 1876. " " Boeck, De Skand. og Arkt. Amph., p. 259, pl. xiii. fig. 4.
 1883. *Oedicerus lynceus*, Schneider, Norges Oedicerider, p. 14, Tab. ii. fig. 12.
 1884. *Oediceros lynceus*, Schneider, Crust. og Pyen. Kvaenangsfjorden, p. 78.

This species has not long since been carefully examined and described afresh by J. S. Schneider. He thinks it highly probable that in this species two or possibly

three years may be required for full development. "Neither Goës," he says, "nor Boeck has been successful in figuring the species; especially in the work of the latter author the head with the rostrum is quite erroneous, while it is precisely the characteristic form of this part of the body that is the best mark of distinction between *Oediceros lynceus* and *Oediceros microps*, which in many respects stand extremely near together." The figures given by Goës seem to agree with the form *microps* as to the head and the form *lynceus* as to the telson; it is possible, therefore, that Goës had a form intermediate between the other two, which are recognised both by Sars and Schneider as extremely close to one another. The mouth-organs in the Challenger specimen closely agree with the account given by Schneider in regard to *Oediceros lynceus*, but whereas he says that in the mandibles both plates are divided into six or seven tolerably acute teeth, I find on the left mandible the secondary plate divided into five rather strong teeth, and on the right mandible more weakly constructed, with numerous denticles, only the lowest of which deserves to be called a tooth. "In the first maxillæ the outer plate has two shorter furcate and five longer serrate spines; the inner plate is broadly oval with one simple and one plumose seta at the apex." Schneider calls attention to the fact that Boeck speaks of two plumose setæ. It is possible that there may be some variation between individuals in these minute details; thus, in the Challenger specimen, on one of the maxillæ one of the furcate spines has an additional tooth by the side of the shorter arm of the fork. In the lower antennæ the gland-cone is narrow and produced. On the telson, besides the two spinules at the flattened or slightly insinuate apex, there is on each lateral margin a little cilium above the rounded apical corner, and a little above this cilium a group of two or three minute cilia, none of these appendages being visible except under a tolerably high power of the microscope.

Locality.—Station 49, south of Halifax, Nova Scotia, May 20, 1873; lat. $43^{\circ} 3'$ N., long. $63^{\circ} 39'$ W.; depth, 85 fathoms; bottom, gravel, stones; bottom temperature, $35^{\circ} 0$. One specimen. Dredged.

Genus *Halimedon*, Boeck.

For the original definition of the genus, see Note on Boeck, 1870 (p. 400). Schneider, in 1883, gives the following definition:—

"Side-plates of the third and fourth pair very large, generally almost entirely

covering the basal joint of the legs. Mandibles apically only a little dentate, the third joint of the palp straight, the molar tubercle of irregular shape, tolerably large, the molar surface not circular. Maxillipeds with the outer plate large, reaching almost to the apex of the second joint of the palp, its inner margin furnished with teeth, apically devoid of setæ. The gnathopods subequal, the second pair more or less elongate; the wrist very long, generally equalling the length of the hand or longer than the hand, produced into a short rounded heel." But as the characters ascribed to the side-plates and the maxillipeds would be unsuitable to the Challenger species which I have placed in the genus *Halimedon*, I feel bound to adhere to the definition of that genus given by Boeck, who instituted it.

Halimedon schneideri, n. sp. (Pl. LIX.).

Head about as long as the three following segments united, with a down-bent apically subacute rostrum; the lateral lobes of the head small and little produced; the back round, with a rather imbricated appearance in the specimen figured; this was perhaps accidental, as a second specimen showed but little of it, the second specimen having also the segments of the peræon more regular, the hinder a little longer than the front ones, and the seventh the longest; the first four, and especially the first three, segments of the pleon exceed in length those of the peræon; the first three have the postero-lateral angles rounded.

Eyes not made out in the specimen figured, but in the second specimen, apparently belonging to the same species, they are dark, elongate, broader in front than behind, not reaching the tip of the rostrum, closely approximate the one to the other.

Upper Antennæ.—The first joint thicker than the second, in length subequal to it, the second carrying some groups of setæ; the third much thinner and shorter than the second, also carrying some long setæ; the flagellum of seventeen joints, of which the first three or four together equal the length of the third joint of the peduncle, the first six or seven its second joint.

Lower Antennæ.—The first joint not greatly expanded, the gland-cone small but distinct, produced along part of the third joint; the third joint about equal in length and breadth, fourth joint longer and thicker than the fifth, both straight, and with numerous groups of setæ; the flagellum tapering, of twenty-four joints carrying spine-like setæ.

Upper Lip.—Both plates distally broad, the outer squared with rounded corners, and quite smooth, the inner less broad at the distal edge but with its sides sloping back across the corners of the outer plate and describing a curve beyond them, this plate also apparently uneiliated. In the figures the distal edge is uppermost.

Mandibles.—Cutting plate strong, divided into three principal teeth, the centre one flanked by two denticles; the secondary plate on the left mandible strong, similar to

the principal plate but on a smaller scale, on the right mandible slighter in its structure, with three slender curved teeth clumped together; the spine-row not well made out, seemingly of five or six pectinate spines; the molar tubercle prominent, with the dentate crown not very large, some of the denticles long, the seta small; a conical process rises near the inner side of the base of the palp; the palp is fixed over the molar tubercle, the first joint not very short, the second curving outwards at the base and then backwards, the upper part being straight and thinner than the bent basal portion, its front margin bordered with spines of various lengths, some very long, a curved row also taking its origin on the surface from near the base to beyond the centre; the third joint very slightly curved, shorter and thinner than the second joint, hind margin smooth, front margin slightly serrate, bordered with small spines gradually increasing from the first to the third in each of four sets, with four long spines at the apex, and as many arising along the surface; on the right mandible this joint in our specimen was longer than on the left.

Lower Lip broad, not deep; the front lobes widely dehiscent, the inner lobes little dehiscent, rounded in front, not reaching nearly as far forward as the principal lobes; the mandibular processes apically narrowed.

First Maxillæ.—Inner plate widest a little distance from the base, the ciliated border then bending round to the curved apex and carrying two small setæ, the longer of which, at some little distance from the other, is plumose and stands near but not on the apex; the outer plate not large, though longer and broader than the inner, carrying nine slender spines on the broad, scarcely oblique, distal margin, five of the spines having but one lateral tooth, the other four denticulate near the apex; the second joint of the palp reaching much beyond the outer plate, with sixteen setiform spines extending round the upper part of the inner margin, the apex, and chief part of the outer margin; an additional row of seven or eight runs on the surface from the middle of the inner margin to the middle of the apex.

Second Maxillæ.—The inner plate broader, very little shorter than the outer, with spines on the apical and upper part of the inner margin, on the latter having also plumose setæ; cilia abundant on both margins; the outer plate carrying longer spines on the apical margin and some little way down the inner margin, and five short setæ spread along the upper half of the hinder border.

Maxillipeds.—Inner plates small, not reaching the apex of the first joint of the palp, with four setæ, not strongly plumose, on the inner margin, the rounded apex set with nine spines besides several slender setæ; the outer plates narrow, reaching beyond the middle of the second joint of the palp, the serrate inner margin being fringed with about thirty spines, the width of which is rather abruptly contracted at some distance from the apex, while the length is irregular, a long one occurring here and there among the shorter, the two near the apex being rather long and curved; to these succeed three on the apex and three on the hind margin which are setiform; the first

joint of the palp very short, the second very long, gradually expanding so that the widest part is near the distal end, the outer margin smooth, the inner thickly set with setæ or setiform spines, a few also on the surface at the upper part; the third joint longer than the first, expanding distally, the inner margin straight and unarmed, the outer margin, one surface and the apex thickly set with spines; the finger short, its inner margin straight, produced a little beyond the base of the very short nail, one or two cilia being here inserted; the dorsal cilium rather nearer the base of the finger than that of the nail.

First Gnathopods.—Side-plates narrow at the base, greatly expanded below and forwards, the lower margin convex, serrate at the corners, fringed all round with setæ of very various lengths; some spines on the hinder margin; the first joint reaching considerably beyond the side-plate, with long setæ on both margins, the second joint short, the third rhomboidal, with the distal end emarginate and the hinder apex a little produced and fringed behind with long spines; the wrist as long as the hand, becoming distally very wide, the free hind border fringed with numerous spines, of which the longest are at the slightly produced free apex; the hand long and broad, widest at the palm, the front margin longer than the hinder; the palm convex, defined by a tooth in which is set a strong spine with plumose accessory thread; there are numerous setæ of different lengths set round the palm, some groups also on the inner surface near both lateral margins and at the front apex; the finger fitting closely to the palm and when closed reaching the inside of the tooth which defines the palm; a dorsal cilium not very close to the base of the finger; a small cap over the nail.

Second Gnathopods.—The side-plates furnished like, but much narrower than, the preceding pair, not expanded, all the lower margin serrate. Marsupial plates with very long setæ. The limb very similar to the first gnathopods but more elongate, the first joint stretching far beyond the side-plate; the third joint more narrowed distally, with its hinder apex less produced than the other; the wrist and hand both longer than in the preceding pair, but not quite so wide distally, armed in the same manner, the extreme length of the wrist scarcely equalling that of the hand.

First Peræopods.—Side-plates longer and broader than those of the preceding segment. Branchial vesicles narrow at the base, widening to the distal end, longer than the side-plates. Marsupial plates narrow, rather longer than the branchiæ, with long setæ. First joint reaching beyond the side-plate, a little expanded distally in front, carrying some long setæ on its margins; third joint widening a little distally, not decurrent, with several groups of setæ on the hinder margin and an apical group in front.

Second Peræopods.—Side-plates very much broader than the preceding pair, also longer, longer than their own breadth; the angle of the hind margin is so low down as scarcely to be suggestive of an excavation; from this angle the fringe of setæ extends all round the lower margin, which bends upwards in front so as to be scarcely distinguishable

from the front margin. The branchial vesicles and marsupial plates resemble those of the preceding pair. This is also probably true of the joints of the limb, some of which in the preceding pair were damaged or missing. The first joint reaches beyond the side-plate and is rather longer than that of the first peræopods; the fourth joint shorter than the third, bordered behind with several sets of long setæ; the fifth joint not much longer than the fourth, the upper part of its hind border peetinate and carrying a few setæ, the lower part smooth; the lower front part of this joint adorned with six or seven rows of long setæ; the finger as long as the preceding joint, slightly boat-shaped; its edges smooth, tipped with a little slightly curved nail protected by a boat-shaped cap.

Third Peræopods.—Side-plates broad and deep, rather broader than deep, the front lobe the larger, both lobes partially fringed with setæ; the branchial vesicle narrowed below. The marsupial plates short. The first joint of the limb much narrower and also shorter than the side-plate; the wing more expanded above than below, both margins fringed with setæ, some very long and densely plumose, some setæ also on the inner surfaces; the third joint widening a little distally, not decurrent, beset with numerous groups of setæ, those on the hind margin long; the fourth joint shorter than the third or fifth; the fifth joint similar to that in the second peræopods, so also the finger, but somewhat shorter.

Fourth Peræopods.—Side-plates deeper than broad, the lower margin fringed with setæ behind. The branchial vesicles bent not far from the base, and thence narrowing downwards. The limb similar in structure and furnishing to those of the preceding pair, but all the joints except the second longer; the fourth joint has distally a little oval-ended process overlapping the following joint behind in one member of the pair of limbs, whether broken off in the other member of this and in the other pairs of peræopods I cannot say; while the finger in the third pair is much shorter than the preceding joint, it is in this pair fully as long.

Fifth Peræopods.—Side-plates much broader than deep, lower margin fringed with short setæ. In the Plate the side-plate and the hinder corner of the segment above it are figured with the lettering *prp. 5.*, but in fact the peræopods themselves were missing. In this figure the hairy nature of the integument is indicated. In the second (much smaller) specimen alluded to above, the first three joints of the fifth peræopod are preserved, the first is very much broader than the corresponding joint in the preceding limb, somewhat ovate, with the upper part much broader than the lower; the front margin longer than the hinder; the third joint narrower below than above, very slightly produced behind.

Pleopods.—Numerous setæ upon the peduncles; the pair of coupling spines (as observed in the smaller specimen) very small and slender, with a terminal hook and one retroverted tooth with its tip upturned; the cleft spines appear to be four in number; the joints of the rami numbered ten to twelve in the small specimen, but seemed to be rather more numerous in the larger.

Uropods.—The peduncles of the first pair longer than the rami, with many small spines on two edges; the rami slender, one longer than the other, the tips curved, the rows of small marginal spines ceasing some way from the tips; the peduncles of the second pair a little longer than the rami; the rami equal, slender, straight; the peduncles of the third pair about equal to the rami, reaching as far back as the peduncles of the second pair, the rami subequal, acute, reaching almost as far back as the rami of the second pair; it should be noticed that in the specimen figured the third uropods are very unequal, one member of the pair having a peduncle much shorter, and the single ramus present also much shorter, than the corresponding pieces of the other member.

Telson short, very far from reaching the end of the peduncles of the third uropods, longer than broad, narrowing a little distally, the distal border scarcely emarginate, furnished with a couple of eilia and perhaps one or two more.

Length.—The specimen, in the position figured, without the antennæ, was rather more than half an inch long. The second specimen was about one-third the length of the first.

Locality.—Kerguelen Island. The larger specimen was only labelled as coming from Kerguelen; the smaller as taken at the surface in Betsy Cove, Kerguelen, on January 10, 1874.

Remarks.—The specific name is given in honour of J. Sparre Schneider, who is doing so much excellent work both among the Amphipoda and other objects of natural history, and to whom I personally am much indebted for many valuable specimens.

The species agrees well with Boeck's definition of his genus *Halimedon*, in which I have therefore placed it, although the upper lip does not appear to be *in apice insinuatum*, nor do the spines of the mandibular spine-row appear to be simple, as required by the characters which Boeck assigns to the subfamily Oedicerinae.

Genus *Œdieeroides*, n. gen.

Head produced into a rostrum on which the elongate eyes (when present) are placed. Upper antennæ much shorter than the lower, fourth and fifth joints of the lower antennæ elongate.

Mandibles with strong molar tubercle, the second joint of the palp large, broader at the base than distally.

The First Maxillæ with from three to eight plumose setæ on the inner plate and setæ on the outer margin of the palp.

The Second Maxillæ with the inner plate broader than the outer, both broad.

The Maxillipedæ as in *Œdiceros*, the outer plates reaching about halfway along the broad and long second joint of the palp.

The First and Second Gnathopods with large hands and with large distally expanded wrists.

The Fourth Peræopods longer than the third, though similar in structure.

The Fifth Peræopods much longer than, but not nearly double the length of, the fourth.

The generic name refers to the great likeness between this genus and *Œdiceros* of Krøyer; but, not to speak of smaller differences in the mouth-organs and in proportions of the peræopods, those in the gnathopods were too great to admit of the inclusion of the new species in the older genus, without modifying the definitions of it given by Boeck and by Schneider, which did not seem to be desirable.

Œdiceroides rostrata, Stebbing (*Œdiceroides conspicua*, Pls. LX., LXI.).

1883. *Œdiceropsis rostrata*, Stebbing, Ann. and Mag. Nat. Hist., ser. 5, vol. xi. p. 204.

The rostrum long and somewhat arched, projecting well beyond the first, if not the second, joint of the upper antennæ, dorsally, laterally, and inferiorly carinate, the dorsal carina, however, not like the other three running out to the little boat-shaped apex, but descending rather abruptly into it; the sides of the head are produced in large squarish lobes, angled above and rounded below; on either side the base of the rostrum and behind it there is a depression, and another crossing the head near its hind margin. The peræon is stout, with rounded back, each of the first six segments having a transverse dorsal depression; the seventh, which is the longest, has a small median tubercle. The pleon is compressed, each of its first four segments carrying a median tubercle of successively greater length, forming a sort of carina, interrupted by a dorsal depression in the fourth segment. The fifth and sixth pleon-segments are very short. The side-plates of the peræon-segments and the lower margins of the first three pleon-segments are, as usual in this family, fringed with setæ. The whole animal appears to be covered with short down.

Eyes wanting; see Note on Willemoes Suhm, 1876 (p. 461). The “finely granulated red pigment,” of which Willemoes Suhm makes mention, occupies all the thickened part of the rostrum, not descending into the boat-shaped apex; in the specimens preserved in spirits the proboscis and its granular contents were no longer bright red, but white like the rest of the animal. It will be noticed that in the other two species assigned to this genus eyes are present on the rostral prominence.

Upper Antennæ not nearly reaching the end of the peduncle of the lower, the first joint broadest at the base, as long as the two following joints united, carrying many cilia and fine setæ; the second joint nearly twice as long as the third, both furnished like the first; flagellum of twenty-one joints, of which the upper, to the number of about twelve, are thick, the remainder thin and longer, these latter having each a distal group of cilia, while the thicker joints, at least in one specimen, might be described as bearded.

Lower Antennæ much stouter and longer than the upper; a small gland-cone on the second joint just below the slightly expanded portion of the first joint; the third joint about equal in length to the coalesced first and second, carrying numerous setæ; the fourth joint longer than the preceding three united, not much shorter than the flagellum of the upper antennæ, with two very long spines on the side, one below the centre, the other almost distal, also a short spine on the upper margin near the distal end, and all along this margin spinules or setules which like the spines are hairy; the fifth joint as long as the first three united, armed with some large spines, two of them very long, and with numerous setules and long feathered cilia; the flagellum of about sixty-five joints, thick at its base and tapering slowly, in every joint except the first two or three and the last dozen showing a small calceolus standing stiffly out on the upper distal end; the above description applies to the specimen figured on Pl. LX.; in another specimen the long spines are altogether absent, the fifth joint is only very little shorter than the fourth, both are fringed all along beside the upper margin with small rows of setules scarcely projecting beyond the edge; the flagellum, not as in the other specimen shorter, but longer than the peduncle, slender throughout, of seventy-four joints, armed only with short cilia; to this specimen, a very large one, belonged the upper antennæ with the bearded flagella.

Upper Lip very broad, the rounded distal margin projecting at the centre in a little point, the central space almost naked, but the tracts on either side of it strongly furred.

Mandibles.—Cutting plate with two or three large teeth at one end and a small tooth at the other, the intermediate space smooth or slightly denticulate; the secondary plate in the left mandible with its edge divided into six strong teeth, in the right mandible of much slighter structure with the edge divided into four slender teeth; the spine-row of six, seven, or eight slender, hairy, or denticulate spines; the molar tubercle large and prominent, with a small hairy tubercle at the upper corner in front, one side of the more or less oval crown smooth-edged, the other finely dentate, the appearance varying considerably according as the smooth or the dentate edge is shown outermost; a conical process stands between the molar tubercle and the palp. The first joint of the palp short, the second long, stouter at the base than above, its hinder margin concave, some long thin setæ on the lower part of the front margin, along which are spines of various lengths; the third joint is not shorter than the second, bordered with short spines along more than the upper two-thirds of the front margin, with long spines at the apex, and a long spine near the base behind, or with two such spines.

Lower Lip broad; the principal lobes broad, the forward margins broad, slightly curved, densely furred; the inner margins with their anterior portions nearly straight, standing widely apart, the interval being partly filled by the front margins of the inner lobes; the mandibular processes bluntly pointed.

First Maxillæ.—Inner plate broader than the outer, its length scarcely greater than its breadth, carrying eight plumose setæ, which commence not at, but close to, the apex, pass along the straight, slightly oblique distal margin, and along the curve which joins it to the convex inner margin; the outer margin is nearly straight; the outer plate narrows distally, and carries on the trunate distal edge nine spines, most of them furcate, in the sense of having only one lateral tooth; the innermost has three lateral denticles, the one next to it is truly furcate, the lateral tooth being nearly as long as the main branch and parallel to it; the first joint of the palp has some setæ at points of its outer margin, the second joint, which is widest about the centre and overtops the outer plate, has setæ at three points of the somewhat serrate outer margin, and round the apex and part of the inner margin has two rows of bristles, twenty-one in all, most of them looking like slender setæ, three at the apex being definitely spiniform, two of them delicately pectinate on two edges, the third with a tendency to be so.

Second Maxillæ.—Both plates broad, especially the inner, which is broader and very little shorter than the outer; both are densely ciliated, the spines of the inner commencing near the inner end of the broad distal margin, and passing far down the inner margin, accompanied on this by plumose setæ, some of which fringe it almost to the base; on the outer plate some short spines are placed on the distal border a little way from its outer corner, and followed by a fringe of long, though slender, spines, which pass about halfway down the inner margin.

Maxillipeds.—The inner plates small, broad in proportion to their length, not reaching nearly so far as the distal end of the first joint of the palp, the distal margin set with several short, distally serrate spines; the outer plates erescent-like, reaching about to the middle of the second joint of the palp, set along the inner margin with numerous seta-like spines, which increase in length towards the apex, passing round the apex and part of the outer margin as long plumose setæ; the first joint of the palp short, with some setæ on the apex, the second joint long and large, bordered on the inner margin with long seta-like spines, longest at the broadest part of the plate which precedes the apex, with a row also on the inner surface; the third joint longer than the first, widening distally, set on the inner surface with some six rows of spines, several of which are longer than the finger, plumose at the centre, distally pectinate; the finger curved, shorter than the third joint, much thicker at the base than at the origin of the little crooked nail; the small dorsal cilium at not quite a third of the distance between the base of the finger and the base of the nail.

First Gnathopods.—The side-plates projected forwards below the head with a straight front margin, the lower half carrying setæ, the lower margin bent abruptly upwards to meet the hind margin, which also carries setæ at intervals. The first joint scarcely reaching beyond the side-plate, with some long setæ on the margins and inner surface, and groups of spines on the distal part of the inner surface, most of these spines, and

those on the three following joints, having abruptly contracted pectinate terminations; the second joint with a distal group of spines at the back; the third joint not greatly longer than the second, with a group of spines round the curve which unites the lower and hinder margins, and another group on the inner surface within the lower front apex, which apex rests against the outside of the wrist; the wrist distally broad, the wing carrying spines on its inner surface and bordered with them, its expansion forming a cup for the hand, it being also slightly produced so as to form a calx, the effect of which is increased by the apparent tendency of the hand to bend towards it; the hand large, oval, longer than the wrist, all the hind margin, except the short piece which the wrist can overlap, being defined as a convex palm densely ciliated and fringed with setules; on the inner surface there are some rows of long pectinate setæ reaching to the front margin; the teeth in many standing at a right angle to the length of the seta; there are also smaller groups near the palm; the long curved finger when closed fits the palm border, reaching the small palmar spine; the dorsal cilium very small, near the base.

Second Gnathopods.—Side-plates with front and hind margins nearly parallel, fringed, though less densely than the lower margin, lower margin rounded, chiefly at the corners. Branchial vesicles large, irregularly folded, seemingly of very thin texture. First joint reaching much beyond the side-plate, carrying long setæ on the margins, this and the remaining joints closely resembling the corresponding joints of the first gnathopods in shape and armature, but exceeding them in length; the third joint rather more squared at the hinder distal angle, the wrist with its wing slightly more produced, the hand considerably longer but only slightly wider, the finger not quite reaching the two small palmar spines; the inner side of each gnathopod is represented in the Plate, from which it will appear that the hand of the second gnathopod is devoid of the long pectinate setæ which adorn the hand of the first.

First Peræopods.—Side-plates rather longer and broader than the preceding pair, otherwise similar. Branchial vesicles in this and the following pair very extensive and lightly crumpled. The first joint not reaching beyond the side-plate, fringed on both margins with long and short setæ, some of them plumose; the second joint short; the third not decurrent, with spines singly or in groups along the straight hind margin, and one group at the front apex; the fourth joint narrower and a little shorter, with numerous groups of spines, some of them large and long, fringing the hind margin, and a group of setæ at the front apex; the fifth joint as long as the third, armed at eight points on each margin, the name of spines being suitable to the furniture of the straight hind margin, of setæ to that of the slightly convex and serrate front margin; the finger a little shorter than either the fifth or fourth joint, slightly boat-shaped, tapering to a very small nail with a narrow cap projecting beyond it.

Second Peræopods.—Side-plates scarcely longer than those of the preceding pair, rather deeply excavate behind, the plate being widest at the lower angle of the

excavation, from which the margin runs obliquely forward, closely fringed with setæ and continuous with the convex lower margin. The limb similar to that of the first peræopods.

Third Peræopods.—The side-plates broad, with the two lobes almost equal. The brachial vesicles seemingly not quite so large as those of the preceding pair. The first joint broadest above, nearly once and a half as long as broad, with numerous setæ arising both on the surfacee and round the front and hind margins, many of them very long and densely plumose; the second joint short; the third fully as long as the first, with the front margin nearly straight, the hinder convex, not decurrent, both densely fringed with spines and long plumose setæ; the remaining joints similar to those of the next pair, but shorter.

Fourth Peræopods.—The side-plates with the lobe behind much deeper than the front margin. The first joint somewhat longer and broader than in the preceding pair, the hind margin sinuous, making the joint more pear-shaped, the armature similar; the third joint longer than the first, apparently more spiny on the hind, and less setose on the front margin than in the third peræopods, but the difference may be accidental, since long plumose setæ are easily broken off; the fourth joint about half the length of the third, and much narrower, with small groups of spines at six points of the front margin, and an apieal group of setæ behind; the fifth joint longer than the fourth, but narrower, with spines at seven points along the front margin, and setæ at a dozen along the slightly convex hind border; the boat-shaped tapering finger as long as the fifth joint; the minute nail in one specimen was upturned, as represented in the figure (Pl. LXI.), from which it may be presumed that these nails are movable, though they are rarely seen except in line with the finger.

Fifth Peræopods.—The side-plates broad and shallow, the hinder part a little deeper than the front, fringed along much of the lower and all of the hinder margin. The first joint broadly pear-shaped, much longer and wider than in the preceding peræopods, the front margin much longer than the hinder, very convex above, much straighter below, fringed with spinules, and on the lower part with small setæ, the sinuous hind margin closely set with setæ; the second joint fringed on the straight front margin with setæ; the third joint almost as long as the first, straight, parallel-sided, a very little decurrent behind, with thirteen groups of spines along the front margin, and many interspersed with setæ along the hind margin, which, like the front, has a strong group of spines at the apex; the fourth joint almost as long as the third, straight, apieally a little widened, fringed in front with spines, behind with two principal groups, one apieal, the other distant about one-third of the length of the joint from the apex; the fifth joint as long as the third or nearly so, slender, straight, crowded with short spines in groups about the front margin, several spines along the hind margin, and along the inner surfacee (not therefore shown in the figure), some thirteen groups of spines of various lengths, five or six being

very long; the finger about as long as the preceding joint, straight, slender, tapering, serrate on both edges, and provided all along with slender spines or setæ. This limb is very much longer than that which precedes it, but not nearly double its length, since it is only in the fourth joint that it attains that superiority, while in the third joint it is but a trifle longer.

Pleopods.—The coupling spines show on one side two lateral retroverted teeth besides that at the apex, and several denticles along the other side; the cleft spines are eight in number, at least on the first and second pairs, the arms very short and nearly equal, one as usual having the form which I have called spoon-shaped, but which might better be likened to the hand of a clock, the other conspicuously denticulate; the first joint of the outer ramus has a conspicuous interlocking process at the base; the joints of the rami number from twenty-six to thirty, those near to the large first joint being very short and broad.

Uropods.—The peduncles of the three pairs reaching back almost to the same point, with the variation in length which this demands, their edges and those of the rami fringed with very numerous spines, the rami of the first pair longer than those of the second, and the second longer than the third, in each pair subequal, lanceolate, the inner margins of the outer and the outer margins of the inner rami being finely pectinate, the apices tapering rather abruptly.

Telson small, nearly square, but with the lateral margins a little convex and the distal a little emarginate, all three more or less ciliated.

Length.—The specimen measured three-quarters of an inch from the tip of the rostrum to the end of the first uropods in the position figured; the largest specimen was an inch and a quarter long.

Localities.—Station 149H, Cumberland Bay, Kerguelen Island; depth, 127 fathoms; bottom, volcanic mud. Five specimens.

Station 150, off Heard Island, February 2, 1874; depth, 150 fathoms; bottom, coarse gravel; bottom temperature, 35°. One specimen.

Remarks.—Originally I placed this species in the genus *Oediceropsis*, Lilljeborg, and named it *Oediceropsis rostrata*, to emphasize its possession of a large rostrum as distinguished from *Oediceropsis brevicornis*, Lilljeborg, to which in some respects it bore a great resemblance. Subsequently I found that in this and two other new species the inner plate of the first maxillæ was large, not small as in *Oediceropsis*, nor was the inner plate of the second maxillæ *much* wider than the outer, as in *Oediceropsis*. Moreover, the last-named genus was specially instituted for a species without a rostrum, and with lateral eyes, in these respects differing from all the three new species in question. For these, therefore, I thought it expedient to institute the new genus *Oediceroides*. But in a genus in which every species has a rostrum, the name *rostrata* was not very suitable for any one species. For this reason it seemed advisable to change the name of the

species to *Œdiceroides conspicua*, as it stands on Pls. LX. and LXI., but I have since reflected that the name *rostrata* has no such inherent depravity as to justify a change, and I suppose that, apart from such defect, the author of a specific name has no more right over it, when once published, than any one else. The name *Œdiceroides conspicua*, being thus strangled before its birth, will, I hope, not swell the future lists of synonyms.

Œdiceroides einderella, n. sp. (Pls. LXII., LXIII.).

The Head as long as the first three segments of the peræon, the rostrum dorsally, inferiorly, and laterally earinate, somewhat depressed, reaching nearly as far as the distal end of the first joint of the upper antennæ, its width at the centre not half its length; the lateral lobes of the head irregularly rounded, produced over the base of the lower antennæ; back of peræon a little imbricated; first three pleon-segments with the postero-lateral angles rounded, lower margins fringed with setæ.

Eyes long, narrow, approximate, occupying most of the rostrum, and narrowing as they approach its blunt point.

Upper Antennæ.—The first joint thicker and longer than the second, the second nearly twice as long and twice as broad as the third, all carrying plumose setæ, the second having several groups, the whole peduncle not reaching nearly to the distal end of the fourth joint of the lower antennæ; of the flagellum only eight joints remained.

Lower Antennæ.—First joint not greatly expanded, gland-cone high up on the second, not decurrent by the side of the third; third joint scarcely longer than broad, carrying groups of setæ; fourth joint long and stout, carrying some setæ and feathered cilia; the fifth joint about as long but less broad, having, besides setæ and cilia, four large spines, two marginal and two apical; the flagellum of fifty-four joints, of which the first is longer than any that follow, the last alone is very slender, each with the exception of the last four carries a small calceolus, a long seta and some short ones.

Upper Lip.—The distal margin centrally smooth, the sides, which retire so as to complete almost a semicircle, are fringed with cilia almost up to the point where they bend round and narrow the lip; the inner plate entirely within the circuit of the outer, a little emarginate.

Mandibles.—The cutting plate broad, with a small tooth at one end, three large teeth at the other, and an intermediate edge which is smooth or slightly dentieulate; this plate folds to some extent round the secondary plate, which in the left mandible is broad, the distal margin divided into five teeth, the lowest the longest; in the right mandible the secondary plate is of slighter construction, and in one specimen exhibited two teeth dentieulate along the edges, while in the other it showed a long tooth with two denticles upon it and three smaller teeth, in the former case the plate being apparently seen end-on, and in the latter case broadside, which suffices partially, not wholly, to account for the difference;

the spine-row consists of six or seven spines, of which some at least are peetinate ; the molar tubercle is prominent, with strongly dentate crown of squarish-oval shape, with forward margin more or less smooth, but in the right mandible carrying a projecting tooth above and below; between the molar tubercle and the palp is a narrow, almost conical process ; the first joint of the palp short, the second as long as or longer than the first and third united, stouter at the basal than the distal portion, with spines of varying lengths along its front, the longest apical, a little curved and distally peetinate ; the third joint has a long spine near the base behind, four shorter on the upper half of the front margin, and three long ones at the apex.

Lower Lip.—The principal lobes broad and shallow, widely dehiscent, the gap being to a large extent occupied by the inner lobes ; the mandibular processes short and broad.

First Maxillæ.—Inner plate short and broad, bowed out on the inner side, narrowing towards the apex, and carrying three slightly plumose setæ, no one of which quite reaches the apex ; the outer plate carrying nine spines on the truncate distal margin, the innermost long, with two lateral teeth, the next adjoining strongly fureate, the remainder with one or two lateral teeth ; the first joint of the palp with two setæ on its hind margin, the second joint with two on the hind margin and many on the dentate oblique apical margin ; in one of the specimens this palp was evidently a little abnormal on one side of the mouth, having a single seta on the outer and two on or near the inner margin.

Second Maxillæ short and broad. Inner plate broader and scarcely shorter than the outer, carrying a couple of slender plumose setæ near the centre of the inner margin, just below which commences a row of setules, short spines and setæ passing round the upper part of the outer margin to the beginning only of the broad, almost flat, distal border ; the spines of the inner plate begin but a little way down the inner margin, with increased length occupy the distal border, though the longest are not outermost, and the outer slope is occupied by four shorter than any of the others.

Maxillipeds.—Inner plates not much longer than broad, not reaching the apex of the first joint of the palp, with two long plumose spines or setæ on the inner margin, and the broad slightly dentate distal margin crowded with serrate spines and spine-teeth ; the outer plates reaching a little beyond the middle of the second joint of the palp, crescent-shaped, the concave serrate inner margin fringed with numerous sharp spines of increasing length towards the apex, the seven which pass round the apex and a little way down the outer margin assuming the character of plumose setæ ; the first joint of the palp short, the second long and large, dilating greatly from the base distally, fringed with spines or setæ round the inner margin and carrying some on the surface ; the third joint a little longer than the first, narrow at the base, with numerous spines on the outer margin, surface and apex, most of them peetinate ; the finger short with the dorsal cilium near the base, and a cilium inserted where the inner margin is prolonged at the base of

the nail. As shown in the figure *map.*, Pl. LXII., in one specimen these maxillipeds were not symmetrical.

The *triturating organs* show an inner row of short sharp teeth, broad at the base and apparently simple, while the outer row consists of long slender spines covered with prickles or denticles.

First Gnathopods.—Side-plates greatly expanded below and outdrawn in front, with cilia along the front margin, plumose setæ fringing the lower, scattered on the inner surface, and occurring at intervals on the hind margin. The first joint broad, rather bent, reaching beyond the side-plate, with groups of spines near and at the distal end; the second joint with a group of spines at the hinder apex; the third joint short, squarish, with no free front margin, the lower hinder corner rounded and set with a group of spines; the wrist broader than long, the hind wing, which gives it something of a cup-shape, being set both round the erenulate edge and on the inner surface with numerous spines, which, like many of those on the preceding joints, are plumose in the middle, then become finely pectinate and end seta-like; the hand is large, longer than the wrist, from a rather narrow base expanding greatly, with four groups of setæ or spines near the long convex front margin; the hind margin is smooth, short, the difference in length between this and the other margin being made up by the great length of the convex palm, defined by a curved spine, and fringed with closely set cilia, numerous setæ and setules taking their origin on each surface along the palm-border, while others arise on the inner surface at some distance from it; the finger is of great length, slender, curving round the palm, the defining spine of which it a little overlaps, being itself smooth except for some microscopic cilia within its inner margin and the dorsal cilium near its base.

Second Gnathopods.—Side-plates of nearly even breadth throughout, the convex lower margin fringed with numerous plumose setæ. Branchial vesicles as long as the first joint of the limb, with a small accessory lobe close to the narrow neck. The limb in shape and details closely resembling the first gnathopods, but of greater length; the first joint extending much beyond the side-plate, the spines near the front apex strong; the third joint with strong spines extending less round the hinder and more round the distal margin than in the first gnathopods; the wrist of equal length and breadth, larger than that of the preceding pair, the hand longer, without being broader, than in the preceding pair.

First Peræopods.—Side-plates as in the preceding segment, but rather broader. Branchial vesicles distally broader than those of the second gnathopods, with a small oval accessory lobe near the neck. First joint reaching beyond the side-plate, with some setæ on the margins; second joint short; third joint longer than the fourth, not decurrent, with three or four groups of setæ on the hind margin, the apical groups long, and an apical group in front; the fourth joint like the preceding, narrowest at the base, subequal in length to the fifth, with an apical group of setæ in front, and on the hind margin four

curved spines, three accompanied with setæ, the apical spine the longest; the fifth joint a little curved, with small incurved spines at three or four points on the hind and setæ at six points on the front margin, some of the latter being very long; also at the juncture with the finger behind, two very small spines curving outwards; the finger shorter than the fifth joint, somewhat boat-shaped, with smooth margins, an oval boat-shaped cap projecting over and beyond the tip of the small nail.

Second Peræopods.—Side-plates very broad, somewhat deeper than broad, a little broader below than above, fringed round the lower margin with plumose setæ of various lengths. The branchial vesicles similar to those of the preceding pair, longer than the first joint of the limb. The limb very similar to that of the first peræopods; the first joint reaching below the side-plate, with some long plumose setæ on the upper part of the hind margin; the third joint with an apical group of setæ on the front, and two or three groups on the hind margin, this and the two following joints being rather shorter, while the finger is rather longer, than in the first peræopods; the fourth joint with an apical group of setæ in front, and on the hind margin three long curved spines, each attended by setæ; the fifth joint has setæ at five points on the front margin, incurved spines at three on the hind margin, and the apical pair of outcurved spines.

Third Peræopods.—Side-plates broad and large, much broader than deep, with setæ on the lower margin, the front lobe larger than the hinder. The branchial vesicles somewhat larger than the first joint of the limb, with a small accessory lobe at the base. The first joint tending to an oval, rather broader above than below, with setæ along the hind margin, rather to be called prickly than plumose (which may also be said of those on the various side-plates), also with setæ on and near the front margin, and some that are very long and plumose on the inner surface; the third joint broad, not much shorter than the first joint, and nearly as long as the fourth and fifth united, fringed with long spines or spine-like setæ along both margins; fourth joint rather shorter than the fifth, with some small groups of short and long spines in front, and an apical group behind; the fifth joint with two slender spines and a spinule on its straight front margin and four spinules on the slightly curved hind margin; the finger longer than the fifth joint, with a slight constriction near the base, in which is inserted, not a cilium, but a seta; the usual cap over the short nail.

Fourth Peræopods.—Side-plates lobed behind, with the lower margin serrate and fringed. The first joint about equal in length to that in the third pair, broadest above, with numerous setæ along the front and hind margins, some long and densely plumose (which are easily broken off) arising on the inner surface; the third joint longer than the first, its margins fringed with numerous setæ, some spine-like, some plumose; the fourth, fifth, and six joints similar to those of the preceding pair, but in each case longer; the fifth joint with three slender spines and a spinule on its front margin, in addition to the little hinge-spines; the seta at the base of the finger not observed, probably broken off.

Fifth Peraopods.—The side-plates shallow, not narrowed behind, serrate and fringed round the lower and hind margins. Branchial vesicles small, apparently with a small accessory lobe at the base as in the other pairs. First joint much longer and broader than in the preceding pairs, about once and a half as long and more than onee and a half as broad, with short spines along most of the very convex front rim, setæ along the shorter, also convex hind rim ; the seeond joint short, all the others elongate, of nearly equal length, none so long as the first joint, all bordered with spines of various lengths and thicknesses, some of which are prickly, many with short bent tips and a small accessory thread, those on the slightly serrate margins of the finger being slender, prickly, not decreasing in length as they approach the tip of the finger, the tip itself broken. This limb, though very much longer than the fourth pereopod, cannot be considered nearly double as long.

Pleopods.—The eoupling spines on the third pair being seen full face showed two lateral retroverted hooks on each side, one of them having a third on one of its sides and an appearanee near the base of two little upturned points ; those on the first pair, less well placed for observation, appeared to have more hooks, and more on one side than the other ; the cleft spines showed a row of five on the first pleopods, of four on eaeh of the following pairs ; the interior roughening of the longer arm was in this speeies very conspicuous. The joints of the rami numbered from fifteen or sixteen to eighteen. On the peduncles there were plumose setæ and some spines.

Uropods.—Peduncles of the first pair eonsiderably longer than the rami ; the rami acute, with small spines on the upper margins, not extending to the apex, one ramus longer than the other ; peduncles of the second pair longer than the inner ramus ; the outer ramus broken, the inner reaching back between the longer and the shorter ramus of the first pair ; the third uropods broken off.

Telson short, not reaehing far beyond the produced sides of the sixth pleon-segment, rather longer than broad, the broad distal margin with a slight tendency to erenulation, set about with plumose cilia and having a small spine on either side of the almost angled centre.

Length.—The speeimen figured life-size on Pl. LXIII. fig. A., measured three-fifths of an inch, exclusive of the antennæ.

Locality.—Station 317, near the Falkland Islands, February 8, 1876 ; lat. $48^{\circ} 37'$ S., long. $55^{\circ} 17'$ W.; depth, 1035 fathoms ; bottom, hard ground (gravel) ; bottom temperature, $35^{\circ}.7$. Two speeimens. The more complete speeimen was mounted on board the vessel, and labelled as obtained “from net at the weight.”

Remark.—The speeific name refers to the glassy slipper-like eap over the nail in the pereopods which is found in this speeies, and indeed in many others of the same family.

Ediceroides ornata (Stebbing) (Pl. LXIV.).

1883. *Acanthostepheia ornata*, Stebbing, Ann. and Mag. Nat. Hist., ser. 5, vol. xi. p. 203.

Two antero-dorsal ridges on the head lead to the neck of the very pronounced rostrum, which is dorsally, inferiorly, and laterally carinated, the top convex, the sides converging to a point reaching beyond the first joint of the upper antennæ, the lower earina produced to a point a little less advanced than the upper one; the whole surface except the neck, the carinæ, and the extreme tips being occupied by the eyes; a small rounded lobe projects on either side of the base of the rostrum, and the sides of the head are studded with tubercles. In the peræon the hinder margin of each segment is adorned all round with teeth alternating in size, the succession of large central teeth almost constituting a continuous carina, while on the other hand the transverse depressions at the base of each segment give the back, viewed laterally, an imbricated appearance. The fringing teeth vary in number from nine to seventeen, presenting an appearance like that of the projecting edges of the septa in many Corals. The seventh segment has a second row of teeth in advance of the hinder margin, the other segments having also some lateral tubercles in this position, and the lateral margins of the segments being fenced in, as it were, with long flattened tubercles. The first pleon-segment has a fringe of very small teeth, and in front of the row a large median tooth flanked by some small ones not in line; the second segment has a long central ridge with small teeth on its flanks, but none on the hind margin; the third segment, dorsally much longer, has the central ridge without other ornament, and in this respect is resembled by the three following segments, which are very small; the first three segments have the postero-lateral angles rounded.

The Eyes are long and narrow, separated only by a narrow carina, their outline on the outer side determined by the shape of the rostrum; the ocelli are numerous, and the colour remains dark after preservation in spirits for many years.

Upper Antennæ more slender than the lower; first joint narrowing distally, second shorter than the first, with a spine near the middle of the upper margin and one at the apex, also two feathered eilia at the apex below; the third joint only half as long as the second and much narrower; the flagellum broken off; the feebleness of the third joint of the peduncle is suggestive of a small flagellum, and the peduncle itself reaches little beyond the base of the fourth joint in the lower antennæ.

Lower Antennæ.—First joint but little expanded; a very small but distinct gland-cone at the lower basal part of the second joint, the two joints being at this part clearly distinguished, though at the upper part they are quite coalescent; the upper margin distally produced; the third joint nearly as broad as long; the fourth joint much narrower, but more than three times as long, carrying short spines and plumose cilia on various parts; the fifth joint rather more than twice as long as the third, narrower

than the fourth, armed like it; the flagellum broken, a small calceolus on the single remaining, somewhat elongated joint.

Upper Lip with a broad apical margin.

Mandibles powerful. The cutting plate at one end has three teeth, of which one is produced considerably beyond the other two; a flat oblique border leads from these to a small tooth at the other end; within the main plate in the left mandible is placed a secondary plate of similar shape, with its lower edge cut into five consecutive teeth, of which the outermost is produced much beyond the others; in the right mandible the secondary plate is much slighter and narrower, apically divided into two denticulate teeth; the spine-row consists of six or seven denticulate spines; the very prominent molar tubercle has its crown set with many rows of denticles; the seta at the upper corner is small; the long palp is inserted over the molar tubercle. The first joint short, the second long, narrowing distally, with some six groups of spines along its course; the slender third joint is almost as long as the second, fringed along almost all the inner edge with spines, and having three, of which two are very long, at the apex; near the base close to the hind margin are two, a long and a shorter one; all these spines being pectinate on two edges in the lower part.

Lower Lip.—The principal lobes rounded, very broad; the mandibular processes rather short, narrow at the apex.

First Maxillæ.—Inner plate very broad, the convex inner margin ciliated, the straight margin which follows at right angles with the convex part carrying five subequal plumose setæ at intervals; the outer plate narrower than the inner, the apical margin not very oblique, armed with nine long spines, four of which are strongly denticulate, the others at the apices strongly furcate; the palp reaching considerably beyond the outer plate, its first joint short, with some small setæ on the outer margin, the second long, having slender spines on the apex and upper part of inner margin, nine or ten in number, and half a dozen spaced along the serrate outer margin, and a row on the surface above near the inner margin.

Second Maxillæ.—The plates short and broad; the inner broader than the outer and reaching as far forward, its inner margin fringed with cilia, plumose setæ, and spines of various lengths, the fringe of spines passing but a little way round the broad apical border, which is not reached by the row of plumose setæ which passes inwards along the surface; the outer plate is fringed with spines round the upper part of its inner margin and the apical border, small spines passing down the upper part of the outer margin.

Maxillipeds.—The inner plates short, not nearly reaching the apex of the first joint of the palp, with slender teeth and curved spines on the flat-topped apex; the outer plates not broad, reaching halfway along the second joint of the palp, the inner margin concave, crowded with spines, the longest of which at the beginning of the apical border is followed by five plumose setæ; the first joint of the palp is less than half the length of the second;

the second is much expanded distally, fringed with setæ along the inner margin, and carrying some groups on the surface; the third joint expanded distally, is crowded, except near the base, with groups of serrate spines; the finger has its lower border prolonged a little beyond the base of the nail, carrying a cilium in the incision thus produced.

First Gnathopods.—Side-plates broader than deep, projecting much forwards, with much of the upper margin free, the front shorter than the hind margin, the front and lower both fringed with long setæ; perhaps homologically the upper is the front margin, the lower being bent round to take the place of the true front; the first joint reaching below the side-plate, channelled along the front, some groups of setæ on the inner surface and about the somewhat expanded distal portion; the second joint short; the third without any free front margin, the hinder carrying groups of setæ, and a little produced on the outside with setæ upon this apical process; the wrist longer than the third joint, with groups of setæ on the front margin and near the hind margin on the inner surface, the lower hinder part forming a large bent process, the border and inner surface of which are armed with spine-like setæ, this process giving the wrist the not uncommon cup-shape; the hand much longer than the wrist, broad, oval; the long palm, defined close to the apex of the wrist-process by two spines and bordered with numerous setæ, occupies the greater part of the hind margin; groups of setæ of different lengths are set upon the inner surface of the hand near each margin; the finger is strong, long, and curved to match the palm, its edges are smooth, except for the small dorsal cilium near the base.

Second Gnathopods.—Side-plates longer than broad, narrower than those of the preceding pair, fringed like all the others with setæ below. The limb in its details closely resembling the first pair, but with the joints somewhat longer, and the lower edge of the third joint fringed with strong unequal spines, which were not observed in the other gnathopods.

First Peraopods.—Side-plates a little broader than those of the preceding segment. Marsupial plates very long and fringed with numerous long setæ. First joint of the limb reaching beyond the side-plate, carrying setæ on both margins, on the serrate hinder margin several that are very long as well as some that are shorter; the second joint short; the rest of the limb broken off.

Second Peraopods.—The side-plates rather longer than the preceding pair, pretty deeply excavate behind, the setiferous lower margin running with a continuous curve up to the point at which the excavation ceases. The marsupial plates like those already described. The first joint of the limb reaching beyond the side-plate, resembling that of the first pereopods; the third joint about half the length of the first, not decurrent or scarcely so, carrying on the serrate hinder margin four or five groups of spines and setæ, and a group at the apex before and behind; the following joints broken off.

Third Peraopods.—The front lobe of the side-plates much larger than the hinder one. The branchial vesicles with a narrow neck, thence expanding rapidly with a triangular

form. The first joint but little expanded, much longer than broad, broadest near the base, hind margin nearly straight and smooth, front margin slightly curved and serrate, both closely fringed with setæ, of which many on the front margin are densely plumose; on the inner surfacee the inner margin of the unexpanded joint, as distinct from that of the wing or expansion of it, carries numerous setæ, some of which are densely plumose and of great length; the second joint very short, the third rather long, shorter than the first, crowded with long spines and plumose setæ on the front margin, and with plumose setæ on the hind margin; it expands a little from the narrow base and contracts towards the distal end. Remainder of the limb missing.

Fourth Peræopods.—Side-plates deeper behind than in front. First joint broader than in the preceding pair, but not longer, the upper part rounded behind; the armature and general struture of the limb similar to that of the third pereæopods, but the third joint longer than the first, with some long spines at and near the apex in front, a suture or groove crossing the joint for half or more of its breadth a little way from the apex; the fourth joint much narrower and shorter than the third, with some short setæ and long spines on the front margin; the spines with curved ends, one of them equalling the length of the joint. Remainder of the limb missing.

Fifth Peræopods.—Side-plates with the upper margin produced to a small point. The first joint expanded, sloping away on both sides from the neck, the front margin very convex, fringed with small spine-like setæ, the hind margin sinuous, convex above, with longer setæ, and a small apical lobe set with spines not overlapping the second joint; the joint being much thickened where the chief museles lie presents a surface depression along the hinder expansion; the second joint with its front and hind margins unusually free; the third joint narrower but not shorter than in the preceding pair, of almost uniform width throughout, the apex scarcely decurrent, eight groups of spines on the front margin, spines and setæ fringing the hinder margin. Remainder of the limb missing.

Pleopods.—The pair of coupling spines very small, the terminal hook bent sharply downwards; a lateral tooth at some distance below; there are many small retroverted teeth along the outer margin; such teeth I believe to be not uncommon, but as they do not project they are in many species very difficult to discern; the outer distal end of the peduncle produced into a curved tongue; the eleft spines forming a row of nine, those at the top short; the joints of the inner rami twenty, of the outer twenty-two in number.

Uropods.—The peduncles of the first pair longer than the inner ramus, closely fringed with spines on two edges, the rami narrow, stiliform, the inner with six spines along the upper margin, not beginning close to the base and not nearly reaching the acute apex; the outer ramus broken, with six spines on the upper part, stouter than those of the inner ramus; the peduncles of the seeond pair longer than the subequal stiliform rami, with a row of seta-like spines on the surfacee, with spines all along the lower edge and along more than the distal half of the upper; several spines along the edges of the

rami, but not extending to the apieal region; peduncles of the third pair a little shorter than the lanceolate rami; with short slender spines on the outer margin, longer and stronger ones on the two inner edges; the inner ramus with eight spines of various lengths on its inner margin, and a row of eleven small ones on the outer, the outer ramus with five along the proximal half of the outer margin.

Telson short, rounded at the top, the greatest breadth near the base, the distal border broad, scarcely emarginate, slightly serrate at the outer corners, above which are placed on either side two pairs of elia.

Length.—The length of the pereon and first three segments of the pleon united was exactly half an inch.

Locality.—Station 162, off East Moneœur Island, April 2, 1874; lat. $39^{\circ} 10' 30''$ S., long. $146^{\circ} 37' 0''$ E.; depth, 38 fathoms; bottom, sand and shells. Dredged. One specimen, female.

Remarks.—The specific name refers to the striking ornamentation of the pereon.

It long appeared to me that this species ought to be placed in the same genus with *Acanthostepheia malmgreni*, Goës, and *Acanthostepheia pulchra*, Miers, although the broken antennæ and pereopods left one or two of the characters in obscurity. But the two northern species just mentioned are both sharply distinguished from the present species by having small lateral eyes remote from the rostral apex, while the generic relationship between this and the other two species assigned to the new genus *Edicerooides* seems to be consistently maintained in all parts; the inner plate of the first maxillæ has much the same shape in all three, although the number of setæ varies, being five in the present species, compared with three and eight respectively in the other two. In *Acanthostepheia malmgreni*, it may also be mentioned, the last three pairs of side-plates in the pereon are acuminate, but Miers does not seem to mention these in describing his species, so that it remains uncertain whether this should be regarded as a generic characteristic.

INCERTÆ SEDIS.

Genus *Amathillopsis*, Heller, 1875.

For the account of this genus given by its author, see Note on Heller, 1875 (p. 442). Heller places it between *Amathilla* and *Gammaracanthus*, that is to say, in the group of

which Boeek constitutes the subfamily Gammarinæ, and there perhaps it ought to stand. It is excluded from the *Œdiceridæ* by the large size of the upper antennæ and the small size of the fifth pereopods, as well as by having an accessory flagellum, though a small one, on the upper antennæ. In the species here assigned to the genus the fifth pereopods are undetermined, being imperfect in our single specimen, the upper antennæ have an appendage which can only very doubtfully be regarded as an accessory flagellum, and the third joint of the mandibular palp is longer than the second, instead of shorter as in Heller's species. In placing the Challenger species next to *Œdiceroides ornata*, I was influenced by the similarity in the mandibles, maxillipeds, gnathopods, and telson, as well as in the palp of the first maxillæ, though, it must be allowed, the outer plates of those organs differ in the number of apical spines. On the other hand, the general structure of the body and the character of the pereopods, so far as observed, bring *Amathilopsis australis* near to the genus *Epimeria*, but the maxillipeds are an obstacle to including it in the family Epimeridæ. Owing to the imperfect condition of the fifth pereopods in the specimen, the generic position of our species is itself a little uncertain, so that a more accurate determination of its family must await more favourable circumstances.

Amathilopsis australis, Stebbing (Pl. LXV.).

1883. *Amathilopsis australis*, Stebbing, Ann. and Mag. Nat. Hist., ser. 5, vol. xi. p. 205.

Rostrum small, with the apex a little depressed, not projecting as far as the lateral processes of the head; these are narrow, apically almost pointed, grooved on the outer surface; the lower margin of the head carinate; a longitudinal groove sweeps round from that of the lateral process almost to the hind margin, another groove descending from it transversely to a little angled point in the lower margin. A carina traverses the centre of the back, leaving the rostrum smooth, and likewise a small piece at the base of each segment; along the head and first four segments of the pereon it is a mere raised line, though raised sufficiently to show a little undulation on a lateral view; on the three following segments of the pereon and the first three of the pleon it is prolonged into acute processes, successively larger, and each overlapping the next following segment, that on the third segment of the pleon having its lower edge, not as in the other cases continuous with the hinder margin of the segment, but originating a little in advance of it; on the fourth segment the carina is indicated beyond the dorsal depression, but does not reach the end of the segment, it traverses the fifth, and is just indicated at the end of the sixth segment. All the pereon-segments have on each side a dimple or oblique groove, and on the first three pleon-segments rather higher up there is an arched groove not dimpled, these three segments have the hinder borders sinuous, and at the postero-lateral angle the first rather tends to form a tooth than actually develops one; in the second

and third the tooth is well developed, larger in the second than in the third. The fourth pleon-segment is much longer than the two following; the fifth is shorter than the sixth; all three are dorsally emarginate. The integument of this handsome species is crustaceous.

Eyes not made out, perhaps indicated by a somewhat roughened tract on either side of the cephalic carina, but probably absent.

Upper Antennæ.—First joint longer than the head, with a linear, not very straight, carina along the top; the joint is robust, thicker at the base than distally; the second joint equal in length, but less thick; the third joint but little more than a third the length of the second, distally dilated, and at the lower corner carrying a strong, flat, incurved spine (which possibly represents an accessory flagellum); the flagellum with the first joint longer than the spine just mentioned, bearded; the following joints numerous, short, closely united, each carrying a small calceolus. The flagellum incomplete, the remaining portion, a little longer than the first joint of the peduncle, contained more than fifty joints.

Lower Antennæ less robust than the upper, with peduncles of about the same length; first joint a little dilated; gland-cone small; third joint subequal in length to the coalesced first and second; fourth joint rather longer than the first of the upper antennæ, carrying spines on three edges; the fifth armed like the fourth, shorter and thinner than that joint, longer than the first three united; the flagellum with a first joint longer than any of those which follow, these, as in the upper antennæ, being short, numerous, and each armed with a small calceolus. The flagellum incomplete, the remaining portion containing seventy joints, those towards the end being longer than those nearer the peduncle with the exception of the first, the whole equal in length to the first four joints of the peduncle. The calceolus is of a peculiar shape in this species; to the foot-stalk succeeds the usual circular cup, but the distal portion beyond this, instead of being as usual oval, has the distal half of each side cut away as it were, so as to leave a narrow triangular piece with the basal half of the oval projecting in a point on either side.

Upper Lip broad and thick, with a flattened space in the centre of an almost semi-circular distal margin, the curve on either side of which has but few cilia.

Mandibles.—Cutting plate produced into a long process set round in front with eight or nine teeth, of which on the left mandible the lowest is the largest; the secondary plate on the left mandible has its edge divided into six teeth, of which the lowest is much the largest; on the right mandible the lowest but one of the teeth in the principal cutting plate is the largest, a circumstance not unusual; the secondary plate is less strong than in the other mandible, somewhat expanded distally, and divided into three teeth, of which the lowest is the longest and is subdivided into two small teeth; the spine-row shows ten spines on the left, nine on the right mandible, the

spines being to some extent dentieulate or pectinate; the molar tubercle is prominent, with oval crown, dentate on one side, ciliated along the other edge; at the top in front a tubercular process and a ciliated ridge at right angles to the crown; there is a broadly oval process between the molar tubercle and the palp; on the outside from the basal part of the shaft, and parallel with it, projects a large, rectangular process, probably serving some interlocking purpose to adjust or strengthen the movements of the mandibles; the first joint of the palp has a group of spines at the outer distal angle; the second joint has the hinder margin concave, with spines along the convex front margin, except a short piece at the base, and a parallel row on the surfacee, many of the spines being very long and most of them pectinate on two edges; the third joint is narrow, tapering, longer than the first and second united, with pectinate spines of various lengths along almost the whole front margin, with groups also at the back and one on the surfacee near the base, also with closely-set cilia on the surfacee of the upper part.

Lower Lip.—The principal lobes broad and deep, and rather thick, strongly ciliated on the broad, rounded, distal margin, and more slightly on the straight inner margin; the mandibular processes with the apex directed a little outwards, the outer margin being broadly grooved, so that the process has a three-sided appearance.

First Maxillæ.—The inner plate oblong-oval, the attachment below narrow, the outer margin overlapping the outer plate; seven plumose setæ, commencing at the top of the inner margin, pass round half the broad, distal margin, the seventh arising on the surfacee a little within the margin; at the inner corner there are three setules; the outer plate, longer but scarcely broader than the inner, carries on the trunate distal margin eleven slightly curved spines, of which none seems to have more than two lateral denticles, most of them having only one; on one of the maxillæ there appeared to be twelve spines; the first joint of the palp is short, the second reaches beyond the outer plate, and carries round the apex and top of the inner margin seven long spine-teeth, the apex itself being serrate or rather cut into broad teeth; eight setiform spines pass along the surfacee from the outer apical angle a little way down the inner margin, within much the same limits a small thicket of cilia occupying the opposite surfacee; on the outer margin seta-like spines are placed at four serrations and at the apex.

Second Maxillæ.—The inner plate has its inner margin for some distance straight, strongly ciliated, at the widest part of the plate the margin turns obliquely towards the rounded apex, having at the turn several plumose setæ, numerous long and slender spines fringing the margin from this point round the apex; the outer plate is very little longer than the inner and scarcely so broad, both its front and hind margins concave below and convex above, the convex portions and the apex fringed with numerous spines, those on the apex very long, those on the outer margin small.

Maxillipeds.—The inner plates small, reaching little beyond the base of the first

joint of the palp, with groups of plumose setæ on or within the upper part of the inner margins, the distal margins broad, sloping outward, carrying two pairs of short teeth on one of the plates, on the other a pair of teeth and a tooth and a spine; these are followed by seven or eight long spines bending inwards; the outer plates narrow, reaching but little beyond the first joint of the palp, with the inner edge smooth for some distance, and then irregularly denticulate to the apex, which forms a tooth, beyond which the distal margin rises in a curve, set closely round with long curved spines to the number of fourteen or fifteen, which are successively longer and thinner, so that those which pass down the outer margin are rather feathered setæ than spines; there are several setiform spines on the surface within the inner margin; the first joint of the palp is short, its inner margin extremely so; the second joint is elongate, carrying on both surfaces near the inner margin numerous groups of spines, many of them long and pectinate on two or three edges; there is also a group at the middle, and at the apex, of the outer margin; the third joint is much longer than the first, and thickly set on both margins and at the apex with large groups of pectinate spines; the finger is long, curved, sharply pointed, longer than the first, but shorter than the third joint, with a small cilium at the nail, both edges and probably the whole joint covered with short down.

First Gnathopods.—The side-plate short, not overlapping the head, its front margin at the lower part sloping backwards, the lower margin a little concave, and the hinder sinuous, fringed with short spines. The first joint projecting much beyond the side-plate, not so long as the hand, its front margin nearly straight, the distal half of the hinder much out-bowed, and the whole fringed with setiform spines, and the lower margin, which at the rear projects beyond the second joint, also set round with spines, the front part of the inner surface covered with groups of setæ; the second joint short, like the first having its distal margin furnished with numerous setiform spines, some very long; the third joint irregularly oblong, no part of the convex front margin free, carrying a group of spines on the inner surface; there is also a bunch of spines near the apex of the hind margin, which itself is embowered in spines rising on the surface near it; the wrist large, about as long as the first joint, the wing widening distally, but not reaching so far as the front margin of the joint, thickly set round with long serrate spines, besides having numerous groups of them on the inner surface, supported by other groups near the front margin on both surfaces, the lower margin of the wing concave and channelled near the attachment of the hand; the hand a very elongate oval, broadest about the centre, nowhere so wide as the wrist at its widest, and abruptly narrowed at the hinge of the finger, with many groups of spines or setæ on the inner surface near each margin; the palm includes without any precise definition almost the whole of the hind margin, and is armed as well with long and short serrate setiform spines as with several short stout spines, for the insertion of all which a

special crenulation is provided just within the palm-margin; the finger is long and curved to fit the palm; by the bending forward of the hand in the channelling of the wrist the finger would be enabled to touch the expanded portion of the wrist, which may thus be adapted to assist in the act of grasping; the dorsal cilium close to the hinge, minute.

Second Gnathopods.—Side-plates larger and deeper than those of the first gnathopods, similar, except that the front margin has no abrupt bend. Branchial vesicles with a narrow crumpled neck, the whole length about equal to that of the first joint. The marsupial plates narrowing distally, set closely round with very numerous and long setæ, more closely on the front than on the hind margin. The limb closely resembling that of the preceding pair in shape and the details of its armature, but the first joint considerably longer and more out-bowed on the hind margin, the wrist shorter than the first joint, its wing, unlike that in the first gnathopods, produced beyond the front margin so as to form a calx, though not a long one; the hand and finger but little longer than in the preceding pair; in each pair the finger has some small stiff hairs on the inner margin.

First Peræopods.—Side-plates with the front margin nearly straight, descending considerably below the preceding pair and free from it except at the convex upper part of the margin; the short slightly emarginate lower border makes a sharp angle with the front; the plate is thickened and its surface almost rigid near the hind margin, which is overlapped by the following plate. The branchial vesicles, of tolerably even width to the rounded apex, are longer than the first joint of the limb. The first joint reaches much below the side-plate, about equals the length of that of the preceding pair, with similar armature and a slight tendency to the out-bowing of the hinder margin, which forms a ridge; the second joint with two groups of spines on the hind margin; the third joint elongate, not quite so long as the first, narrow, slightly curved, a very little expanded and decurrent at the distal end, with spines at some seven points of the hind margin, and some spinules in front; the remainder of the limb missing, unfortunately, not only in this but in all the peræopods.

Second Peræopods.—The side-plates shorter than in the preceding pair, excavated behind for little more than a quarter of the depth, from the angle of the excavation the margin slanting forwards to form a sharp angle with the lower point of the sinuous front margin. The branchial vesicles, marsupial plates, and joints of the limb as in the preceding pair.

Third Peræopods.—The side-plates broader than deep, the front lobe larger than the hinder, the hinder with its lower margin flattened. Branchial vesicles broader than in the preceding pairs; marsupial plates similar. First joint of the limb rather longer than in the preceding pairs, a little expanded behind near the base, and distally in front, the armature slight, both front and hind margins carinate; the third joint similar to that of

the preceding pair, but rather shorter, with six groups of strong spines on the front margin.

Fourth Peraopods.—The front margin of the side-plates almost straight, shorter than the hind margin, the lobe behind resembling that in the third peraeopods. The first joint rather shorter than in the preceding pair, but more dilated behind near the base; the limb in other respects like the preceding.

Fifth Peraopods.—Side-plates small, not bilobed. First joint shorter than in the preceding pair, more expanded above, other details similar.

Pleopods.—The coupling-spines with two lateral retroverted teeth, the apical tooth seemingly double, bent, but not downwards; the cleft spines on the first pair nine in number, with seven or eight plumose setæ on the margin above them, and as many on the same joint below them; the joints of the outer ramus thirty-eight, of the inner thirty-four; the peduncles carrying numerous setæ.

Uropods.—The peduncles of the second pair reach back just beyond those of the first pair, and those of the third just beyond those of the second; the peduncles of the first pair longer than the rami, the rami lanceolate, the outer a little shorter than the inner, which it partially clasps, the marginal spines small; the peduncles of the second pair rather shorter than the longer ramus, the rami similar to those of the preceding pair, but reaching rather beyond both those and the third pair; the peduncles of the third pair much shorter than the rami, which, as in the other pairs, are broad, lanceolate, the outer shorter than the inner.

Telson subequal in length to the peduncles of the third uropods by which it is closely clasped, longer than broad, slightly narrowing distally, the distal end slightly emarginate.

Length.—The specimen is figured life-size at the top of the Plate. From the lateral lobe of the head to the dorsal apex of the first pleon-segment is nine-tenths of an inch; the total length without the antennæ may be considered to be an inch and a half, the imperfect upper antennæ measure seven-tenths of an inch.

Locality.—Station 184, between Australia and New Guinea, August 29, 1874; lat. $12^{\circ} 8' S.$, long. $145^{\circ} 10' E.$; depth, 1400 fathoms; bottom, Globigerina ooze; bottom temperature, 36° . One specimen, female. Trawled.

Remarks.—The specific name refers to the great distance between the habitat of the present species and that of the two earlier known species of the same genus, which are both Arctic. From the type-species, *Amathilopsis spinigera*, Heller, the present is distinguished by the palp of the mandibles, which in Heller's species has the third joint shorter than the second, by the absence of dorsal processes on the first four segments of the peraeon, and the fourth of the pleon, by the shape of the side-plates, and by the peduncles of the third uropods, which in Heller's species are double the length of the telson. From *Amathilopsis affinis*, Miers, it is distinguished by the absence of dorsal

processes on the anterior peraeon-segments, by the different shape of the gnathopods, and other particulars.

Heller places the genus between *Amathilla* and *Gammaracanthus*, apparently therefore, as already observed, including it in the subfamily Gammarinæ as defined by Boeck, but with Boeck's definition it does not well agree either in regard to the first maxillæ, the spines of which are neither fureate nor serrate, while both the palps are similarly not differently armed, or in regard to the maxillipeds, in which the inner plates are small, not elongate, or in regard to the pereiopods, of which the three last pairs, according to Heller, successively decrease in length, instead of increasing in accordance with the definition. The objections are of less importance which may be urged against affiliating this genus to Boeck's subfamily Epimerinæ.

Genus *Zaramilla*, n. gen.

Antennæ short.

The Upper Lip distally rounded.

Mandibles with strongly dentate cutting plates; a secondary plate on each mandible; several denticulate spines in the spine-row; the molar tubercle prominent; the palp three-jointed, the second and third joints large.

The Lower Lip broad.

First Maxillæ.—The inner plate with many plumose setæ.

Second Maxillæ.—The inner plate with many plumose setæ on or near the inner margin; the outer plate rather longer and broader than the inner.

Maxillipeds.—The outer plates with spine-teeth on the inner margin; the second joint of the palp long, the fourth slender and acute.

The First and Second Gnathopods similar, subequal, the wrist subequal in length to the hand.

The third joint large in all the *Pereiopods*, in the last three pairs remarkably developed; the fingers of the pereiopods having a little cap over the point of the nail.

The Uropods biramous, the rami equal in the first and third pairs, the outer branch the smaller in the second pair.

The Telson not very elongate, deeply cleft.

The generic name is taken from an imaginary personage in *Don Quixote*.

The genus, in regard to the head, antennæ, gnathopods, and pleon, would reasonably be arranged among the Atylidæ, while the pereiopods, except the last pair, and in some respects the mouth-organs, would bring it near to the Oediceridæ. From the Pontoporeiidæ it is separated by the absence of the secondary flagellum from the upper antennæ.

Zaramilla kergueleni, n. sp. (Pl. LXVI.).

Back round, not broad, the animal compressed; head a little angularly advanced between the upper antennæ, medio-lateral lobes but little advanced; postero-lateral angles of the first two pleon-segments acute, of the third, which is the longest, right-angled.

Eyes large, dark, oval, placed near the front margin, with no great interval on the top of the head.

Upper Antennæ.—The peduncle as long as the flagellum, the first joint much thicker and somewhat longer than the second, which is thicker and longer than the third, all three with setæ on the lower margin; the third as long as the first three or four joints of the eleven- or twelve-jointed flagellum; on some of the joints of the flagellum, besides setæ, were long and broad cylinders, and also short ones, in the male also calceoli.

Lower Antennæ.—First joint little expanded, gland-cone small and little prominent, third joint very short; fourth joint broader, but a little shorter, than the fifth, both these with setæ on the lower margin; flagellum of fourteen joints, for the most part longer and shorter alternately, the longer being also more expanded distally, and, in the male, carrying small calceoli.

Upper Lip very broad, the distal margin rather irregularly convex; in the specimen figured this is folded back, probably by accident.

Mandibles.—Cutting edge divided into five or six strong teeth; the secondary plate on the left mandible similarly divided; on the right mandible the cutting edge does not seem to antagonize squarely with that of the left mandible, its secondary plate is of much slighter construction, by no means as on the other mandible a reduced duplicate of the cutting edge, but laminar, the apex divided into two portions, each with a gaping, serrate emargination, so that four terminal teeth are formed, of which the central two overlap; the spine-row of numerous, seven or more, long, curved, pectinate spines; the molar tubercle prominent, with denticulate crown; the palp set well forward, just over the molar tubercle, the first joint short, the second rather longer than the third, fringed for the greater part of its length on and near the inner margin with slightly plumose setæ, the third joint a long oval, pointed at the apex, fringed like the second, and also carrying on the outer surface, near the base, a transverse row of eight setæ of various sizes; an articular process stands out between the molar tubercle and the base of the palp.

Lower Lip short but very broad, forward lobes little dehiscent, the broad apical and inner margins well ciliated; inner plates faintly distinct.

First Maxillæ.—Inner plate broad, narrowing to the apex, fringed with a dozen plumose setæ, of which the apical is the longest; outer plate carrying on the apical margin nine multidentate spines, of which the innermost is straight; the large second

joint of the palp overtops the outer plate, and has a small spine-tooth below the apex, and a row of six on the apex, the outermost being longer and more slender than the rest; a row of small setæ runs below the apical margin.

Second Maxillæ.—The plates moderately broad, with rounded apices; the inner plate a little shorter and narrower than the outer, with ten or a dozen plumose setæ, beginning on the inner margin near the base and passing round towards the outer apex; the apical margin fringed with rows of curved spines; the apical margin of the outer plate fringed in like manner, the largest spines outermost, followed by a few smaller ones down the outer margin.

Maxillipeds.—Inner plates reaching about as far as the apex of the first joint of the palp, apical margin straight, with three spine-teeth and a row of plumose setæ beginning below the apex on the inner side, passing along it and ending just below it on the outer side, some long plumose setæ on the inner margin; outer plates small, not nearly reaching the end of the second joint of the palp, with eight long spine-teeth on the inner margin, followed by a longer spine-tooth and five plumose setæ round the apical, and a little descending the hinder, margin; there are also numerous groups of setæ on the outer surface, within the inner margin of the plates; the second joint of the palp longer than the first; the third as long as the first, with setæ on surface and apex, some of the latter strongly pectinate; finger slender, with a sharp nail.

First Gnathopods.—Side-plates oblong, rounded lower margin fringed with setæ, two or three of which also occur on the hind margin. The first joint reaching a little below the side-plate, with some setæ along the hinder, and two or three near the base on the front, margin, some pectinate spines at the apex behind; the third joint short, with pointed apex, just above which is a row of setæ and a pectinate spine; the wrist in the male a little shorter, in the female a little longer, and distally a little broader, than the hand, with rows of pectinate spines on the hinder margin and the surfaces near it, a group of setæ at the front apex; the hand between oval and oblong, with groups of seta-like pectinate spines on both surfaces and near both margins; the palm oblique, a little sinuous, minutely crenate, bordered with cilia, defined by a group of stout but slenderly pointed spines of various sizes, the smallest outermost; the finger reaching just to the extremity of the palm, with a little constriction of the outer margin at the base of the nail; the dorsal cilium short.

Second Gnathopods.—Side-plates a little longer and broader than those of the preceding segment, otherwise similar. The branchial vesicles a long oval, longer than the first joint of the limb; the marsupial plates in the female specimen figured were short, oval, smooth-rimmed. The joints of the limb scarcely differ from those of the first pair, the first joint longer, and descending further below the side-plate, the hand considerably longer in the male, and a little longer in the female, than the wrist; armature practically identical.

First Peræopods.—Side-plates similar to the preceding pair. Branchial vesicles expanding from a narrow neck so as to be widest distally, as long as the first joint, and almost as wide as long. First joint extending a little below the side-plate, second joint very short, third longer than fourth or fifth, with some setæ on the hind margin and apex of front; fourth a little longer and much broader than fifth, with setæ on both margins; fifth not broad and not tapering, with setæ on both margins, those on the straight hind margin short; the finger very short, with short cilia near the hinge and near the nail; the nail with a pointed projecting cap.

Second Peræopods.—Side-plates not much longer but very much broader than the preceding pair, the excavation behind descending a very small distance. The first joint not reaching the end of the side-plate, the limb in other respects scarcely differing from the preceding pair.

Third Peræopods.—Side-plates broad but not deep, the hind lobe less broad than the front, of about the same depth, crenulate and ciliated round the lower part of its hind margin. The first joint large, oblong, oval, rather broader below than above, with small setæ in the crenulation of the hind rim, and longer setæ on the front margin; second joint very small; third of great size, nearly as long as the first joint, much broader than the fourth, somewhat decurrent, with setæ, some of which are spiniform, along both margins; the fourth joint longer and much broader than the fifth, with setæ on both margins; the fifth not so long as the straight, slender finger, with setæ on both margins, and at the front apex close to the hinge of the finger a group of spines, two short and stout, and a third half the length of the finger, of great strength; the finger tapering, minutely pectinate in front, the nail spine-like, with a cilium at its base, and sheltered by a long cap, the peak of which projects beyond it.

Fourth Peræopods.—The hind lobe of the side-plates produced much below the front one. The first joint more rounded than in the preceding pair, rather broader, but rather shorter, especially behind; the other joints similar but longer, the third and fourth also wider, the third more strongly armed with spines.

Fifth Peræopods.—Side-plates small, not bilobed. Branchial vesicles small, ovate, a little larger than the side-plates. First joint broader and behind much longer than that of the preceding pair; the third joint large, broad, and strongly spined; fourth joint longer than in the preceding pairs, with spines as well as setæ on the front margin; the fifth joint equal in length to the finger, the dorsal cilium of which in this, as in the two preceding pairs, is very small.

Pleopods.—Groups of setæ on the peduncles, two hooked spines both apically sharp, one with three, the other with two retroverted teeth, the opposite margins with backward serrature; the rami with fourteen joints to the inner, sixteen to the outer; the first joint of the inner with three cleft spines at the upper part, some plumose setæ below, and groups of setæ on the opposite margin.

Uropods.—Peduncles of the first pair longer than the rami; the rami subequal, each with three spines on the margin, and at some distance from these a large terminal one at the apex, surrounded by three shorter ones; the peduncles of the second pair shorter than one ramus, longer than the other; this pair is shorter but stouter than the preceding, very similar in armature, but the longer ramus has four marginal spines; the peduncles of the third pair much shorter than the rami, which are lanceolate, subequal, with spines on both edges, and some on the surface, some of the spines being in pairs.

Telson as long as one and a half the breadth at the base, extending beyond the peduncles of the third uropods, cleft for three-quarters of its length, only dehiscent near the end, the two halves apically pointed; pairs of unequal spines at three points on the surface of each half, seemingly not quite symmetrically placed, also a couple of cilia midway down between the upper and next pair of spines.

Length.—The length of the female specimen in the position figured, from the front of the head to the back of the third pleon-segment, was three-tenths of an inch.

Locality.—Kerguelen, January 14, 1874; at the surface. Several specimens.

Remark.—The specific name refers to the place of capture.

Family PLEUSTIDÆ.

For the characteristics of the subfamily Pleustinæ, in which Buchholz places the genera *Pleustes* and *Parapleustes*, see Note on Buchholz, 1873 (p. 424); in changing the subfamily into a family I propose to omit from the definition the statement that the mandibles have no molar tubercle.

Genus *Pleustes*, Spence Bate, 1858.

- 1858. *Pleustes*, Spence Bate, Ann. and Mag. Nat. Hist., ser. 3, vol. i. p. 362.
- 1859. *Paramphithoë* (*pars*), Bruzelius, Skand. Amph. Gamm., p. 68.
- 1860. " Boeck, Forh. ved de Skand. Naturf. 8de Møde, p. 662.
- 1862. *Pleustes*, Spence Bate, Brit. Mus. Catal. Amph. Crust., p. 61.
- 1865. *Paramphithoë* (*pars*), Goës, Crust. amph. maris Spetsb., p. 7.
- 1866. *Pleustes*, Lilljeborg, On the Lysianassa magellanica, p. 18.
- 1870. *Paramphithoë*, Boeck, Crust. Amph. bor. et arct., p. 95.
- 1874. *Pleustes*, Buchholz, Die zweite Deutsche Nordpolarfahrt.
- 1876. " Boeck, De Skand. og Arkt. Amph., pp. 299, 496.
- 1884. " Schneider, Crust. og Pycn. Kvænangsfjorden, p. 97.
- 1886. " Gerstaecker, Bronn's Klassen und Ordnungen, Bd. v. Abth. ii. p. 503.

Sars, who in 1876 named a species *Pleustes euacanthus*, in 1885 re-named this species *Paramphithoë euacantha*, and takes occasion to remark that he considers that the genus

Paramphithoë should be classed among the Epimeridæ, and that he has "seen fit to retain Spence Bate's genus *Pleustes* for *P. panopla*, Kröyer, and the species nearest related to that form." He does not, however, say whether he places *Pleustes* also in the family Epimeridæ. For the original definition of the genus, see Note on Spence Bate, 1858 (p. 308). Boeck gives the following more expanded description:—

"Upper Lip deeply cleft.

"Mandibles unlike one another; one with, the other without, an accessory plate; the third joint of the palp almost equalling the second in length.

"First Maxillæ having the outer plate furnished with slender spines, some of them serrate on the inner margin, some apically furcate; the palp apically furnished with spines; the inner plate small, with few setæ.

"Maxillipeds with the inner plate short but broad; the outer plate small, with slender spines on the inner margin; the palp elongate, its last joint forming a long nail, serrate on the inner margin.

"Upper Antennæ longer than the lower.

"First four pairs of side-plates large or of moderate length and successively larger.

"Head produced into a frontal rostrum, which is generally strong.

"First and Second Gnathopods more or less robust, of nearly the same shape; the wrist short, sending out a small heel from the lower hinder angle.

"Uropods with the outer ramus shorter than the inner.

"Telson small, undivided."

To this he appends the remark in brackets, that "the genus *Pleustes* can scarcely be included in the Oedicerinæ." Accordingly, at p. 496 of the work just quoted, he places the genus *Pleustes* among the Leucothoinæ, the sixth subfamily of the Leucothoidæ, without, however, noticing that his definition of this subfamily disagrees in some respects with his generic definition of *Pleustes*. Thus, in describing the side-plates of the Leucothoinæ, he says, "1mo majore qvam 2do et 3tio," of the uropods he says, "ramis ultimi paris longitudine fere æqualibus," and of the telson, "appendix caudalis elongata."

The new species here assigned to the genus differs from Boeck's generic account in having a secondary plate on each mandible, and in having the third joint of the mandibular palp longer than the second, in that particular, however, agreeing with Boeck's own, as well as Schneider's, specific account of *Pleustes panoplus*, Kröyer.

Pleustes panopla, Krøyer (sp.).

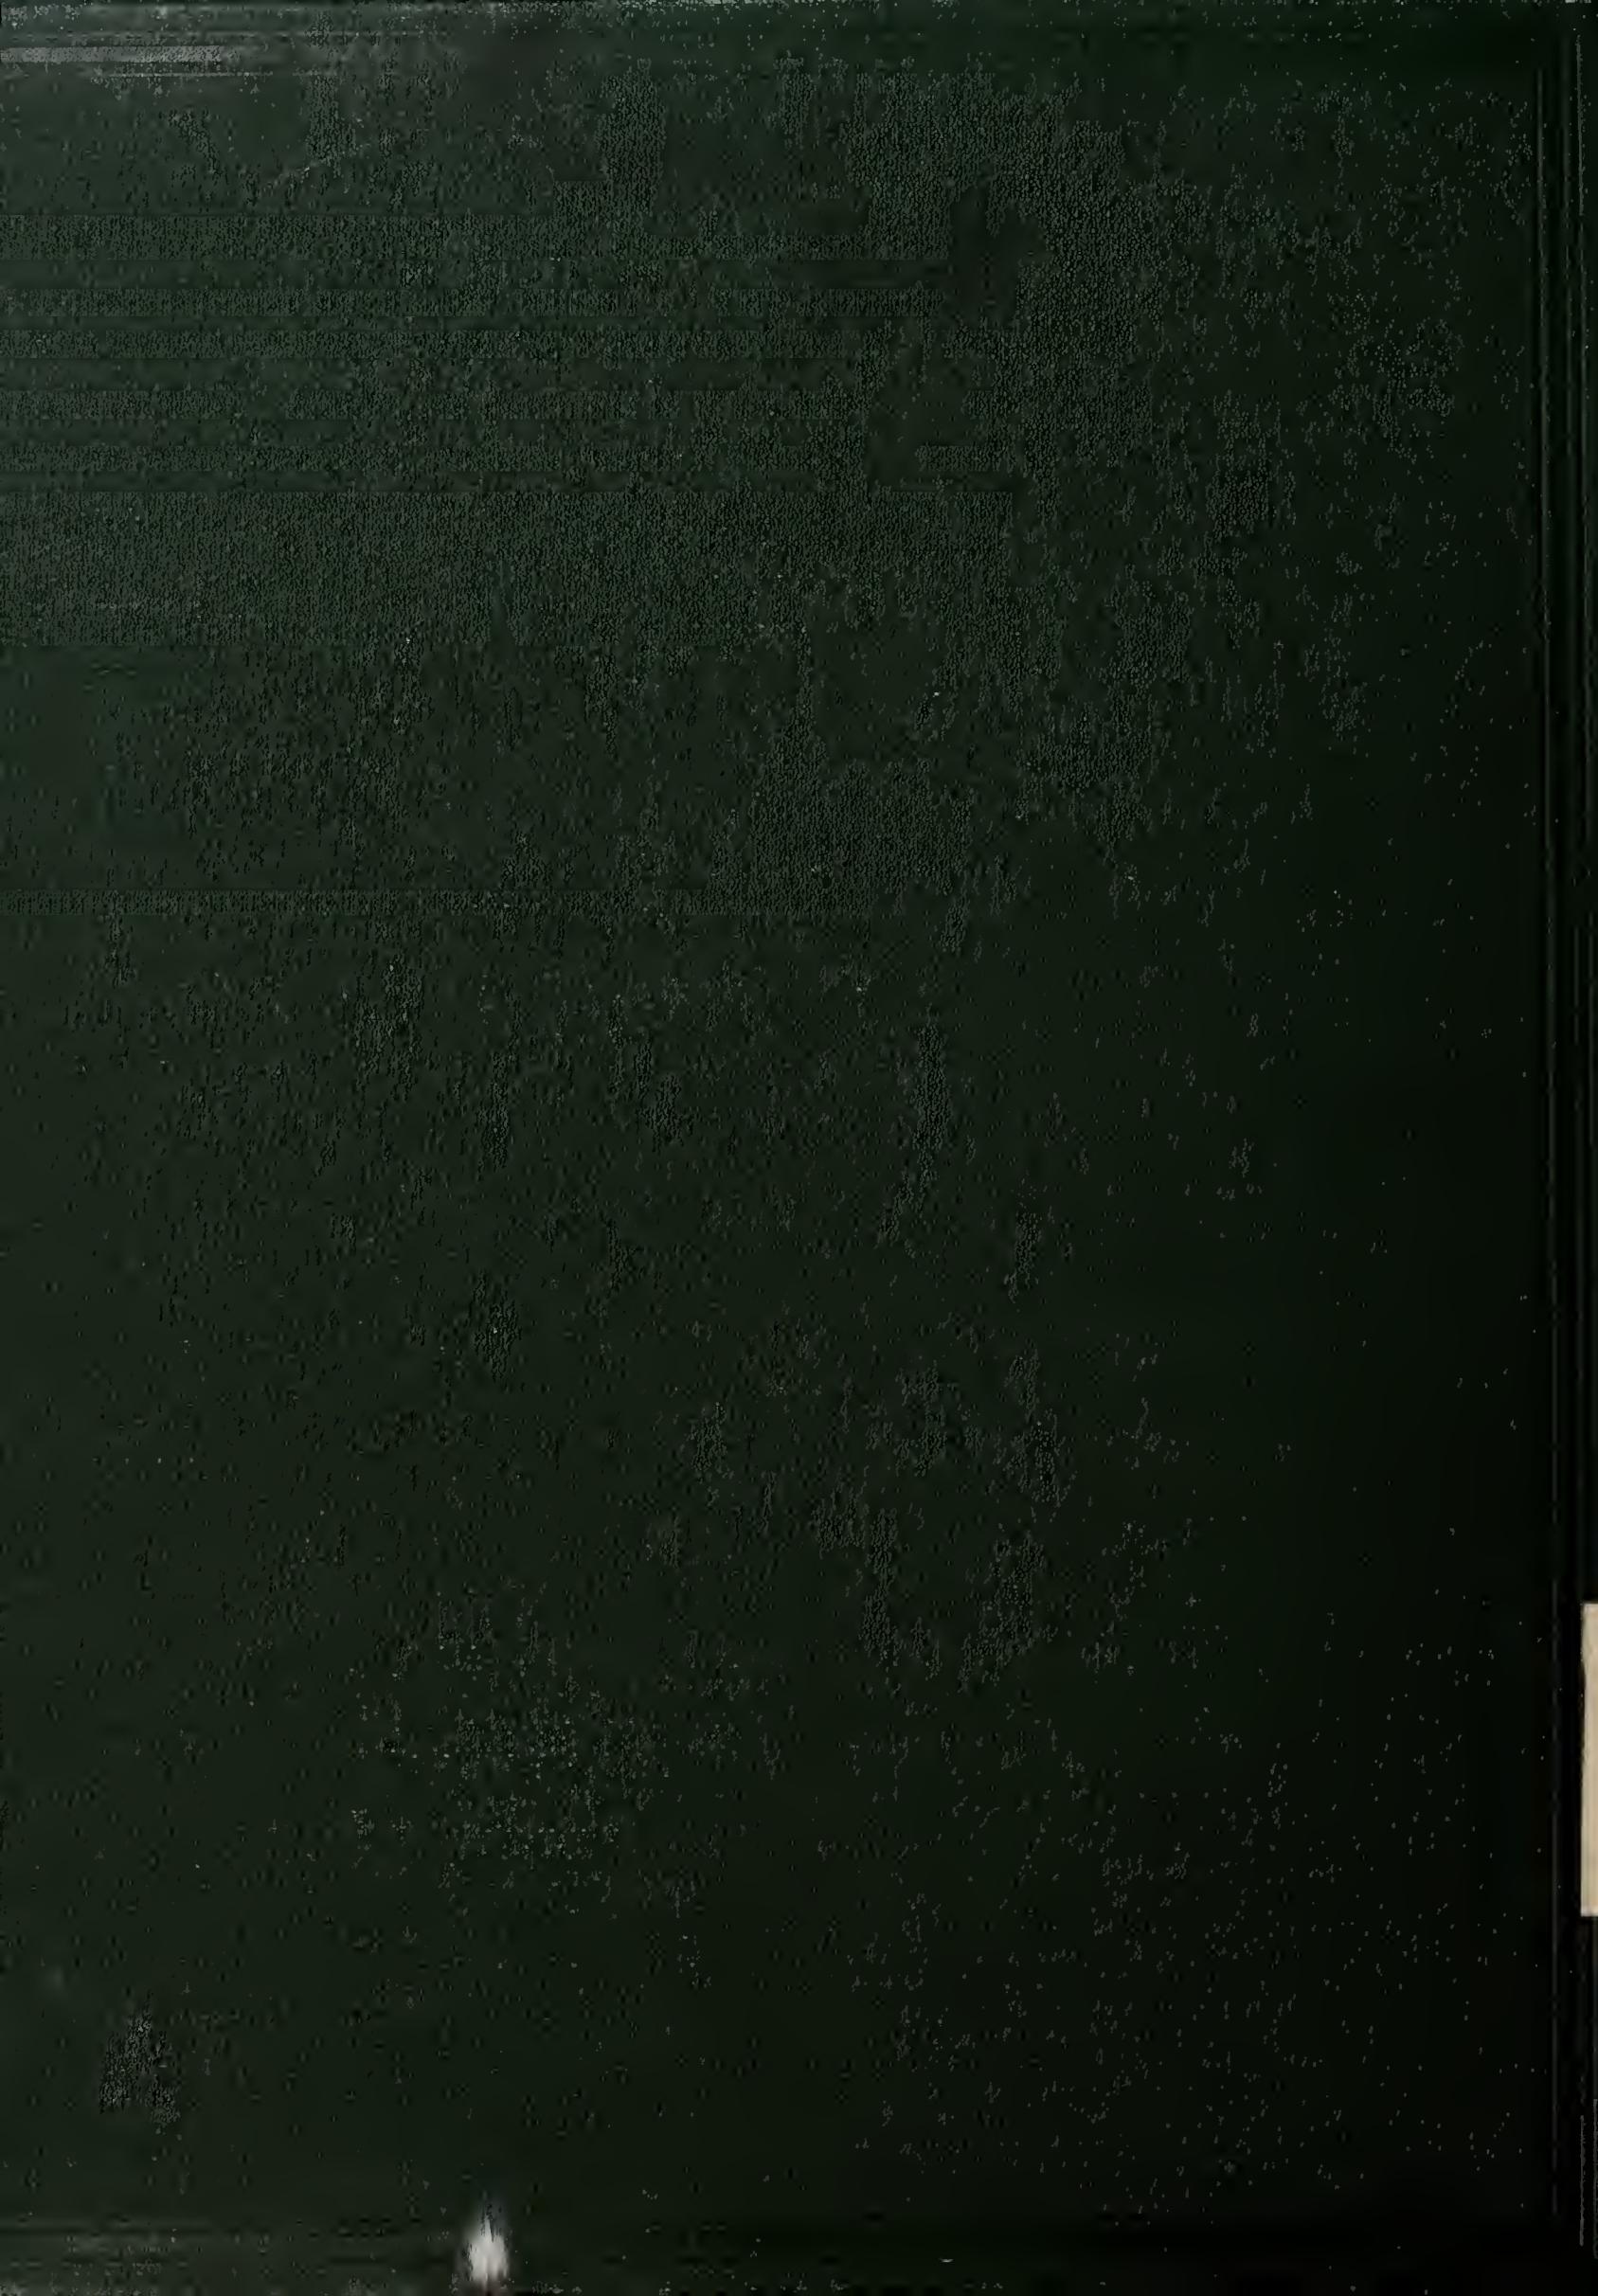

1883. *Amphithoë panopla*, Krøyer, Grönlands Amphipoder, p. 270, tab. ii. fig. 9.
 1840. " " Milne-Edwards, Hist. des Crust., vol. iii. p. 41.
 1846. " " Krøyer, Voy. eu Scand., pl. xi. fig. 2, *a-x*.
 1858. *Pleustes tuberculatus*, Sp. Bate, Ann. and Mag. Nat. Hist., ser. 3, vol. i. p. 362.
 1859. *Amphithoë panopla?* (*panoploides*), M. Sars, Oversigt norsk-arct. Krebsdyr.
 1859. *Paramphithoë panopla*, Bruzelius, Skand. Amph. Gamm., p. 69.
 1862. *Pleustes tuberculatus*, Sp. Bate, Brit. Mus. Catal. Amph. Crust., p. 62, pl. ix. fig. 8.
 1862. " *panoplus*, Sp. Bate, Brit. Mus. Catal. Amph. Crust., p. 63, pl. ix. fig. 9.
 1865. *Paramphithoë panopla*, Goës, Crust. amph. maris Spetsb., p. 7.
 1870. " " Boeck, Crust. amph. bor. et arct., p. 96.
 1874. *Pleustes panoplus*, Buchholz, Die zweite deutsche Nordpolarfahrt, Bd. ii. p. 334, Taf. vi.
 1876. " " Boeck, De Skand. og Arkt. Amph., p. 302, pl. xxi. fig. 2.
 1882. " " Hoek, Die Crust. der Fahrten des "Willem Barents," p. 52.
 1884. " " Schneider, Crust. og Pycn. Kvænangsfjorden, p. 97.
 1885. *Pleustes panopla*, G. O. Sars, Den norske Nordhavs-Exp., p. 168.
 1886. *Pleustes panoplus*, Koelbel, Crust. Pycn. und Arachn. von Jan Mayen, p. 7.

Locality.—Station 49, south of Halifax, Nova Scotia, May 20, 1873; lat. $43^{\circ} 3'$ N., long. $63^{\circ} 39'$ W.; depth, 85 fathoms; bottom, gravel, stones; bottom temperature, 35° . One specimen. Dredged.

Remark.—It may be noticed that in this specimen the rostrum is proportionally longer than in the figures of the species given by Krøyer, Boeck, and Sp. Bate. J. S. Schneider observes that Boeck in his figure of the maxillipeds makes the first joint of the palp too long, and produces the outer plate to the middle of the palp's second joint, whereas in reality it only reaches the base. The Challenger specimen agrees very well with Krøyer's figures, but it seems scarcely possible that the figure of *Pleustes tuberculatus* in the British Museum Catalogue can represent the same species. Boeck, in speaking of the tuberculated form for which Professor M. Sars suggested the name *panoploides*, declares that the apparent difference between the Norwegian and Greenland specimens rests only on an oversight of Krøyer's. The matter seems to need some further investigation.

Pleustes abyssorum, n. sp. (Pl. LXVII.).

Rostrum long and narrow, carinate underneath, and channelled on either side of the carina, projecting over the first joint of the upper antennæ almost to its distal end, lateral lobes of the head very small, acute; all the segments of the peræon and pleon carinate, except the fourth of the pleon; the back has an imbricated appearance, the hind margin of the second segment of the pleon in especial being dorsally raised above the next segment; the third segment of the pleon has a dorsal dentiform process erect near the distal end; the fourth segment has a dorsal depression; the postero-lateral angle of the third is produced in a small point; in the two preceding segments this angle is not produced.

REPORT

ON THE

SCIENTIFIC RESULTS

OF THE

VOYAGE OF H.M.S. CHALLENGER

DURING THE YEARS 1873-76

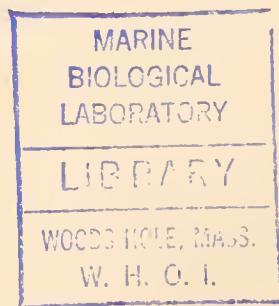

UNDER THE COMMAND OF
CAPTAIN GEORGE S. NARES, R.N., F.R.S.
AND THE LATE
CAPTAIN FRANK TOURLE THOMSON, R.N.

PREPARED UNDER THE SUPERINTENDENCE OF
THE LATE
Sir C. WYVILLE THOMSON, Knt., F.R.S., &c.
REGIUS PROFESSOR OF NATURAL HISTORY IN THE UNIVERSITY OF EDINBURGH
DIRECTOR OF THE CIVILIAN SCIENTIFIC STAFF ON BOARD
AND NOW OF
JOHN MURRAY, LL.D., Ph.D., &c.
ONE OF THE NATURALISTS OF THE EXPEDITION

ZOOLOGY—VOL. XXIX.

C O N T E N T S.

REPORT on the AMPHIPODA collected by H.M.S. CHALLENGER during the years 1873-1876.

By Rev. THOMAS R. R. STEBBING, M.A.

SECOND HALF.

EDITORIAL NOTE.

THE collections of AMPHIPODA procured in the trawls, dredges, and tow-nets during the voyage of H.M.S. Challenger were placed in the hands of the Rev. Thomas R. R. Stebbing for examination and description in the summer of 1882. From not long after that date up to the present time Mr. Stebbing has been almost exclusively occupied in the work connected with the preparation of this extensive and valuable Report, which will be welcomed by all students of the Crustacea.

There is the same uncertainty connected with the Amphipoda as with several other groups of animals taken in the trawls and tow-nets, as to the depths at which the specimens were captured. Some were undoubtedly taken at or near the bottom, while others were as certainly taken in the surface and subsurface waters, but with others again there is a great deal of doubt. Although a record of the depths to which the nets were let down was attached to the specimens, the naturalists of the Expedition did not intend to convey the impression that the specimens necessarily came from the depths indicated.

This Report, which forms Part LXVII. and Volume XXIX. of the Zoological Series of Reports, consists of 1774 pages of letterpress, with 212 Plates and a Map. The whole is bound up in three separate portions, two of letterpress and one of Plates.

The first Instalment of the Manuscript was received by me on the 5th December 1885, and the last on the 30th November 1888.

JOHN MURRAY.

CHALLENGER OFFICE, 32 QUEEN STREET,
EDINBURGH, *December 5, 1888.*

Eyes small, oval, situated near the lateral lobes of the head.

Upper Antennæ.—First joint of the peduncle much thicker, but not much longer than the second, twice as long as broad; third joint scarcely more than half the length of the second; flagellum of forty-four or more joints, of which the first is longest, the first six carry short cylinders, and of the rest each alternate joint; the joints of the peduncle have a few short cilia or setules, and have their distal margins more or less lobed; the third has also on the inner side a minute representative of a secondary flagellum, rounded, armed with a single cilium.

Lower Antennæ thinner and much shorter than the upper. Peduncle shorter than the peduncle of the upper antennæ. The first joint not greatly expanded, the second produced on one side all along the third, which it partially clasps, the opening of the (not conical) gland-cone being on the inside at the distal angle of the clasping part; the third joint short, its distal margin irregular, armed with small spines that show each an accessory thread; the fourth joint equal in length to the preceding three united, with groups of spines on its surface and at the apex; the fifth joint a little longer than the fourth, with groups of spines or short setæ on the surface and at the apex; the flagellum of twenty-four joints, of which the first is the longest; these joints are distally furnished with groups of setules.

Upper Lip having the outer plate apically divided by a small oblique emargination into two unequal lobes.

Mandibles.—The cutting plate rather small, its edge divided into six or seven consecutive teeth; the secondary plate on the left mandible nearly as large as the principal, divided similarly into six teeth; this plate on the right mandible is slighter, divided into two teeth, one of which, having the appearance of being broken or much worn, is approached by the serrate outer edge of the plate; the spine row of thirteen slender, backward curving, spinuliferous spines, the row filling up the small space between the cutting plates and the prominent molar tubercle; crown of the molar tubercle oval, dentate, and ciliated; the articulating process blunt, close to the base of the palp which is just over the molar tubercle; the first joint of the palp carrying one or two spines, the second joint having several along the front margin and surface adjoining it, its hind margin a little concave; the third joint subequal in length to the first and second united, its outer border convex, its outer surface covered with adpressed cilia, its inner margin for almost the whole extent fringed with pectinate spines, of which there are on the apex two very long followed by two shorter.

Lower Lip.—The principal lobes very broad and thick, much ciliated apically; the mandibular processes very short.

First Maxillæ.—Inner plate squarish oval, with four plumose setæ on the apex, alternately long and short; the outer plate much broader than the inner, with ten spines on the truncate distal margin, the one row slender and denticulate, the

other rather shorter and stouter, and with a single lateral denticle or none; the palp, which is densely ciliated on the surface, has on the distal border of the long and much curved second joint seven or eight spine-teeth, that at the outer angle longer than the rest; there are also setæ on the surface near the distal margin.

Second Maxillæ.—Both plates a little curved, much ciliated, with spines round the apical margins, and descending a little way down the inner margins, at the distal part of which the shorter inner plate has two large plumose setæ.

Maxillipeds.—The inner plates, which do not reach to the middle of the first joint of the palp, on the inner margins have several plumose setæ, which pass over towards, but not to, the outer apex; the distal margin sloping outwards, carries on the truncate inner angle three small teeth set close together, the central the longest, beyond which the margin has two short and two longer incurving plumose spines; the outer plates reach just beyond the first joint of the palp; the inner margins smooth, except for a microscopic crenulation, at the apex forming an angle, behind which the distal margin rises a little, and is set with a close row of six short curved spines; there are a few setiform spines on the outer surface at some little distance from the inner margin; both the inner and outer plates are strongly ciliated; the first joint of the palp is as long as the second, its inner margin not so long as the outer, but longer than usual and fringed with spines as in the two following joints; the second joint a little longer than the third; the third equal in length to the sharply pointed finger; the spines on the palp are spined on two edges, coarsely at the centre, finely towards the apex; the finger has a couple of cilia at the base of the sharp slender nail.

First Gnathopods.—Side-plates bent forwards to a rounded point, front border concave, hinder and lower continuous, to a certain extent serrate; some spines on the upper part of the hinder margin and on the inner surface; the first joint widening distally, with groups of spines at the apex and on the surfaces, chiefly on the inner surface near the concave front margin; the second joint short; the third oblong, with groups of pectinate spines on the serrate hind margin, and along and near the distal margin; the wrist triangular, distally broad and cup-like, the length and breadth nearly equal, armed like the preceding joint; the hand irregularly oval, longer than the two preceding joints united, as broad as the wrist, the front margin smooth and little curved, the hind margin at first smooth, then crenulate, and finally showing two broad emarginations, the inner surface carrying numerous groups of spines, the outer a few; the palm not specially defined; the finger closing down not quite to the end of the indentured part of the hind margin, which is set with groups of slender spines, stout spines and setules, of the groups including the stout spines with accessory threads there being two on the outer and four on the inner side, between which the apical part of the finger closes.

Second Gnathopods.—The side-plates similar to the preceding, but longer and less

bent; the limb also similar, but in all parts larger, the chief difference of shape being in the hand, which has a well-defined palm, the border of which turns at first almost at right angles to the spine-beset hind margin, then forming a great cavity by its junction with a large triangular process which projects just below the hinge of the finger; over the end of the triangular process and the outer part of the cavity the broad finger bends, resting its tip among spines on the inner surface above the commencement of the palm; some strong spines are set near the commencement of the palm, while the cavity and the process above mentioned are fringed with setules.

First Peraopods.—Side-plates longer and less pointed than in the preceding pair
The limb similar to the following pair.

Second Peraopods.—The side-plates longer than in the preceding pair; the surface vertically ridged or raised in this as in the two preceding pairs; the front margin straight, the hinder excavate just at the top, then sloping forwards to the narrow lower margin. The branchial vesicles broadly oval, shorter than the first joint of the limb. The first joint not reaching the end of the side-plate, its front margin fringed with setiform spines of various lengths; the second joint comparatively long; the third much longer than the fourth, with spines at two points of the hind margin and at the apex, which has a little lobe, spines at two or three points of the front margin and at its long, acute, decurrent apex. The fourth joint like the third widening distally, shorter than the fifth, with three groups of spines on the serrate hind margin and a large group round its apex, the front margin free, its apex pointed; the fifth joint shorter than the third, somewhat curved, almost parallel-sided, with spines at five points of the hind margin, some spinules on the front; the finger curved, considerably shorter than the fifth joint; dorsal cilium short, near the hinge; two or three more cilia on the hind margin and at the base of the nail.

Third Peraopods.—The side-plates broader than the preceding pair, strongly bilobed, the hind lobe narrower, but considerably deeper than the front one, distally pointed. The branchial vesicles much as in the preceding pair; the whole series is very uniform in shape, graduated in size, so that the central pairs are the largest; none are very large, all inflated, and more persistent than usual; whether the last peraeopods had any I did not perceive. First joint of the limb oblong, broader below than above, the lower hinder lobe overlapping the second joint; the front margin with spines at a few points, the hind margin almost smooth, sinuous, but all the central part concave; the upper surface is longitudinally ridged; the second joint has spines at two points in front; the remaining joints are like those of the preceding peraeopods in shape and armature, but are thicker and stronger, the fifth and sixth joints also a little longer; the third has spines at five points in front, the fifth at six points, and the finger six cilia on the outer margin.

Fourth Peraopods.—The side-plates with an inconspicuous lobe in front, the hind

lobe similar to that of the preceding pair, but smaller. The limb closely resembling that of the third peræopods; the front margin of the first joint more strongly spined; that of the third joint with spines at four points only, this margin being shorter than in the preceding pair.

Fifth Peræopods.—The side-plates small. The first joint and the third larger than in the preceding pairs; the limb in general similar.

Pleopods.—The coupling spines small and slender, apparently with three small hooks near the apex, and two long ones on the side lower down; the cleft spines on the first joint of the inner ramus numbering eight in the first pair, the margin above them strongly ciliated, the outer arm of the cleft much longer than the inner; the joints of the rami numbering from twenty to twenty-three.

Uropods.—Peduncles of the first pair a little longer than the rami; the outer ramus rather shorter than the inner; peduncles of the second pair longer than the outer, but rather shorter than the inner, ramus; peduncles of the third pair scarcely so long as the short outer ramus, much shorter than the inner; the rami less broad than in the two other pairs; many small spines on the edges of all the rami, and of the peduncles of the first two pairs, which have also spines at the apices of the rami; the peduncles of these two pairs reach equally far back, the inner ramus of the second as far as the outer of the first, or a little further; the peduncles of the third less far than the other two, the inner ramus about as far as the outer of the second pair.

Telson short, little longer than its breadth, not reaching the end of the peduncles of the third uropods, narrowing distally to a very small extent, carrying some few cilia at points on the surface.

Length.—The specimen, in the position figured, from the point of the rostrum to the dorsal apex of the second pleon-segment, measured eleven-twentieths of an inch.

Locality.—Station 147, near Marion Island, December 30, 1873; lat. $46^{\circ} 16' S.$, long. $48^{\circ} 27' E.$; depth, 1600 fathoms; bottom, Diatom ooze; bottom temperature, $34^{\circ} 2$. One specimen.

Remark.—The specific name refers to the great depth from which the specimen was brought up.

Family EPIMERIDÆ, G. O. Sars, 1882.

In 1870 Boeck established the Epimerinæ as twelfth subfamily of the Gammaridæ, between the Iphimedinae and Dexamininae; in his latest work he retains the subfamily unaltered, but places it fifth, immediately after the Oedicerinæ in the list on page 74, while in the body of the work he places it fourth, preceding the Oedicerinæ. He assigns to it only two genera, *Acanthozone* and *Epimeria*. In 1882 Sars named a family Epimeridæ, including in it the genera *Epimeria*, *Iphimedia*, *Vertumnus*, *Odius*,

Laphystius, *Acanthozone*, thus interposing between the two genera of Boeck's Epimerinæ the four genera which Boeck assigns to the subfamily Iphimedinae, but this union of the two groups scarcely seems admissible in view of the marked distinction exhibited by the mouth-organs respectively of the one and the other. Boeck gives the following definition of the Epimerinæ :—

“ *Upper Lip* very broad, apically little insinuate.

“ *Mandibles* very strong, apically broad and dentate ; the secondary plate robust and dentate ; the spines of the spine-row numerous, broad, lanceolate, and serrate on the convex margin.

“ *First Maxillæ* strong ; the palp two-jointed, its second joint apically armed with few teeth ; the inner plate furnished with many setæ on the inner margin.

“ *Second Maxillæ* broad.

“ *Maxillipeds* with the outer plates broad and dentate ; the palp elongate, robust, its last joint unguiform.

“ The body very thick, robust, carinate and dentate (*spinis armatum*). The side-plates large, rigid. The eyes prominent.

“ *Antennæ* with long flagella ; the *Upper Antennæ* without accessory flagellum.

“ *First and Second Gnathopods* slender ; the rest of the legs strong.

“ *Uropods* biramous ; the second pair shorter than the first, with the inner ramus a little longer than the outer ; the third pair with the rami equal in length.

“ *Telson* rigid, of moderate size, apically a little incised.”

For the original definition, see Note on Costa, 1851 (p. 250). Boeck defines it thus :—

“ Segments of the trunk carinate.

“ Four anterior pairs of side-plates very long, narrow, towards the apex acuminate, rigid ; the fourth and fifth pairs prominent.

"The frontal rostrum very large and curved between the antennæ.

"In the *Third, Fourth and Fifth Peraopods* (and especially in the *Third and Fourth*) the first joint only a little dilated.

"*Third Uropods* with very narrow rami."

The Rostrum projecting almost to the end of the third joint of the upper antennæ, long, acute, apically depressed, laterally and inferiorly carinate, longer than the part of the head to the rear of it; there is a minute angular projection of the sides of the head between the upper and lower antennæ, and the lower front angle of the head is acute. A central earina traverses the back from the first segment of the peræon, on which it is slight and blunt, to the fourth segment of the pleon, attaining its greatest development on the first three pleon-segments; it is constituted by backward-directed processes almost nose-like in profile, all but the first three or four being sharp-edged and very prominent; on the third and fourth segments of the pleon, and to a slight extent on the second, there is shown a tendency to develop an anterior process; on either side a lateral carina is formed by an oblique ridge on each segment running downwards and backwards, the peræon-segments (of which the fourth and fifth are the broadest) showing several small tubercles below the ridges, the first two segments of the pleon showing two, the third three prominent tubercles behind close to the hind margin, and another lower down, while on the fourth pleon-segment there is a single lateral tubercle and an arched ridge below it; the first three pleon-segments have the postero-lateral angles produced into a short sharp point, which in the second and third is slightly upturned; in the second segment the antero-lateral angle also forms a backward-directed tooth.

Eyes prominent, hemispherical, adjoining the lateral tooth on each side of the head. They are, according to Sars, "a rich vermillion in colour."

Upper Antennæ.—Peduncle short, first joint longer than the second and third united, not twice as long as broad, with a group of spines at the lower distal angle; the second joint a little longer than wide, with groups of spines at the middle and

¹ The references to the American Journal of Science are borrowed from Professor Smith's paper.

apex of the lower margin, third joint shorter and narrower, with long slender spines at the lower apex; flagellum of more than twenty-eight joints, the first longer than the third joint of the peduncle and equal to the four following joints of the flagellum, with five groups of setules on the under side; the secondary flagellum of one short narrow joint, almost rudimentary, as in *Epimeria cornigera* of Fabricius. Sars, on the other hand, says, "secondary flagellum entirely wanting."

Lower Antennæ.—The peduncles and flagella longer than those of the upper antennæ; first three joints short, distally emarginate, the gland-cone long and narrow; the third joint with slender spines at the lower apex; the fourth joint equal in length to the preceding three united, with spines on the lower margin; the fifth shorter than the fourth; there are short hairs or spinules on various parts of the peduncle; the flagellum of fifty joints, or more, the first equal in length to four or five that come next, the terminal joints slender, longer than the earlier except the first.

Upper Lip broad and deep; apical margin narrowed, in the slightest degree emarginate and minutely furred.

Mandibles.—The cutting plate narrow, slightly clasping the secondary plate, its long edge divided into about nine teeth, of which the last four or five are prominent; the secondary plate on the left mandible with the oblique edge divided into five teeth, of which the lowest is the most produced; on the right mandible this plate is slighter, has a much narrower distal edge, divided into one long tooth and three minute denticles; spine-row of some fifteen denticulate spines with some that are shorter and smooth, or setiform and ciliated; molar tubercle long, prominent, with a ciliated ridge along the inner surface, the dentate crown very small; there is a process on the inner surface between the molar tubercle and the palp, which is set just over it; the second joint of the palp scarcely so long as the third, carrying several long slender spines mixed with some that are shorter along the inner margin, beginning below the centre; the third joint a little curved, with the inner margin less so than the outer, fringed along the inner margin with numerous spines of different lengths, three of those at the apex being strongly peetinate.

Lower Lip.—The principal lobes widely dehiscent, each carrying at the apex a short but dense row of blunt-headed cilia, the margins ciliated, a long dense row of cilia on the surface within the inner margin; the mandibular processes short, divergent.

First Maxillæ.—Inner plate short and broad, with nine plumose setæ on the oblique distal margin; the outer plate broad, with eleven variously dentate spines on the obliquely truncate distal margin, the inner part of which is ciliated; the long curved second joint of the palp reaches beyond the outer plate, and on its irregularly toothed distal margin carries four spine-teeth, the outermost the longest, with four or five seta-like spines on the surface within the distal margin.

Second Maxillæ.—Both plates broad, the inner shorter and rather broader than the

outer, its broad oblique distal margin crowded with pectinate spines and having four or five plumose setæ along the lower inner part; there are a few small spines at the distal part of the outer margin; the distal margin of the outer plate carries fifteen long distally pectinate spines, besides several smaller ones, a few of which also are found on the outer margin.

Maxillipeds.—The inner prismatic plates not reaching so far as the distal end of the first joint of the palp, with very numerous setæ on the inner margin, three small spine-teeth and several incurving spines on the distal margin; the outer plates large and broad, but not reaching the distal end of the second joint of the palp; the inner margin almost smooth, with a few seta-like spines on the surface near them; the rounded distal border separated from the inner margin by the apical angle of the latter, set round with eight spine-teeth and four setæ, graduating as usual from the one to the other; first joint of the palp not much shorter than the second, the second much longer than the third; the finger short, its inner margin armed with six teeth; the nail sharp.

First Gnathopods.—Side-plates narrow, triangular, extending a little below the lower angle of the head, channelled at the back, the apex of the hind margin forming the point of the triangle. The first joint reaching beyond the side-plate, bent at the upper part, both margins carrying numerous long setæ, the front margin, much of which is straight, having also many spines, the third joint longer than the second, both with spines at the apex; the wrist subequal in length to the hand, twice as long as broad, with four large groups of spines on the hinder margin, and one at the apex of the front; the hand oblong, a little broader at the palm than at the base, with short spines at the apex in front, a group about one-third of the hand's length from that apex, several on the inner surface and hind margin; the serrate palm is connected by a gentle curve with the hind margin, which is here finely pectinate, some rather stronger spines being inserted on the surface near; the finger strong, much curved at the slender nail, reaching beyond the palm border, and having its inner edge armed with twelve teeth, or rather spines, since they appear to be inserted in the margin, not to be part of it.

Second Gnathopods.—Side-plates rather longer than the preceding pair, and a little more squared below. The limb like the preceding, but the joints, especially the hand, a little longer; many of the spines in both gnathopods pectinate on two edges.

First Peraopods.—Side-plates similar to the preceding pair, but longer and broader, the lower edges of the first three side-plates forming a continuous line. First joint of the limb reaching below the side-plate, carrying long setæ and short spines on the margins; second joint short, with spines at the apex before and behind, this and the remaining joints as in the following pair.

Second Peraopods.—Side-plates with the front margin long and sinuous, ending below in a sharp angle which points backwards, the hind margin excavate about a third of its length, then with a deep curve joining the front margin at its apex; the hinder

part of the plate is deeply channelled and below the excavation sends back a long process on the inner side, which interlocks it with the deep channelling of the front of the following segment. First joint of the limb not reaching below the side-plate; third joint rather longer than the fourth, with spines at four or five points behind, and spinules here and there on the front margin and surface; fourth joint subequal in length to the fifth, armed like the third; fifth joint with spines at seven points of the hind margin, the spines shorter than on the two preceding joints; the finger strong, much shorter than the fifth joint, nail sharp.

Third Peræopods.—The lower apex of the side-plate pointing downwards and backwards, the free front margin continuing the curve of the free hind margin of the preceding plate, the hind margin slightly toothed near the centre. The first joint reaching below the side-plate, a little wider above than below, channelled behind, distally lobed on both edges, the inner lobe crenulate, the front margin carrying several groups of spines and near the top some long setæ; the short second joint distally lobed on both edges behind, carrying some short spines in front; the remaining joints similar to those of the preceding pair, but longer and stronger. The integument of the limbs and apparently of the whole structure is covered with scale-markings.

Fourth Peræopods.—The side-plates short and thick, channelled below, on the outer surface a vertical ridge running down to a central apex. The first joint more expanded than in the preceding pair, the inner side developing a wing with convex hind margin, crenulate at the lower end; the following joints as in the preceding pair, except that the third, fourth, and fifth are longer.

Fifth Peræopods.—Side-plates small, not pointed. First joint of the limb pear-shaped, a little longer than that of the preceding peræopods and much more expanded behind, except at the distal lobe, which overlaps the short second joint; the remaining joints as in the two preceding pairs, but shorter than in either.

Pleopods.—Coupling spines very small, the base broader than the shaft, with six retroverted teeth (including the apical) along one side in succession; cleft spines eight or nine, with long arms to the left, the outer little longer than the inner; joints of the rami numbering from twenty-four to twenty-seven on the first pair.

Uropods.—The peduncles of the first pair a little shorter than the subequal rami, which reach as far as or beyond the second, but not so far as the third pair; peduncles of the second pair shorter than the rami, the outer ramus shorter than the inner; peduncles of the third pair short, the rami long, broadly lanceolate, subequal, closely overlapping. The marginal spines throughout are small.

Telson little longer than broad, reaching beyond the peduncles of the third uropods, distally with a triangular emargination, which with the incurving of the lateral margins forms on either side a triangular apex.

Length.—The length of the largest specimen, in a straight line from the tip of the (ZOOL. CHALL. EXP.—PART LXVII.—1887.)

rostrum to the extremity of the third uropods, was four-fifths of an inch. In Den norske Nordhavs-Expedition, p. 167, Sars says, "Length of the largest of the specimens collected about 40 mm., for an Amphipod a truly imposing size."

Locality.—Station 49, south of Halifax, Nova Scotia, May 20, 1873; lat. $43^{\circ} 3' N.$, long. $63^{\circ} 39' W.$; depth, 85 fathoms; bottom, gravel, stones; bottom temperature, 35° . Three specimens. Dredged.

Remarks.—This species I at first named *Epimeria conspicua*, though with some doubt as to its distinctness from the species *Epimeria loricata*, of which G. O. Sars had given a preliminary description. The further description and admirable figure since given by Sars of his species show clearly that *Epimeria conspicua* must rank as a synonym. Of this indeed I had earlier become aware, as upon my application to Mr. Sidney Irving Smith for specimens of *Epimeria loricata*, he with his accustomed kindness sent me specimens from lat. $38^{\circ} 37' 30'' N.$, long. $73^{\circ} 11' 0'' W.$, which agree too minutely with the Challenger specimen to admit any question of specific distinctness. Two of these specimens were considerably larger than the largest Challenger specimen, and retained, and still retain, traces of bright red colouring, of which the Challenger specimens show not a vestige. Sars says "Colour a gorgeous red," and again, "Colour a magnificent coral-red, a trifle more vivid on the posterior margin of each segment."

In Boeck's definition of *Epimeria*, the character "Pedes saltatorii ultimi paris ramis perangustis" is not appropriate to the present species.

Family IPHIMEDIDÆ.

In 1870 Boeck made the Iphimedinæ the eleventh subfamily of the Gammaridæ, placing in it the genera *Vertumnus*, *Iphimedia*, *Odius*, and *Laphystius*; in his later work he made it the seventh subfamily of the Leucothoidæ, with the same genera, but substituting the name *Acanthonotozoma* for the preoccupied *Vertumnus*, and in the table of errata reading *Lafystius* in place of *Laphystius*; in the body of the work the Iphimedinæ appear as the fifth subfamily of the Gammaridæ, but the editor explains (p. iv.) that this was due to a wrong arrangement of the manuscript, being contrary to the scheme of classification given on page 74. As already noted, Sars in 1882 placed the genera assigned by Boeck to the Iphimedinæ in the family Epimeridæ. The characters most open to observation certainly unite the two groups very closely, but on the other hand they are rather sharply distinguished by the mandibles and maxillipeds. I rely upon Boeck's definition of the Iphimedinæ as being almost equally applicable to the new family Iphimedidæ, which is new chiefly in the form of the name; the definition is as follows:—

“*Upper Lip* elongate, apically strongly insinuate.

“*Mandibles* elongate, often strong, apically produced, little or not at all dentate; secondary plate also produced and narrow, molar tubercle little, often obsolete; palp elongate, robust, three-jointed.

“*Lower Lip* with the inner plate small, situated near the apex.

“*First Maxillæ* more or less elongate; the palp sometimes long, two-jointed, sometimes almost obsolete, one-jointed.

“*Maxillipeds* with the inner plates long, narrow, furnished only with setæ; the outer plates tolerably large or of moderate size and little setose; the palp not very elongate, its last joint not unguiform; the two last joints of the palp sometimes absent.

“Body either compressed, thick, and furnished with large side-plates, or [sub-depressed] not depressed, and furnished with smaller side-plates.

“*Upper Antennæ* without accessory flagellum.

“*First and Second Gnathopods* sometimes slender and not subchelate, sometimes robust and subchelate.

“*First and Second Peræopods* strong.

“*The Fourth Peræopods* longer than the *Third* and the *Fifth* than the *Fourth*.

“*Uropods* biramous.

“*Telson* small, sometimes apically incised.”

It is obvious that the words “non depressum” applied to the body, although occurring in both of Boeck’s works, are due only to an accidental error, and must be corrected into “subdepressum,” the word actually given in the account of *Lafystius*, the only genus which can be in question. The description given of the *Upper Lip*, which probably induced Boeck to transfer the Iphimedinae from the Gammaridae to the Leucothoidae, is itself open to criticism, as inapplicable at any rate to some of the genera, and it should, therefore, in my opinion, be removed from the definition. To include the new genus *Acanthechinus*, I propose to make a slight change in the account of the maxillipeds, describing the last joint as “not always unguiform,” and in the account of the mandibles to say that the molar tubercle is “generally little.”

Genus *Acanthechinus*, n. gen.

General habit rigid, developing long pointed processes.

Mandibles having a long palp, with a process on the first joint, the third joint not shorter than the second; the spines of the spine-row differing greatly in size and shape; the molar tubercle very prominent.

First Maxillæ with the inner plate small, carrying three plumose setæ at the apex; the first joint of the palp not more than half the length of the second.

Outer plate of *Second Maxillæ* broader than the inner; the inner margins of the plates not fringed with spines or setæ.

Palp of the *Maxillipeds* slender, the first joint longer than the second, the fourth short, unguiform.

Both pairs of *Gnathopods*, but especially the second, of great length and tenuity, the wrist much longer than the elongate hand, the finger very small yet making the hand subchelate.

The Second Uropods intermediate in length between the first, which are longer, and the third.

The Telson undivided.

The generic name is derived from the Greek words *ἀκανθα*, a spine, and *ἐχῖνος*, a hedgehog or sea-urchin. The genus appears to come near both to Boeck's subfamily *Epimerinæ* and his subfamily *Iphimedinae*, disagreeing from his definition of the latter, however, in having the last joint of the maxilliped palp unguiform. From *Acanthonotozoma* of Boeck it differs in respect of the first maxillæ and the gnathopods, and in other points. With *Iphimedia* it is to a certain extent allied by the gnathopods, which nevertheless are to some extent unique. From Boeck's *Acanthozone*, with which I at first identified it, it is separated by the spine-row of the mandibles, the inner plate of the first maxillæ, the outer plate of the maxillipeds, in respect of the characters assigned to these parts in the definition of the subfamily *Epimerinæ*, while the gnathopods in the two genera are also very different.

Acanthechinus tricarinatus, Stebbing (Pls. LXIX., LXX.).

1883. *Acanthozone tricarinata*, Stebbing, Ann. and Mag. Nat. Hist., ser. 5, vol. xi. p. 205,

March 1883.

1885. " " " Stebbing, Narr. Chall. Exp., vol. i. part ii. p. 621.

Body cylindrical, except the after part of the pleon, which is a little depressed and strongly flexed.

Head very small, almost concealed, with a small rostral angle, and two small adjacent lateral lobes on either side; each segment of the peraeon armed with three large pointed processes, three-sided, with sharp, serrate edges, the central connected by a transverse ridge on each side with the lateral, all three rising on the hinder part of the segment; the central process on the first segment is bifurcate, the front arm pointing forwards, the hinder backwards, which is the direction assumed by those on the following segments; the length of the processes increases in each segment successively. The first segment of the pleon has a long central process, like that on the last segment of the peraeon, and on each side two tubercles, one below the other, at a little distance from the hind margin; the hind margin itself juts out a little before reaching the angle with

the lower margin ; the second segment is similar to the first, but deeper ; the third has a smaller central process with a tubercle or denticle below on each side, a little in front, while to the rear from the hinder margin rise three processes, or one that is tridentate, while beyond this on either side there is an upward-bent lateral process ; the fourth segment begins with a small hump and a depression, the latter being followed by a central process with serrate edges, and this by a second at the distal end of the dorsal line ; the fifth segment is short and unarmed ; the sixth, also short, carries a central, and on either side of it a lateral, process.

Eyes not observed.

Upper Antennæ.—The first joint of the peduncle distally dilated and produced in three long processes, one shorter than the other two ; the second joint subequal in length, distally produced in two long processes ; the third joint much shorter and more slender, not nearly reaching to the end of the processes of the preceding joint, with two small distal angles ; the flagellum broken, but at least of more than eight joints, the first very long, longer than either the first or second of the peduncle apart from their processes, equal to about four of the succeeding joints of the flagellum ; the other joints successively diminish in thickness, but not in length, each carrying a small distal spine in a group of setules ; the first joint has three such groups, and from the fifth to the eighth there is an additional group at the centre of the margin.

Lower Antennæ.—The composite first and second joints show two large processes, the upper with its upper margin serrate and carrying spines, the lower much smaller, both apparently forming part of the first joint, while the second is not prominent, with the gland-cone small and obscure ; the third joint has one rather long, and two short, distal processes ; the fourth joint, much longer than the third, has two long distal processes, the lower longer than the upper, and two small processes, one on either side between the larger ones ; the fifth joint is long and straight, with two small adjacent distal processes above and one below, and is nearly as long as the total length of the previous joint ; the flagellum, rather longer than the peduncle, consists of eleven, or possibly twelve joints, of which the first is very long and tapering, equal to the four following joints united, which with the rest successively decrease in thickness but not in length.

Upper Lip with the distal margin bilobed, one lobe rather larger than the other, the ciliation not strong. There appear to be traces of a small inner plate, adnate at the distal corners to the surface of the outer.

Mandibles.—The shaft much bent so as to present a deep concavity between the base and the palp, where it makes a right angle, the upper margin passing in a sinuous line to the narrow cutting plate, which is apically divided into some small teeth, about five or six in number, and lightly clasps the secondary plate, which is of nearly equal length, apically divided into five teeth on the left mandible, two of the teeth being double ; on the right mandible this plate is much more slender, and so far as observed has much

smaller teeth; adjoining the secondary plate is a broad, backward curving spine, of two-thirds the length of the secondary plate, with its broad end divided into sharp teeth of different lengths; to this succeeds a much shorter spine with two teeth at the end, and this again is followed at short intervals by three successively diminishing spines, so short as to be rather called teeth than spines, the first of the three appearing to be a process of the margin itself; between the shaft and this very peculiar spine-row projects the very prominent molar tubercle, its round or oval crown set thickly with rows of sharp teeth, too large to be called denticles; a process is placed between the molar tubercle and palp, a little to the rear, the shaft behind this appearing to be double-bladed; the first joint of the palp, which is comparatively long, has at the upper end, projecting from the outer surface, a tooth-like process which seems to be movable; the second joint, more than twice as long as the first, is rather shorter than the third, and has a short seta at the apex; the third joint has numerous distally pectinate spines arising not far from the base a little within the inner margin, which they closely fringe at the distal end, those at the apex being long, one at the apex being strongly pectinate on one edge for two-thirds of its length, and more finely pectinate on two edges for the remaining third; the hind margin not far from the base carries a row of ten or eleven setæ, while almost the whole of the outer surface, which is ridged and two-sided, is covered with lines of short spines or denticles. In the Plate the inner surface is shown of the left mandible, the outer surface of the right.

Lower Lip.—The principal lobes large, together forming a half circle, their inner margins not greatly dehiscent, the inner lobes seemingly adnate to the outer; the mandibular processes somewhat pointed.

First Maxillæ.—Inner plate narrow, with three plumose setæ on the apex; outer plate long, the apical margin narrow, carrying seven spines, the inner with their bases covered by a brush of cilia; three of the spines are broken; all appear to be more or less strongly dentate, the central one having three lateral teeth, the outermost one or two lateral teeth; the first joint of the palp is rather broader than the second and about half its length; the second joint has on its indented apical margin seven spines, pectinate on both edges, and on the surface adjoining these five more, similarly armed but longer and more setiform.

Second Maxillæ.—The plates broad, the outer broader as well as longer than the inner, the broad distal margins of both fringed with very numerous pectinate spines of different sizes, some large and strong; the outer and inner margins of both devoid of spines.

Maxillipeds.—The inner plates comparatively long, yet not reaching far beyond the base of the first joint of the palp, their inner margins fringed far down with plumose setæ, which pass on the surface round the inner apex and fringe the outer part of the distal margin, these appearing rather like curved spines than setæ; the distal margin

carries two spine-teeth at its inner apex, and a larger one at the centre; the outer plates broad, reaching just beyond the first joint of the palp; the inner margin thin and smooth below, above finely pectinate, the pectination passing round part of the apex, and the appearance of it repeated three or four times over in parallel lines on the surface, which carries two rows of longer and shorter setæ, neither of them very numerous; there are also setæ round the outer part of the distal margin; the first joint of the slender palp is longer than the second, the second a little longer than the third, the finger slight, half the length of the second joint; the first joint has a spine or two at the inner apex, the second some along the upper part of the inner margin, and the third several along the upper two-thirds of that margin, these spines being pectinate on two edges at the centre.

First Gnathopods.—The side-plate takes the form of a triangular process directed forwards, carinate below, channelled above, sharply pointed, with the sides near the point serrate. The limb is long and slender, the first joint being the thickest part; this is slightly sinuous, very elongate, a little shorter than the wrist and hand united; it has some minute spinules on the margins and a spine on the hinder apex; the second joint has the hinder margin straight, much longer than the front, with some small spines at the apex; the third joint is longer than the second, the front margin very short, the hinder with a row of spines along it near the sharply pointed apex, no part of the very oblique lower margin being free; the wrist longer than the hand and more than twice as long as the third joint, carries spines all along the free hind margin, pectinate at or near the centre; the hand long and slender, about five times as long as its greatest breadth, which is near the base; it has a spinule here and there on the hind margin, and at the slightly serrate distal end of it a row of five short spines, each with an accessory thread, and accompanied by one or two setules; these spines may be considered as occupying the palm margin together with one stronger, curved, closely set within with denticles, at a little distance from the others and close to the finger hinge; over these spines the small finger closes, having at its centre a strong tooth, with two broad apically hooked setules arising at its base; beyond the tooth the finger is prolonged in a slender much-curved nail.

Second Gnathopods.—The side-plates are similar to those of the preceding segment except that the carina appears above instead of below, and the triangle is a little longer and thinner. The branchial vesicle is about the length of the side-plate, without folds, a somewhat bent oval. The marsupial plates are narrow, longer than the branchiæ, with no setæ present, but some setules and marks of the points at which setæ apparently had been or were to be developed. The limb membranaceous and otherwise similar in structure to the first gnathopods, but much longer; the first joint a little longer than the third and fourth united; the third joint with fewer spines than in the preceding pair; the wrist of great length and tenuity, having scarcely any armature, the hand of about

the same length as in the first gnathopods or a little longer, thinner, similarly armed, but with the palmar spines spread over rather more space; the finger similar; the wrist in this remarkable limb is three times as long as the elongate hand.

First Peraopods.—Side-plates forming below a triangular channelled and earinate serrate-edged process as in the preceding pairs, but also throwing out from the centre of the upper part a similar process which takes a backward curve. The branchial vesicles and marsupial plates similar to those of the preceding pair, but rather larger. The first joint reaching beyond the side-plate, very slightly produced and furnished with spinules on the hinder apex; the second joint produced and furnished in like manner, and with one or two spinules on the hind margin on the inner surface, each of these joints having a small semicircular lobe on the distal margin; the third joint, which is nearly as long as the first, is distally a little expanded and a little produced in front; it has three or four spinules on the rather irregular margins both in front and behind; the fourth joint, which is considerably shorter, has four spinules on the front margin, and short spines at six points of the hind margin; the fifth joint longer than the fourth but shorter than the third, has seven or eight spinules in front, spinules at eight points behind, the distal margin slightly lobed on the inner surface; the finger is short and broad except at the curved tip, and at intervals along the inner edge carries some eight spinules; there is a cilium at the base of the nail, and some cilia apparently along the hind margin.

Second Peraopods closely resembling the first; the side-plates throwing out an angle behind to assist in interlocking it with the following side-plate.

Third, Fourth, and Fifth Peraopods.—The side-plates of these three pairs are much alike, the basal part or body of the plate successively smaller, the back-turned serrate process successively longer; when examined from below there is seen to be a flat process or lobe to the rear of the great process, the lower angle of which is turned forwards. The limbs are similarly formed, the fourth rather longer than the third, the fifth than the fourth. The first joint is so much channelled that it presents four longitudinal earinae or ridges, its lower hinder margin on the outer surface is produced in a rounded lobe which completely overlaps the short second joint, which like the three following joints is earinate in front; the third joint is decurrent behind with a long pointed process, and has some spinules along the front margin; the fourth joint is rather shorter, similarly decurrent, with spines on the front margin; the fifth joint has the hind margin longer than the front, but without an elongated apex; the front margin has several small spines; the finger is similar to that of the first peraeopods.

Pleopods.—The coupling spines very small, with two lateral teeth and an apical one; the eleventh spines slender, five in number, at least on one of the pleopods; the joints of the rami from twenty to twenty-three in number.

Uropods.—The peduncles channelled above, all reaching back nearly to the same point, the first pair a little beyond the second, and the second beyond the third, and the

rami in like manner, these being all lanceolate, but not broadly so, and, as well as the peduncles, being bordered with small spines; the peduncles of the first pair longer than the rami, those of the second pair a little shorter, and those of the third pair much shorter; in the first and second pairs the outer ramus a little shorter than the inner, in the third pair the rami equal.

Telson rather longer than broad, somewhat boat-shaped, shorter than the peduncles of the third uropods, the lateral margins and broad distal margin convex.

Length.—The specimen, in the position figured, measured eleven-twentieths of an inch from the front apex of the front (broken) horn of the first pereon-segment to the apex of the horn of the first pleon-segment.

Locality.—Station 150, off Heard Island, February 2, 1874; lat. $52^{\circ} 4'$ S., long. $71^{\circ} 22'$ E.; depth, 150 fathoms; bottom, coarse gravel; bottom temperature, $35^{\circ} 2$. One specimen, female. Dredged.

Remarks.—The specific name refers to the triple earina formed by the processes on the pereon-segments. The animal seems to have developed a spiky process at every available point, so as to become a veritable ball of prickles. Its cylindrical figure distinguishes it strongly from *Acanthonotozoma serratum*, Fabricius, of which Mr. J. Sparre Schneider has kindly sent me specimens. That species is comparatively compressed, has a long rostrum, and no special flexure of the pleon. With *Acanthozone*, Boeck, of which the type is *Oniscus cuspidatus*, Lepechin, the present species agrees in general habit.

 1886. *Panoplaea* (*pars*), Thomson and Chilton, Critical List Crust. New Zealand, p. 150.

For the original definition of the genus, see Note on Rathke, 1843 (p. 204). For Krøyer's definition of *Microcheles*, see Note on Krøyer, 1846 (p. 216), and for Thomson's definition of *Panoplaea*, see Note on Thomson, 1880 (p. 524). Boeck defines the genus as follows :—

" *Upper Lip* not much elongated, broad, apically insinuate.

" *Mandibles* a little shorter and broader than in the genus *Vertumnus* [*Acanthonotozoma*].

" *First Maxillæ* with the palp two-jointed, the first joint short; the inner plate smaller than in the preceding genus [*Acanthonotozoma*].

" *Maxillipeds* with the last joint of the palp wanting.

" *First and Second Gnathopods* slender, but furnished with a very narrow, cheliform hand.

" Body thick, yet deep; with the side-plates large, rigid."

In the definition of the compared genus, *Acanthonotozoma*, Boeck does not mention the mandibles; of the first maxillæ he says, "inner plate very large, triangular, furnished with many plumose setæ."

Iphimedia pacifica, Stebbing (Pl. LXXI.).

1883. *Iphimedia pacifica*, Stebbing, Ann. and Mag. Nat. Hist., ser. 5, vol. xi. p. 207.

The Head almost concealed; the long rostrum, curving slightly downwards, reaches nearly to the end of the first joint of the upper antennæ; the lateral margins of the head below the upper antennæ form two sharp processes, of which the lower is rather the larger; the first segment of the peræon curves over the head and is dorsally longer than any one of the five following segments, but much shorter than the seventh segment; each has the postero-lateral angles acute, forming backward-directed processes, more and more developed in each successive segment, in the last three, and especially in the last, the process becoming prominent and directed a little outwards as well as backwards; in the last peræon-segment and in each of the first two of the pleon there is a pair of large dorsal backward-directed teeth or processes; the first three pleon-segments have an inchoate dorsal carina, the postero-lateral angles produced into an acute upturned tooth, and the hinder margins likewise produced into a sharp tooth near the centre, this tooth in the third segment being longer than the lower tooth and curved upwards at the point; dorsally, the hind margin of the third segment forms a small lobe on either side; the

fourth pleon-segment has a deep transverse dorsal depression; the sixth segment runs out into a sharp point on each side of the telson.

Eyes small, oval, situated near the front of the head almost between the upper and lower antennæ.

Upper Antennæ.—First joint much longer and thicker than the second, distally produced into a long acute tooth, and a shorter one minutely and unequally bifid; the second joint is also distally produced into a bifid tooth of some size on one side and a minute denticle on the other; in the specimen from Station 150 the remainder of the upper antennæ was missing; in a specimen from Kerguelen the third joint was very small, the flagellum longer than the peduncle, of some twenty joints, decreasing in thickness and increasing in length successively downwards (see fig. *a.s.*).

Lower Antennæ.—First joint forming a small lobe on the lower side, the gland-eone of the second joint small, the distal margins of both the second and third joints irregularly dentate; the fourth joint as long as the preceding three united, having distally a produced tooth and a denticle; the fifth joint narrower and rather shorter than the fourth; the flagellum longer than the peduncle, consisting of thirty-five joints, of which the first is the longest.

Upper Lip.—The front plate is wider at the base than at the smooth flattened distal margin, with the sides evenly convex.

Mandibles long and tongue-like, the cutting edge sloping backwards, so that in the row of seven teeth on the right mandible, three large and four small, the top one is the largest and most prominent; it has a small tooth on the outer side of it; on the left mandible the teeth seem to be less numerous and larger; on the right mandible the secondary plate was obscure; on the left it was well defined, long, and strap-shaped, lying close to the lower margin of the principal plate, but not reaching its apex, the upper margin convex, the distal part of the lower cut into four teeth; no spine-row was visible; the molar tubercle on the left mandible is very small, with a narrow crown minutely denticulate; on the right mandible no dentate crown could be perceived; the first joint of the palp is long and distally dilated, with a spine at the inner distal corner, the second joint is longer than the first or third, but is drawn too long in the figures; it has two spines near the inner apex; the third joint is a little longer than the first, the outer margin convex, the surface ciliated, the apex and much of the inner margin fringed with spines. In the figures *m.m.* the new growth of the cutting-plates is seen within the trunk of each mandible, and separate figures more highly magnified are given to show the details of these still-unworn edges. The left mandible is figured on the right, and the right mandible on the left, of the Plate.

Lower Lip thin in texture, the principal lobes dehiscent, with the inner margins straight or slightly concave, the apex angular; the inner lobes are doubtfully distinct from the principal; the mandibular processes are long and divergent.

First Maxillæ.—The inner plates narrow, with seven or eight plumose setæ on the apex and distal part of the inner margin; the outer plates long, with a brush of cilia along the distal part of the inner margin; of the eleven spines on the oblique apical margin, the innermost four have many lateral denticles, the next four or five fewer, and the outermost two have none; the first joint of the palp is long, more than half the length of the second; the second reaches scarcely beyond the outer plate and has several pectinate spines on the distal end.

Second Maxillæ.—The inner plates rather broader and a little shorter than the outer, with numerous strongly pectinate spines passing from the apex of the outer margin in a curve so oblique that it may be reckoned as well part of the inner as of the apical margin; the outer plates have longer spines round the apical margin and descending the inner margin to a very short distance; its sides are nearly parallel.

Maxillipeds.—The inner plates long and narrow, their inner margins fringed with setæ, and the somewhat conical apices also fringed with long plumose setæ; the outer plates are large, with long spines or setæ on the distal part of the inner and outer margins and shorter spines set very closely round the narrowed apical part of the plates. The first joint of the palp is longer than the second or third, with a few setæ along the inner margin and a group at the outer apex; the second joint has also some long setæ at the apex of the straight outer margin, on the inner side it is apically produced, the process being set round with long spines; the third joint is short, with one or two spines on the outer margin, and many long ones from the apex round the distal part of the inner margin; there seems to be no trace of a finger.

First Gnathopods.—The side-plates triangular, the front margin convex, with one or two dentations below, the apex very sharp, the slightly concave hind margin forming a little tooth just before reaching the apex. The limb slight and feeble, much twisted, probably being so when the creature is alive to secure the protection its feebleness requires. The first joint narrowest at the two extremities, the front margin very sinuous, with a few setæ, the hind margin very convex; the second joint as long as the third, apically produced to a point; the third joint with convex margins converging to an apical point; the wrist narrow, a little longer than the hand, which is also very narrow, somewhat curved, the hind margin concave, produced into a small thumb, against which lies a short finger, the two together forming a minute chela, about which four or five setæ of different lengths are arranged; the finger, which is beset with setæ, has a hooked tip, and two retroverted teeth on its inner margin.

Second Gnathopods.—Side-plates not unlike the preceding pair, but longer, more slender towards the apex and more curved, with five teeth or serrations on the lower part of the front, and two at the lower end of the hind margin. The branchial vesicles long and very narrow. The first joint of the limb longer than in the first gnathopods, narrow, not much bent; the second joint shorter than the third; the third widening towards the distal

end, then running out into a point ; the wrist subequal in length to the hand, widening a little distally, with some setæ on the hind margin and its apex ; the hand long and almost parallel-sided, the straight hind margin being fringed for almost its whole length with pairs or larger groups of long setæ ; there are some short setæ near the apex of the front margin ; the thumb and finger seem to resemble those of the first gnathopods.

First Peræopods.—Side-plates like the preceding pair, but longer. The third joint of the limb apically decurrent in a short sharp point.

Second Peræopods.—The side-plates with very convex front margin, serrate below, the hind margin concave, forming two large curves separated by a sharp process, the lower curve the longer, serrate near the acute apex. The third joint of the limb as in the preceding pair.

Third Peræopods.—The side-plates bilobed, the hinder lobe having a very acute backward-directed process. The first joint of the limb has the hind margin very sinuous and strongly serrate, forming with the serrate lower margin a sharp backward-directed apical tooth ; the second joint is very small ; the third is longer than the fourth, being behind decurrent in a long apical tooth ; the fifth joint is longer than the fourth, and like both the third and fourth has small spines along both margins ; the finger is a little curved, longer than half the fifth joint.

Fourth Peræopods similar to the third, but larger.

Fifth Peræopods.—The side-plates have a backward-directed process as in the two preceding pairs. The sinuous hind margin of the first joint is produced downwards in a sharp tooth at an angle with the lower margin, in other respects the limb seems to resemble the two preceding pairs, but exceeds them in size.

Uropods.—The peduncles of the first pair longer than the rami, the margins and apices carrying rather large spines ; the rami long and slender, nearly equal, the outer slightly the shorter, the apical portion in each narrowed so as to look like a nail, yet with no sign of jointing or suture ; both rami having marginal spines and pectinate edges ; the peduncles and rami of the second pair not reaching so far back as those of the first and third pairs, the peduncles longer than the outer, shorter than the inner ramus, the rami armed like those of the first pair ; the peduncles of the third pair much shorter than the ramus, with three acute distal prolongations, two of which are rather long ; one of the rami missing, the other long, tapering, with marginal spines and pectinate edges.

Telson concave above, almost oblong, longer than broad, the lateral margins scarcely converging, apically produced to a sharp tooth on either side of the trunate distal border, in the centre of which there is a very small emargination.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the back of the third pleon-segment, about three-tenths of an inch.

Localities.—Station 150, off Heard Island, February 2, 1874 ; lat. $52^{\circ} 4'$ S., long.

71° 22' E.; depth, 150 fathoms; bottom, coarse gravel; bottom temperature, 35°·2. One specimen.

Station 149H, off Cumberland Bay, Kerguelen, January 29, 1874; depth, 127 fathoms; bottom, volcanic mud. One specimen. Dredged.

Remark.—The specific name refers to the ocean in which the specimens were found, and has, it must be allowed, no special appropriateness.

Iphimedia pulchridentata, Stebbing (Pl. LXXII.).

1883. *Iphimedia pulchridentata*, Stebbing, Ann. and Mag. Nat. Hist., ser. 5, vol. xi. p. 206.

The Rostrum long, somewhat curved and depressed, rather broad near the base, acute at the apex; the lateral margins of the head produced below and at the centre into two sharp processes, that in the middle curving a little downwards, the lower curving rather upwards; peræon broad across the back, rounded, pleon much more compressed; all the segments of the peræon and the first three of the pleon have the postero-lateral angles sharply produced, in the sixth and seventh segments of the peræon the processes being very long and downward curving, in the second and third of the pleon slightly upturned; the sixth and seventh segments of the peræon have also two, the first and second of the pleon three, the third of the pleon two, large backward-directed processes on either side of the dorsal line, in the peræon-segments the upper pair larger than the lower, both with the upper margin convex; in the first two pleon-segments the upper margin of the upper and the lower of the lowest pair are convex, in the third segment the lower margins of both pairs; the first four segments of the pleon are dorsally carinate, the carina being produced backwards in a large tooth or process, on the top of which in the second and third segments there is a small denticle, while in the fourth segment the process is slightly tip-tilted; the sixth segment is acutely angled beyond the base of the telson; there is a marked transverse dorsal depression on the seventh segment of the peræon and on the fourth of the pleon, the intervening segments having slighter depressions.

The Eyes are round, rather prominent, situated close to the margin of the head below the rostrum.

Upper Antennæ.—The first joint has a tooth near the base, and three large but unequal distal teeth; the second joint is as long as the first, having on one side a small distal tooth, on the other a very long one which outreaches the third joint; the flagellum is missing, but there is present what appears to be a rudimentary one-jointed secondary flagellum.

Lower Antennæ.—The first three joints very short, the first particularly small but produced into a long tooth, the second forming three large pointed processes of differing widths, the widest apparently being the gland-cone, the third joint shorter than the second, with an irregular distal margin carrying a small tooth on one side and a more

prominent one on the other; the fourth joint longer than the preceding three united, distally dilated and produced into large teeth, the lower margin carrying a small spine; the fifth joint as long as the fourth, a little dilated distally, with the lower apex acute, the lower margin carrying a few spinules; the flagellum with twenty-eight joints remaining, of which the first is the longest and shows three or four joints in preparation within it.

Upper Lip.—The distal margin broad, evenly and slightly convex, almost smooth; two blunt tooth-like processes project on either side of the surface of the epistome.

Mandibles narrow and tongue-like, the cutting edge resembling a broad horny tooth not divided into denticles; even in the plates in preparation no such division could be made out; the secondary plate on the left mandible lies close to the lower edge of the principal plate, and from a narrow base expands with a convex upper margin, its distal margin sloping inwards like that of the principal plate, faintly divided into five or six teeth, its greatest breadth about half that of the principal plate, against which it is closely applied; in the other mandible the secondary plate is similar in position but much smaller, strap-like, not reaching the distal border of the principal plate; of spine-row I could discover no trace, nor could I make out any dentation of the molar tubercle; the articulating process is large; the palp set far back, has the first joint rather long, about half the length of the second, the third is longer than the first, shorter than the second, with some spines on the oblique inner margin of the apex. In the figures of the mandibles *in situ* on either side of the upper lip, the outer surfaces are shown, so that the left mandible is to the right, the right mandible to the left; the transparency of the principal plates permits a view of the inner secondary plates.

Lower Lip with the distal margin and much of the surface strongly ciliated, the lobes dehiscent, with a small emargination near the apex of the convex inner margin; the inner lobes so far as observed were narrow; the mandibular processes long, a little bent, very divergent.

First Maxillæ.—The inner plates oval, with ten or eleven plumose setæ passing from the apex some way down the inner margin; the outer plate with a bush of cilia at the upper part of the inner margin, many of them spine-like, and near the apex giving place to broad short spines; of the eleven spines on the distal margin, the two innermost have ten or a dozen lateral denticles, the next pair have, the one three, the other four, stronger teeth, the next pair two apiece, the next pair one and three, and the three outermost which are strong and much curved have no lateral teeth; the first joint of the palp is long, half the length of the second; the second reaches much beyond the outer plate, and carries at the upper part of the inner margin and on the apex many long pectinate spines.

Second Maxillæ.—The inner plates narrow at the base, then widening with a convex inner and straight outer margin, the distal margin broad, obliquely truncate, crowded with

spines, many of which are strongly pectinate; the series is continued some way down the inner margin with spines that are partly pectinate, partly plumose; the outer plates are narrower and longer than the inner; there are many long pectinate spines on the narrow apex, and a little way down the inner margin, besides four or five more slender than the rest down the outer margin.

Maxillipeds.—The inner prismatic plates very long, fringed far down the inner margin with a series of fifteen plumose setæ, this margin ending in a small apical point, the distal margin not broad, but set with two rows of strongly pectinate spines of different lengths, two near the inner apex comparatively short, but still too long to be regarded as spine-teeth; two or three slender spines pass down the outer margin. The outer plates scarcely larger than the inner, not reaching the distal end of the palp's second joint, the inner margin in its upper part fringed with feathered setæ, near the rather pointed apex becoming serrate and carrying pectinate spines; four or five feathered setæ pass down the outer margin; the three joints of the palp are rather narrow, the first a little longer than the second, with a few setæ on the inner margin and outer apex, the second with several long setæ near and at the apex of the inner margin; the third about as long as the second, with numerous setæ along the upper half of the inner margin, and at least one long pectinate spine at the apex; no trace of a finger could be perceived among the parasites which beset the apical setæ.

First Gnathopods.—The side-plates have the narrowed distal portion divided into two large acute processes, of which the hinder curves slightly forwards, and has a small denticle on its front or inner margin; the front process has a small denticle on the front margin, below which it slopes slightly backwards. The limb closely resembles the first gnathopods of *Iphimedia pacifica*, but the specimen being larger some of the details are more easily observed; thus the tip of the thumb has a small spine, against which the hooked tip of the finger impinges; at the base of the thumb there are three or four pectinate setæ and two long ones on its inner margin, the finger having two dorsal setæ, one near the base, the other near the tip, the pectination of these setæ being turned backwards in the limb as mounted for the microscope, but this is perhaps accidental; besides the strong apical hook, the finger has at least one retroverted tooth on the inner margin.

Second Gnathopods.—The side-plates similar to the preceding pair, but narrower, a little longer, with the hinder process rather more produced in comparison with the front one. The limb is very like that of the second gnathopods in *Iphimedia pacifica*; the first joint widens a little distally, is as long as the wrist and hand united, and much broader than either; the second joint is longer than the third; the wrist has six groups of setæ along the distal half of the hind margin; there are seventeen or eighteen groups of long setæ along the distal two-thirds of the hand's hind margin, and eight groups along the distal half of the front margin.

First Peræopods.—The side-plates similar to those of the preceding pair, a little

broader and longer. The limbs of this and the following pairs robust, not feeble like the gnathopods. The first joint not reaching beyond the side-plate; the second joint short, the third longer than the fourth, with spines at four points of the hind margin, the front margin apically acute and a little decurrent; the fourth joint with spines at three points of the hind margin, distally widened, and apically acute in front; the fifth joint about as long as the third, with spines at four points behind and at two or three in front; the finger more than half the length of the fifth joint.

Second Peræopods.—The side-plates with the front margin convex, produced below the preceding pair in a sharp apex, the hind margin concave in two curves separated by a sharp process, the lower curve being much the longer.

Third Peræopods.—Side-plates bilobed, the hinder lobe the larger, its hind margin forming two large processes, of which the upper is the longer and narrower, curving downwards. The first joint of the limb long, with the front margin nearly straight, apically forming a small sharp tooth, the hind margin deeply cut into five acute, large, unequal teeth or processes, of which the lowest is the smallest; the second joint short, the front margin apically produced into a sharp tooth; the third joint with one or two spines on the front margin, the hind margin produced in a long, very acute, decurrent apex. The rest of the limb missing.

Fourth Peræopods.—The side-plates broader than the preceding pair, not bilobed, the hind margin produced into two very long, narrow processes. The first joint like that of the third peræopods, but larger and with larger processes; the second and third joints also a little longer; the fourth joint short, with spines at three points in front, widened distally, the hind margin apically acute, almost entirely overlapped by the decurrent apex of the third joint. The rest of the limb missing.

Fifth Peræopods.—Side-plates similar to those of the preceding pair, but of the hind processes the upper is larger and much more produced than the lower. First joint of the limb not unlike that of the fourth peræopods, but much larger, the uppermost process of the hind margin small, with an extra denticle on the top of it, the process next below and the process lowest but one being both very much produced; the third joint longer than in the preceding pair, with spines at three or four points on the hind margin; the fourth joint longer than in the preceding pair, having a little spine within the slightly produced acute hinder apex; the fifth joint longer than the fourth, not quite so long as the third, slightly curved, with spines at four points of the front, and three or four of the hind margin; the finger not half the length of the fifth joint, rather broad, curved at the nail, with a dorsal elium close to the hinge, another at the base of the nail, and four spinules along the convex hind margin.

Uropods.—Peduncles of the first pair a little longer than the rami, armed with marginal and apical spines; the rami long and slender, subequal, with spines on both margins, and each ending in a small nail; the peduncles and rami of the second pair

not reaching back so far as those of the first and third pairs, the peduncles about as long as the inner ramus, with spines fringing the lower half of one margin, the other smooth, except for an apical spine; the outer ramus shorter than the inner, each ramus having marginal spines and an apical nail (in one of the second uropods the inner ramus was less elongate than in the other); the peduncles of the third pair much shorter than the rami, apically cut into three unequal teeth; the rami broad, lanceolate, unequal, with marginal spines and some feathered setæ.

Telson longer than broad, the sides converging to form an acute apex on either side, the two apices being separated by an emargination of about equal length and breadth, the length being between a third and a quarter of the total length of the telson. The actual apices are perhaps rounded, each carrying a sort of nail broad at the base and acute at the tip.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the back of the third pleon-segment, very nearly half an inch.

Locality.—Station 151, off Heard Island, February 7, 1874; lat. $52^{\circ} 59' 30''$ S., long. $73^{\circ} 33' 30''$ E.; depth, 75 fathoms; bottom, volcanic mud. One specimen.

Remarks.—The specific name refers to the handsome dentation of the back and the peraeopods.

 p. 49.

Locality.—The specimens were labelled as having been taken “Parasitic on *Cottus*, Halifax, May '73.” This refers therefore to a point in the voyage between Stations 48 and 49.

Remark.—The mouth organs of this species are beautifully drawn by Schiødte; they are figured in this Report, as well for identification of the species, as to give facility of comparison with the corresponding parts in kindred genera.

Among numerous drawings of Amphipoda by Sir Joseph Hooker, prepared during the Antaretic expedition of 1840–41, there is one of a species in many respects resembling *Acanthonotozoma cristatum*, Owen, and like it reddish-white in colour, with red eyes. If this fine species should prove to belong to the genus named it will be an addition to the family Iphimedidæ.

Family ATYLIDÆ, G. O. Sars, 1882.

In 1865 Lilljeborg made the Atylinæ the eighth subfamily of the Gammaridæ, with the definition “Antennæ superiores flagello appendiculari earentes. Oeuli compositi. Pedes trunci (thoraciei) 7:mi paris antecedentibus minime vel parum longiores, segmento ultimo unguiformi. Laminæ pedum maxillarium bene evolutæ.” To it he assigned the genera *Odius*, *Iphimedia*, *Laphystius*, *Calliopius*, *Paramphithoë*, *Atylus*, *Dexamine*, *Acanthonotus*, the first three and the last one being the same genera as Boeck afterwards grouped together in his subfamily Iphimedinæ. In 1870 Boeck constituted the Dexamininæ the thirteenth subfamily of the Gammaridæ, to receive the genera *Dexamine* and *Lampra*, and at the same time made the Atylinæ the fourteenth subfamily, to receive the genera *Atylus*, *Pontogencia*, *Halirages*, *Calliopius*, *Amphi-*

thopsis, *Cleippides*, and *Laothoës*. In his later work, 1872–1876, he retained these two subfamilies as respectively the sixth and seventh of the Gammaridæ, only changing the preoccupied name *Lampra* into *Tritæta*, and almost uniformly printing the name of the subfamily as Dexaminæ, even when referring to the earlier work in which it is Dexamininæ. In 1882 Sars established, though without defining, the family Atylidæ, placing in it the genera *Lampra*, *Dexamine*, *Atylus*, *Halirages*, *Calliopius*, *Amphi-thopsis*, *Laothoës*, no doubt omitting *Pontogeneia* and *Cleippides* only because they were not included in the fauna with which he was concerned.¹ If Boeck's definition of the Dexamininæ were correct, it would be proper to uphold that group as distinct, for he states that in it the mandibles are without palp, the first maxillæ have a one-jointed palp, and the maxillipeds are without the last joint of the palp, whereas in all these particulars the Atylinæ are normal. But of these three important characters of the Dexamininæ two seem not to be constant, since in *Tritæta kergueleni* at any rate the palp of the first maxillæ is apparently two-jointed, and in *Dexamine flindersi* the ungiform fourth joint is certainly present on the palp of the maxillipeds.

Genus *Halirages*, A. Boeck, 1870.

For the original definition of the genus see Note on Boeck, 1870 (p. 401).

Boeck, it will be observed, says that "the mandibles have the palp elongate, the third joint shorter than the second," yet in describing *Halirages fulvocinctus*, M. Sars, he rightly says that the palp's third joint is a little longer than the second; the statement in the definition, that the back is not earinate, is not essential, and would not suit the species now to be included; the statement that the upper antennæ are shorter than the lower may be less rigidly expressed by saying that they are not longer; Boeck's further statement that the third uropods have a peduncle longer than the telson is not in agreement with *Halirages huxleyanus*, but neither is it with *Halirages inermis*, Sars, nor apparently with *Halirages tridentatus*, Bruzelius, if I rightly understand Boeck's own remark upon the proportions in that species; it should therefore be omitted from

¹ Oversigt af Norges Crustaceer.

the definition; finally, of the telson it may be said that it is whole or emarginate, the latter epithet applying to *Halirages fulvocinctus*, M. Sars, and *Halirages huxleyanus*, Sp. Bate.

Halirages fulvocinctus (M. Sars).

- 1884. " " J. S. Schneider, Crust. og Pycn. Kvænangsfjorden, p. 102.

Upper Antennæ.—The second and third joints of the peduncle crowded with small calceoli on the under side; the third joint distally produced below in a thin laminar process with serrate edges, about which calceoli and small spines are attached; the very numerous joints of the flagellum, so far as observed, were all armed with a calceolus apiece and some cylinders, the projecting distal points to which these are attached not being in line, give the flagellum a strongly serrate appearance on the under side.

Lower Antennæ.—The first three joints are short, with short spines on the upper margin; the fourth and fifth joints subequal, slightly curved, the upper margin convex, serrate, carrying many calceoli; the joints of the flagellum very numerous, armed with calceoli, the first joint long but showing rings as of many short joints in preparation, the joints immediately following the first much broader than long.

First Maxillæ.—Inner plate between oblong and oval, with five very unequal, strongly plumose setæ on the slightly oblique apical margin, the setæ graduated in size, the largest innermost; the outer plate on the broad apical margin carrying eleven spines of various lengths with teeth of various sizes, varying in number from two to six; the long second joint of the palp strongly ciliated, having a row of setiform spines passing from the distal part of the inner margin towards the outer apex, the distal margin strongly denticulate and set with spines or spine-teeth. Boeck assigns *six* setæ to the inner plate and *ten* spines to the outer, of which half are pectinate (kamdamnet), the other half serrate (saugtakket); Schneider says, "I have only seen *eight* short spines, which are all pectinate (alle har kamtaender), on the outer plate, while the inner plate only has *five* plumose setæ on the apex."

Second Maxillæ long and rather narrow, the inner plate a little shorter than the outer, with four plumose setæ on the inner margin graduated in size, the lowest the longest; the apical margin fringed with spines shorter than these setæ; the apical margin of the outer plates fringed with feathered spines longer than the spines on the inner plate. Schneider says, "The inner plate has below on the inner rim *three* thick plumose setæ, the outer has only simple fine setæ."

Maxillipeds.—The outer plate has a smooth inner margin, the spine-teeth being set back at a little distance, although distally projecting beyond it; the palp's short finger has several setules on the inner margin near the base of the very acute nail, which is nearly as long as the basal part of the joint. In general these organs agree well with the description given by Boeck.

Gnathopods.—To the figures of these given by Goës Schneider objects that the lower hinder angle of the third joint is represented as rounded, "whereas in reality it is very sharply right-angled," but in the Challenger specimen, though this angle is scarcely to be called rounded, neither is it to be called sharply right-angled. One of the second pair of gnathopods in this specimen has the hand and finger so abnormal that had the other member of the pair been wanting this accident might have led to the institution of a new species.

Pleopods.—The cleft spines are very strong; the series numbers seven in the first pair, six in the second, five in the third.

The Telson is rather deeply concave or boat-shaped above, apically a little emarginate as well as serrate.

Length.—The larger specimen measured, from the front of the head to the end of the third pleon-segment, half an inch, and from the end of the third pleon-segment to the extremity of the uropods, a quarter of an inch, this part of the pleon being bent at right angles to the rest of the body in the specimen measured.

Locality.—Station 49, south of Halifax, Nova Scotia, May 20, 1873; lat. $43^{\circ} 3'$ N., long. $63^{\circ} 39'$ W.; depth, 85 fathoms; bottom, gravel, stones; bottom temperature, 35° . Two specimens, females.

Halirages huxleyanus (Sp. Bate) (Pl. LXXIII.).

- 1862. *Atylus Huxleyanus*, Spence Bate, Brit. Mus. Catal. Amph. Crust., p. 135, pl. xxv. fig. 4.
- 1870. " *? Batei ?*, Cunningham, Trans. Linn. Soc. Lond., vol. xxvii. p. 498.
- 1870. " *Huxleyanus*, Cunningham, Trans. Linn. Soc. Lond., vol. xxvii. p. 498.

A short acute rostrum; head and peræon as far as the sixth segment dorsally rounded; back of peræon with an imbricated appearance, postero-lateral angles of the three last segments acutely produced backwards; the sixth and seventh segments of the peræon and first three of the pleon produced backwards dorsally in large pointed processes, that on the second pleon-segment being the longest; the three first segments of the pleon dorsally carinate, with their postero-lateral angles produced in short sharp points. There are markings on the integument, described by Mr. Spence Bate as "somewhat resembling the representation of a flying bird."

Eyes round, of moderate size, dark coloured in the specimen preserved in spirits, the numerous ocelli long, so as to present a broad outer ring, uncoloured.

Upper Antennæ.—The joints of the peduncle successively decreasing in length and thickness, the first about twice as long as broad; the flagellum three or four times as long as the peduncle, rather thick near the base, the joints numbering sixty-two, none very long, most of them widening a little distally, and some widening much, namely the first, third, sixth, ninth, eleventh, thirteenth, eighteenth, twenty-fourth, twenty-ninth, thirty-fifth, fortieth, forty-fourth; these carry cylinders, in groups of three or four, about as long as two succeeding joints; all the joints, except perhaps the last two, carry small calceoli, many of the upper ones having the lower margin fringed with four or more; some are found at the apex of the first joint of the peduncle, and there is a row along the distal half of the lower margin of the second and third joints.

Lower Antennæ.—The peduncles a little longer than in the upper antennæ, the flagella of about the same length; the first joint not much inflated, the gland-cone minute, not prominent; the distal rim of the coalesced first and second joints a little crenulate, with a few setæ or slender spines; the third joint more than half the length of the fourth, which is rather longer than the fifth; all three have spines on the lower margin and at the apex of the upper; the flagellum of fifty-six joints, evenly tapering, armed as in the upper antennæ with small calceoli, some of the upper joints having as many as six, and the third, fourth, and fifth joints of the peduncle having two or three rows of them along the under (or perhaps the inner) side.

Upper Lip not well made out, but apparently membranous in texture, with the rounded distal margin strongly ciliated and slightly projecting at the centre. These characters, however, must not be regarded as very definitely ascertained.

Mandibles.—The cutting-plate narrow, with its edge divided into seven teeth, none of them very large; the secondary plate on the left mandible similar to the principal one, which to a certain extent clasps it, but smaller, its edge divided into five teeth; on the right mandible this plate is as usual of slighter construction, it is curved, divided apically into two slender teeth, and has a denticle on the outer convex margin; the spine-row of seven slender, denticulate, more or less curved spines; the molar tubercle prominent, the oval crown set with numerous rows of denticles; a blunt-headed process adjoins the base of the palp, just over the molar tubercle; the first joint of the palp is short, the second is broader than either the first or third, a little longer than the third, concave behind, widening distally, with some small spines at intervals on the front margin, and on the outer surface a couple about one-third of the length from the base, and (commencing at about the centre of the same surface) a curved row of sixteen, slightly curved, pectinate spines, graduated in size, those in the middle of the row being the longest; the third joint has its concave front margin crowded with pectinate spines of various lengths, and two or three long ones close to the base of the hind margin.

Lower Lip.—The principal lobes much ciliated, somewhat dehiscent, distally

broad, but much broader at the base; the inner plates seemingly adnate, their inner margins marked by a line of backward-pointing cilia; the mandibular processes small, with rounded apices.

First Maxillæ.—Inner plate small, with five plumose setæ at and near the apex; outer plate broad, with eleven slender denticulate spines on the truncate distal border, the lateral denticles numbering from two to six, all except the outermost of the shorter spines having at least four; the palp broad, its long second joint reaching beyond the outer plate, the truncate margin fringed in one of the maxillæ with five short teeth and a spine, in the other maxilla with six spine-teeth and a spine; in both there are four spine-like setæ rising on the surface just within the distal margin.

Second Maxillæ.—Inner plate a little broader and shorter than the outer, the spines running round the apex and about halfway down the inner margin, at which point are five plumose setæ, the lowest small, the two uppermost large and long; the spines of the outer plate, which are as usual longer than those of the inner, do not descend the inner margin.

Maxillipeds.—The prismatic inner plates rather long, but not nearly reaching as far as the distal end of the first joint of the palp, with several plumose setæ on the inner margin, which pass round towards the outer apex, at that part being short and incurved; the truncate distal margin has three small teeth; the outer plates not reaching far beyond the first joint of the palp; the inner margin smooth, but the surface at a little distance within it set closely with longer and shorter spine-like setæ, which are continued round the apical margin, being there setiform and plumose; the outermost but one is the longest, the outermost being abruptly much shorter; the first joint of the palp is longer than the third; the second longer than either, very broad, its length not twice its own breadth, fringed on the inner margin with numerous setæ, of which it has groups about the distal margin and on the outer surface near the inner margin; the third joint bending inwards, with numerous groups of setæ or spines on the inner surface and round the finger; the finger shorter than the third joint, its inner margin nearly straight, armed with a row of five setules; the nail a little curved, almost spine-like.

First Gnathopods.—Front margin of side-plate short, convex; lower margin a little concave, carrying some microscopic spinules, forming a rounded angle with the hinder margin, the whole plate very small. First joint of the limb reaching much beyond the side-plate, front margin almost straight, with a small lobe of the outer surface within its distal angle, the hind margin bent above the centre, and at the bend carrying a group of four long setæ, and another group on the inner surface near these; second joint short, like the preceding distally fringed on the lower inner margin at the back with spines of various lengths; third joint almost triangular, hind margin irregular, inner surface with four groups of spines, the largest near the acute apex; the wrist nearly as long as the first joint, widening distally, fringed with groups of spines round the serrate hind margin,

and carrying other groups on the inner surface; the hand oval, narrowest at the finger hinge, longer than the wrist and wider, the front margin with some small spines beyond the centre, and longer ones at the apex, the hind margin for the first quarter smooth, the second serrate, the remainder smooth and thin; after the first quarter it is set all the way along with setæ, setules, or setiform spines, the inner surface shows six groups of spines near the hind margin, and four near the front, the most distal of these four having spines of great length; at the fourth serrature of the hind margin begin groups of stout spines of many different lengths, with short accessory threads, and accompanied by groups of setæ on the outer surface; the spine-groups, about four in number, may be considered as defining the palm, but the curved, rather stout finger is not long enough to reach the lowest group; the inner margin of the finger has some stiff short hairs or spinules, and some spinules can be perceived on or near its outer margin; the nail has two cilia at the base; the dorsal cilium of the finger is very short, near the hinge.

Second Gnathopods.—Side-plates a little larger than those of the preceding segment, produced below to a backward-directed angle. The branchial vesicles much longer than the first joint of the limb, broadest near the centre, rather more than twice as long as the greatest breadth. The limb presents a very close resemblance to that of the first gnathopods. The first joint is a little longer and not quite so broad, and is without the group of long setæ on the inner surface; the second joint has an apical group of spines on the hind margin, but not a small intermediate group which is found in the first gnathopods; the hand also appears to have rather fewer groups of spines on its inner surface.

First Peræopods.—Side-plates produced backwards below in a rounded point, above which there is a small prominence. The branchial vesicles widening out below, retaining much of their breadth distally, not reaching the distal end of the first joint. The first joint reaching beyond the side-plate, in shape and armature as in the second gnathopods, but longer and broader; the second joint short; the third narrow at the base, then widening, in length subequal to the fourth joint, a little decurrent in front, with spines at two points on each margin; the fourth joint widest distally, with spines at the apex in front and behind, and also at one point high up on the hind margin; the fifth joint not much shorter than the two preceding joints united, with spines at four points of the hind margin, at the apex in front, and at one point a little way above it; the finger short, stout, strongly curved, with two cilia near the base of the nail, and a short dorsal cilium near the hinge.

Second Peræopods.—Side-plates a little broader at the base than in the preceding segment, otherwise similar. The limb scarcely distinguishable from that of the preceding pair; an extra spinule may be noticed on the hind margin of the fourth joint, another on that of the fifth, and an extra group of small spines on the front margin of the fifth joint. These limbs do not seem to differ in length.

Third Peraopods.—Side-plates broader than in the preceding segment, produced below in two rather long lobes, the lower ends of which are wide apart. The first joint broader above than below, with spines at four points on the nearly straight front margin, the hinder with only some minute spinules; the lower part of the joint squared on the outer side, while the inner surface is pear-shaped; the rest of the limb resembles the preceding peraeopod, but is a little larger, and the fourth joint has three groups of spines on the front margin, that is, the margin corresponding to the hind margin in the preceding limb.

Fourth Peraopods.—Side-plates with a long lobe decurrent behind. The branchial vesicles with an accessory pouch at the upper part. The first joint similar to that of the third peraeopods, but considerably larger, especially in breadth; the rest of the limb similar to the preceding, but the third and fourth joints considerably longer, and each with spines at a point in the hind margin; the fifth joint also rather longer.

Fifth Peraopods.—Side-plates small, not decurrent. The first joint longer and broader than in the preceding peraeopods, rather more pear-shaped, although distally broad; the rest of the limb similar to the preceding, but all the joints longer.

Pleopods.—Coupling spines very small; cleft spines five in the first and second pairs, four in the third pair, the branches of the eleventh short and equal; the joints of the rami number from eighteen to twenty-two.

Uropods.—The peduncles of the first pair longer than the rami, reaching just beyond those of the second pair, but not so far as those of the third, with three or four spinules on the inner margin, the outer clear; the rami slender, the outer shorter than the inner, each tipped with a large nail-like spine, having a small one by its side, the inner ramus also carrying four or five small spines on its margin; the peduncles of the second pair shorter than the inner ramus; the outer ramus much shorter and narrower than the inner, each tipped as in the first pair, the inner also having two spines on the outer and five or six on the inner margin; the inner reaches back about as far as the inner of the first pair, the outer not so far as the outer of that pair; peduncles of the third pair shorter than the rami, which are broad, lanceolate, subequal, the outer rather the longer, both reaching a little further back than those of the other pairs; the inner ramus has its inner margin fringed with thirteen spines with plumose setæ of different lengths; on the serrate lower portion of the more convex outer margin there are six spines with setæ; the outer ramus has six or seven spines on its inner margin, and two or three on the lower part, besides spinules on the upper part, of the outer margin.

Telson reaching beyond the peduncles of the third uropods, elongate, with the lateral margins very slightly sinuous, on the whole tapering to a narrow emarginate termination.

Length.—The specimen, in the position figured, measured half an inch from the rostrum to the apex of the dorsal process on the second pleon-segment.

Locality.—The single specimen was labelled as taken “from the kelp in Stanley Harbour, Falklands, Jan. 1876.”

Remarks.—This appears to be the same species as that named *Atylus huxleyanus* by Spence Bate, which was brought from Hermit Island by the Antarctic expedition. Hermit Island is in lat. $55^{\circ} 51' 20''$ S., long. $67^{\circ} 32' 10''$ W.; Stanley Harbour in lat. $51^{\circ} 40'$ S., long. $57^{\circ} 35'$ W.

The species is separated from the genus *Atylus* by the robust mandibular palp, by the maxillipeds, of which the outer plate is not dentate, and the palp broad instead of narrow, by the fifth and sixth segments of the pleon, which are distinct, not coalesced, and by the telson, which is not divided, but very slightly emarginate. Its nearest ally seems to be *Halirages tridentatus*, Bruzelius.

For the original definition of the genus, see Note on Leach, 1815 (p. 89).

Boeck defines it as follows:—

“*Mandibles* with the palp weak and slender; the length of the second joint surpassing that of the third.¹

“*First Maxillæ* with the inner plate of moderate length, furnished with from seven to eight plumose setæ.

“*Second Maxillæ* elongate, narrow.

“*Maxillipeds* having the outer plate armed on the inner margin with many strong teeth, which as they approach the apex are elongate, curved, and finally become setiform; the inner plate elongate, strong; the palp short and narrow; the outer plate extending beyond the second joint of the palp.

“The body compressed; the back carinate; the keel on several segments forming backward-directed teeth; the head with a long curved rostrum, compressed or sub-depressed; the side-plates not very deep, sometimes rigid, plumose on the lower margin, the last two segments of the pleon coalesced.

“*Lower Antennæ* longer than the upper.

“*First and Second Gnathopods* with the hand small.

“*Second Uropods* shorter than the *third*.

“*Third Uropods* with the peduncle shorter than the telson; the rami equal.

“*Telson* cleft.”

Atylus homochir, Haswell (Pl. LXXIV.).

1885. *Atylus homochir*, Haswell, Proc. Linn. Soc. N.S.W., vol. x. pt. i. p. 7 (sep. copy), pl. xiii. figs. 5–7.

A sharp slender rostrum projecting a little beyond the triangular lateral lobes of the head, below which its lower angles are acutely produced; the whole of the back sharply carinate, the carina continuous from the tip of the rostrum to the end of the third pleon-segment, except that the seventh pereon-segment and the first three segments of the pleon are distally produced in minute teeth; the carina of the fourth pleon-segment forms two teeth, the hinder one the larger; the hinder part of the dorsally coalesced fifth and sixth segments is also produced into a large tooth, with a spine-tooth on the centre of its dorsal line, and separated by a small depression from that narrow front part of the segment which carries the second uropods; the postero-lateral angles of the first three segments of the pleon produced into small points, above each of which is placed a spine, but the lower convex lobe of the hind margin in each segment swells out beyond the lower angle; many submarginal spines on the lower margins of these segments. The integument with a scale-covered appearance.

Eyes oval or reniform, retaining colour in spirits, situate near the convex margin of the head between the rostrum and the lateral lobes, ocelli numerous, rather elongate.

Upper Antennæ.—Peduncles carinate, first joint long, about twice the length of the

¹ Not so in all species, e.g., *Atylus homochir* and *Atylus swammerdamii*.

rostrum, distally produced into a short tooth below; second joint thinner, a little longer; third joint about one-fourth the length of the second, distally a little widened, and showing a little tubercle which seems to be the rudiment of a secondary flagellum; the principal flagellum of forty joints, which widen a little distally, and are furnished with short setules, and almost every one with a cylinder shorter than the joint.

Lower Antennæ.—First three joints very short, the first with a small produced point below, the second distally angled below the gland-cone, the third equal in length to the first two united; the fourth much longer than the first three united, longer than the second joint of the upper antennæ; the fifth joint longer than the fourth, like it carinate and carrying numerous groups of slender spines; flagellum of thirty-five joints, not distally dilated, but besides having two or three groups of setules, carrying either successively or alternately (the last six excepted) a short stout spine with a bent tip.

Upper Lip with the apex furred, not very broadly rounded.

Mandibles.—Cutting plate divided into three or four small, followed by three large teeth; those represented in the Plate are worn and rounded; the new teeth as seen in preparation for the change of skin are much more sharp and distinct; the secondary plate on the left mandible divided into four teeth, of which the lowest is the most prominent; the secondary plate on the right mandible is bifid, each division showing a slender apical tooth, attended by three denticles; the spine-row of seven denticulate spines; the molar tubercle moderately prominent, with a large crown occupied by many rows of denticles, the plumose seta conspicuous; the slender palp set just over the molar tubercle, its first joint distally dilated, the second straight or nearly so, with four or five small setæ or spines on the inner margin, the third joint longer than the second, with the hind margin slightly convex, carrying at the top of the oblique apex a pectinate spine longer than the joint, two others shorter, and two more much shorter, and on the inner margin two small spines, one at the centre, the other near the apex.

Lower Lip.—Principal lobes broad, very slightly dehiscent; mandibular processes narrow, divergent.

First Maxillæ.—Inner plate small, oval, with six plumose setæ on the distal margin; the outer plate with eleven variously denticulate spines on the truncate margin, the denticulation near the apex, the two innermost spines shorter than the rest; of these eleven nine only are shown in the enlargement of fig. *mx.1.*; first joint of the palp with a spine on the outer margin, the second joint reaching much beyond the outer plate, dilated distally, carrying on the distal margin six or seven pectinate spine-teeth, shorter on one maxilla than the other, in accordance with Boeck's character for the subfamily Atylinæ, that the palp of the first maxillæ is two-jointed, *in apice maxillæ sinistræ dentibus, in apice maxillæ dextræ spinis armato*; there are also some slender submarginal spines. On the outer margin of the trunk below the palp some unequal slender spines are present.

Second Maxillæ.—The inner plate a little shorter and considerably narrower than the outer, the spines numerous and strong round the apical margin, descending the inner margin a little way, where the series ends with some densely plumose setæ, the largest lowest, the outer plate also with numerous and strong spines round the apical margin, extending a little way down the front and hinder margins.

Maxillipeds.—Inner plates rather short and broad, reaching beyond the short first joint of the palp, with five plumose setæ along the inner margin, and three stout spine-teeth on the slightly convex distal border, which is fringed with about a dozen submarginal curved plumose spines; outer plates long and rather narrow, reaching about to the end of the narrow second joint of the palp, inner and apical margins fringed with spine-teeth, passing gradually into long curved spines; in the specimen examined there were ten of the former on the inner, four of the latter on the apical, margin; second joint of the palp more than twice the length of the first, with many groups of slender spines about the inner margin; third joint much longer than the first, a little shorter than the second, with many groups of spines about the inner margin, and one group at the centre of the hind margin, which is not as usual evenly convex; there are also many spines about the apex, which is produced on the outer side; the finger small and weak, with a spine-like nail, a dorsal cilium not far from the base of the nail, and on the inner margin several setules near and at the base of the nail, those at its base being the longest.

First Gnathopods.—The side-plates narrower below than above, the front margin bent a little forwards, the corner rounded and eruncate, with spinules in the interstices, the lower part of the hind margin also carrying spines. The first joint extending much beyond the side-plate, expanding distally, the front margin almost straight, with numerous setiform spines, the hind margin more convex, armed with setæ and spinules, and on the outer surface carrying six or seven groups of curved spines, and an apical group of about twelve accompanied by long setiform spines; the short second joint has three groups at the hind margin, followed by an apical group or row of some twenty-four graduated spines, together with some long and slender ones; the third joint has scarcely any free front margin, some eight groups of spines on the hinder margin, those towards the apex being long and pectinate; the wrist is long, triangular, with five groups of spines on the front and four on the hind margin, the latter having near them rows on the inner surface; the hand is equal in length to the wrist, with an oblique palm, bordered with many spinules, and defined by several stout palmar spines among which the finger closes; besides these there are three other groups of spines on the hind margin, with attendant groups on both surfaces, but the most conspicuous ornamentation of the hand is on the inner surface (that shown in the Plate) along the front margin; here there are seven groups or rows of spines, the number in a row gradually increasing from three near the base to twenty-seven near the finger; distally the long spines of the hand and wrist are very finely

pectinate, more coarsely near the middle, at which part it is easily seen that the pectination is on two edges; the inner margin of the finger is produced into a tooth at the base of the nail; the dorsal cilium near the base of the finger is small.

Second Gnathopods.—Side-plates with the front margin convex, its lower portion serrate and spined, its lower angle rounded and crenulate as in the preceding pair. The branchial vesicles oval, broadest below, reaching much beyond the side-plates; in the specimen examined one of the pair was distally bilobed. Marsupial plates long and rather broad, longer than the branchial vesicles, the edges finely crenate for the long setæ. The limb like that of the first gnathopods, but all the joints longer, especially the hand and wrist; the armature similar, except that the hand is more simply adorned.

First Peraopods.—Side-plates broad, the front corner and much of the lower margin crenate and spined. The branchial vesicles long and broad. The marsupial plates long, not broad except near the middle. First joint, as in the preceding and the following pair, having its base close to the lower border of the side-plate, long, and nearly evenly broad, with many spines on both margins, those near the base very slender, some very long ones on the hinder margin, also with several submarginal groups on the surface near it; the short second joint has spines at three points of the hind margin, some of which, as in the preceding joint, are long and plumose.

Second Peraopods.—Side-plates very similar to the preceding pair, a little broader, the hind corner a little drawn down, as in the preceding pair with numerous spines on the lower part of front and hind margins, only a small part of the lower margin being without spines or crenulation; there are also many setæ on the inner surface of the plate in this and the three preceding pairs; the branchial vesicles large. The marsupial plates long and slender. Limbs like those of the first pair but a little shorter; the third joint longer than the next two united, with six groups of spines at the hind margin, and three on the front; the fourth joint much shorter than the fifth, like the fourth somewhat dilated distally, with two groups of spines on the hind margin, the front smooth except at the apex; the fifth joint with four groups of stout spines on the hind margin, the front slightly convex, smooth except at the apex; the finger strong, curved, longer than the fourth, shorter than the fifth joint, with two setules at the base of the strong curved nail; a small dorsal cilium near the base of the finger. In the Plate the last four joints are drawn facing the wrong way.

Third Peraopods.—Side-plates with the front lobe much narrower and deeper than the hind one, of which the lower margin is sinuous; both have the lower portion set about with spines. First joint pear-shaped, broader above than below, the hind margin fringed with curved spines, the expanded part serrate, the front margin with numerous groups of slender setæ or setiform spines, the lower margin squared, neither lobed nor decurrent; the second joint short; the third shorter than the first, longer than the fourth, not expanded, sparingly spined; the fourth longer than the fifth, with spines at three

points on each margin; the fifth a little curved, with spines at four points on each margin; the nail as in the preceding pair, but rather smaller.

Fourth Peraopods.—The side-plates in shape much like those of the preceding segment, but with the front margin straight instead of convex, and fringed with setiform spines, while the lower margin behind is strongly spined. The first joint is longer and broader than in the preceding pair, of even breadth for some way down, the convex front margin carrying numerous setiform spines on the upper part, stronger groups of spines on the serrate lower part, the hind margin serrate, fringed with many slightly plumose spines, the upper ones curved; the short second joint with two or three groups of small spines in front; the long third joint with spines at eight points of the front, and four of the hind margin; the fourth joint long and slender, shorter than the third, but longer than the fifth.

Fifth Peraopods.—Side-plates deeper behind than in front, armed like the preceding pair. The first joint shorter but broader than that of the fourth peraeopods, the armature similar, the front margin nearly straight, the hinder evenly convex; the second joint short; the third shorter than in the preceding pair, with four groups of spines on the front margin besides one or two spinules, three groups and a spinule on the hind margin, which is scarcely decurrent, with the apex squared; the fourth joint longer than the third, and considerably longer than the fifth, with four groups of spines on each margin; the fifth joint with five groups of spines on the front, and four on the hind margin; the finger as in the other peraeopods; this and the hand are twisted away from their normal position in the Plate.

Pleopods.—Coupling spines very small; a sharply produced interlocking process connects the peduncle and the first joint of the outer ramus; cleft spines seven in number on the first pair, six in the following pairs, the arms very short, and the outer but little longer than the inner; in the specimen examined the number of joints of the inner ramus of the third pair was twenty-one.

Uropods.—Peduncles of the first pair a little longer than the rami, the inner ramus a little longer than the outer, both with numerous marginal spines; the peduncles of the second pair longer than the outer ramus, shorter than the inner; the rami, like those of the first pair, tipped with spines and having many spines on the margins; neither the peduncles nor the rami reach back so far as those of the other two pairs; peduncles of the third pair short; the rami long, broadly lanceolate, bordered and tipped with spines, subequal, the outer broader and a little the longer, reaching back as far or nearly as far as the rami of the first pair.

Telson short,¹ longer than the breadth at the base, cleft for three-quarters of its length, little dehiscent, the slightly sinuous outer margins converging to the tolerably broad distal margin, each half of which carries a spine and is produced to a small point on the inner side. There are some cilia on the surface.

¹ Contrary to the generic character, not longer than the peduncles of the third uropods.

Length.—The specimen, in the position figured, from the front of the head to the back of the third pleon-segment, measured half an inch.

Locality.—Station 161, off Melbourne, April 1, 1874; depth, 33 fathoms; bottom, sand. Several specimens; the one examined was a female.

Remarks.—The relationship of this species to *Atylus veddomensis*, Bate and Westwood, is striking and close, and that species is itself not far removed from *Atylus swammerdamii*, Milne-Edwards, with which Mr. Haswell compares this. When figuring it, now some years ago, I had named the species *Atylus acutus*, but upon comparison with Mr. Haswell's account of *Atylus homochir*, I have thought it better to accept his name for the species, since the differences in his account and figures may be probably attributed to the smallness of the specimen he examined.

Genus *Atyloides*, n. gen.

Mandibles with palp well developed, the third joint as long as the second, or nearly so.

First Maxillæ with many plumose setæ on the inner plate.

Second Maxillæ with the plates elongate, many plumose setæ on the side of the inner plate.

Maxillipeds as in *Atylus*, except that the outer plate does not reach the apex of the second joint of the palp.

Body not carinate or dentate; the fifth and sixth segments of the pleon separate, not coalesced.

Upper Antennæ with a one-jointed accessory flagellum.

In other respects like *Atylus*.

The generic name refers to the likeness between this genus and *Atylus*.

From *Pontogeneia*, Boeck, the new genus is distinguished by the palp of the mandibles, by the spine-teeth (not slender spines) on the inner margin of the outer plate of the maxillipeds, by the antennæ, of which the upper are not longer than the lower, and have an accessory appendage which appears to be wanting in *Pontogeneia*. From *Amphithopsis*, Boeck, which is a synonym of *Pherusa*, Leach, it is distinguished in like manner by the antennæ, by the numerous setæ on the inner margin of the inner plate both in the first and the second maxillæ, and by the cleft telson. The name *Paramæra*, Miers, was given under a misapprehension of the characters of the species for which the genus was instituted, and being suggestive of an affinity which does not really exist, is scientifically unsuitable. It was upon fuller knowledge withdrawn by Mr. Miers himself, and cannot, I think, be conveniently revived; see Note on Miers, 1875 (p. 447).

 1882. " " Haswell, Catalogue of the Australian Crustacea, p. 244.

Rostrum minute; animal rather compressed; postero-lateral angles of the third pleon-segment rounded, the lower part of the hind margin a little serrate, the lower border of this and the preceding segment having several submarginal spines.

Eyes close to the little-developed lateral lobes of the head, rather large, reniform, dark in the specimens preserved in spirits. A few of the ocelli, as seen from the inner side, are figured on Pl. LXXV., fig. *oc*.

Upper Antennæ not long, the peduncle shorter than the flagellum, the first joint in large specimens twice as long as broad, equal in length to the next two united, in small specimens longer than broad, longer than the next two united; the third joint about half the length of the second, all three with groups of setæ on the lower side, which in the larger specimens is rough with short spiny or sealy hairs; flagellum in a large specimen of fifty-five joints, in a small specimen of twenty-one joints, tapering, the earlier joints broader than long, every other widening at the lower apex, and there armed with a group of setæ, and in large specimens two or three cylinders; the accessory flagellum consists of a single tapering or triangular joint, shorter than the first of the principal flagellum, tipped with a long seta and a shorter one.

Lower Antennæ subequal in length to the upper, the peduncle longer than that of the upper antennæ, the first joint a little expanded, the gland-cone decurrent along the side of the short third joint; the fourth joint about as long as the three preceding united, subequal in length to the fourth, but broader; the gland-cone carrying three or four setæ, the third, fourth, and fifth joints furnished with several groups of them; the flagellum of fifty-six joints in a large specimen, of twenty-four in a small specimen, the first joint longer than any of the following.

Upper Lip with the distal margin rounded, closely ciliated.

Mandibles.—The cutting plate with its edge divided into seven or eight teeth, of which the outermost but one is the largest; the secondary plate on the left mandible is similar to the principal, on a smaller scale; on the right mandible it is slender, ending in three or four teeth, of which one is more prominent than the others but very slender; the spine-row of nine or ten slender curved spines, showing serration on the convex margin; the molar tubercle broad and massive, the crown set with many denticles, the

external pointed tooth-like, the internal appearing like concentrically sinuous serrate blades; there is a small process between the molar tubercle and the base of the palp; the palp is set just over the molar tubercle, its second and third joints subequal in length, the second with the outer margin more or less concave, and with many spines along the front margin, those near the distal end long; the third joint having from five to seven on the outer surface near the base, and on the front margin an even row of close-set spines attended by others longer and more widely spaced, and at and near the apex six that are long; all or nearly all these spines are pectinate, the three terminal more finely than the three below them.

Lower Lip.—The principal lobes strongly ciliated on the inner part of the distal margin, lightly also on its outer part, little dehiscent; the mandibular lobes short, squared at the ends.

First Maxillæ.—Inner plates small, with thirteen (in small specimens seven or eight to ten) plumose setæ on the inner or oblique distal margin, those nearest the actual apex the longest, thickest, and most coarsely plumose; outer plate with eleven strong spines on the obliquely truncate distal margins, some of the spines denticulate for much of the length below the apex, others more strongly denticulate close about the apex; the second joint of the palp reaching beyond the outer plate, carrying on its distal margin seven to twelve short spines or spine-teeth, with several setæ or plumose spines adjoining, and three setæ on the outer margin.

Second Maxillæ.—The plates elongate, the inner a little narrower but scarcely shorter than the outer, carrying on its surface a row of fourteen to seventeen plumose setæ, the row beginning low down on the inner margin; the distal margins of both plates carrying numerous spines, those of the outer as usual the longer; these are curved and finely pectinate; a few short spines descend the outer margin of the outer, and the inner of the inner plate.

Maxillipeds.—The inner plates comparatively large, yet scarcely reaching as far as the distal end of the first joint of the palp, carrying several plumose setæ on the inner margin, and smaller incurving plumose setæ or spines on the distal, and distal part of the outer, margin; the truncate distal margin has three strong triangular teeth, and a fourth is inserted just below its inner apex on the outer surface; the outer plates not reaching the distal end of the second joint of the palp, having the inner margin bordered with eighteen rather long spine-teeth, succeeded round the distal margin and distal half of the outer, by eight or ten plumose setæ; there are also numerous groups of setæ on the outer surface in the neighbourhood of the inner margin for almost its whole length; this outer surface is figured on Pl. LXXV.; the first joint of the palp is short, with setæ on the inner margin and outer apex; the second joint broader and much longer, with numerous setæ in a row along the inner margin, in groups upon the surface and outer margin; the third joint longer than the first, with several groups of setæ upon the surface

and at the margins, and at the apex a graduated row of strongly pectinate spines ; the finger short and broad, with a sharp nail having a cilium at its base ; the inner margin of the finger smooth near the base, then set with eight setules ; in the small specimens there are fewer spine-teeth on the outer plate, and fewer setules on the edge of the finger.

First Gnathopods.—Side-plates rounded below. First joint reaching much beyond the side-plate, the front margin straight, with small setæ, the hinder with some long and short setæ near the base and a group of spines at the apex, some of them pectinate ; the second joint short, with spines at the apex behind ; the third joint rhomboidal, with spines on the hinder and lower margins, the front margin apically produced ; the wrist shorter than the hand in the young and female, very much shorter in the adult male, with numerous distally pectinate spines about the free portion of the hind margin, which is somewhat serrate ; the hand in the adult male broader than the wrist, widest at the palm, with six groups of spines along the straight hind margin and several small groups on the inner surface ; the palm convex, a little oblique, fringed with setules, a row of five or six broad spines of different lengths on the surface on either side of it ; the curved finger when closed shows its tip just beyond the palm ; it has some spinules or teeth on the inner edge and a small dorsal cilium not very far from the base.

Second Gnathopods.—Side-plates oblong, with rounded ends, deeper than the preceding pair. Branchial vesicles long and of great breadth, narrowing little distally. Marsupial plates very long and broad, narrowing distally, with many long setæ round the distal end and inner margin. The limb closely resembles that of the first gnathopods, but with the first, third, fourth, and fifth joints more elongated ; the apical spines on the hind border of the first joint show the same pectination. Both the first and second gnathopods of the male specimen examined were beset with a parasitic zoophyte in great number ; their appearance on the first joint of the first is figured Pl. LXXV. fig. *gn.1.♂*. In both gnathopods the hand is very much narrower in the young and female than in the male.

First Peræopods.—Side-plates like the preceding pair but larger. Branchial vesicles with a narrow neck, then gradually expanding and again narrowing slightly, very long. Marsupial plates broad, even distally, longer than the branchial vesicles, with long setæ all round, sparsely on the outer side. First joint of the limb reaching beyond the side-plate, with short spines along the straight front margin, some long setæ on the hinder margin and groups of spines ; a group of spines on the hinder apex of the second joint ; several groups on both margins of the third joint, which is broader than the fourth or fifth, longer than the fourth, but subequal in length to the fifth, its front apex somewhat decurrent ; the fourth and fifth joints have numerous groups of spines on the hinder margin, while the front margin is slightly armed ; the finger is short, curved, with a small dorsal cilium near the base, and two cilia at the base of the nail.

Second Peræopods.—Side-plates much broader but very little deeper than the pre-

ceding pair, excavate behind but not far down. The limb and its appendages not materially different from the preceding pair.

Third Peræopods.—Side-plates broader than deep, the hind lobe deeper than the front one. Branchial vesicles much larger than the first joint. Marsupial plates small. First joint tending to oval in form, broader above than below, with setæ on the upper part of the front margin, succeeded by several groups of spines, the more convex hind margin very slightly serrate and scarcely armed; the second joint short, with two groups of spines in front, partly overlapped behind by the lower lobe of the first joint; the third joint like that of the preceding peræopods, but rather larger; the fourth and fifth joints likewise resembling those of the preceding pair, but being rather wider; the finger similar.

Fourth Peræopods.—Side-plates with a downward-produced hind lobe. Branchial vesicles broad but not descending quite to the lower end of the first joint, with an accessory pocket quite at the base. The limb resembling that of the preceding pair, but with the joints longer, except perhaps the second and the finger.

Fifth Peræopods.—Side-plates as usual small, deeper behind than in front. Branchial vesicles broad, but short, not reaching the middle of the first joint. The first joint broader and longer than in the preceding pair; the second and third joints similar, but the spines on the front margin of the third differently grouped.

Pleopods.—The peduncles produced on one side into an irregular tongue-like process beside the first joint of the outer ramus; the coupling spines slender, with three or four denticles; the cleft spines in the adult numbering six on the first pair, five on the third; in the young there appear to be but four on the third pair; the joints of the rami numbering fifteen or sixteen in the young, twenty-five or twenty-six in the adult.

Uropods.—Peduncles of the first pair longer than the rami; outer ramus shorter than the inner, both spined along the edges and tipped with spines; peduncles of the second pair shorter than the longer inner ramus; the rami armed as in the preceding pair, which they much resemble, carrying many more spines in the adult than in the young specimens; peduncles of the third pair much shorter than the rami, reaching back beyond those of the second, and just level with those of the first pair; the rami long, broad, lanceolate, acute, fringed on the margins with numerous spines and setæ, the outer scarcely shorter than the inner, reaching back just as far as the inner ramus of the first pair.

Telson much longer than the peduncles of the first uropods, cleft beyond the centre, tapering, not dehiscent, with a small emargination carrying a spine on the side just above each apex, or it may be said that each apex is emarginate, with the outer horn of the emargination shorter than the inner.

Length.—One of the specimens, in a very slightly curved position, measured three-fifths of an inch, exclusively of the antennæ; this was an adult female.

Locality.—The specimens were all obtained at Kerguelen Island, the larger from a depth of 25 fathoms, the small ones, which were numerous, from the surface.

Remarks.—I was at first disposed to consider the small specimens a distinct species from the larger; the integument does not show the covering of spiny hairs which are conspicuous on parts of the large specimens, the proportions of the peduncular joints of the antennæ are not the same, the number of joints in the flagella are very different; on the inner plate and palp of the first maxillæ, on the inner plate of the second maxillæ, on the outer plate of the maxillipeds, there are differences in the number of teeth or of setæ; on gnathopods, pereiopods, and uropods there are similar differences of proportion or of number of spines and spine-groups; but all these distinctions explain themselves very naturally and consistently on the hypothesis that the small specimens are the young and the large full-grown.

The species has a considerable resemblance to *Atylus austrinus*, Spence Bate, from Sydney, but in that the "dorsal surface is not denticulated," though the specimen was large, " $\frac{1}{2}$ ths of an inch," and notably it differs from the present in having "posterior pair of pleopoda naked, and considerably longer than the two preceding pairs."

That the present species is the same as *Atylus australis*, Miers, cannot, I think, be doubted, although Mr. Miers did not find the accessory appendage of the upper antennæ in any of his four specimens, and though he speaks of the maxillipeds as being *five-jointed*, a description possibly suggested by the groove which runs across the base of the outer plate of the maxillipeds.

So far as I can judge from Mr. Haswell's description and figure of his *Atylus megalophthalmus*, from Clark Island, Port Jackson, that is synonymous with the present species. Mr. Haswell speaks of it as very variable, "the size of the eyes and their degree of approximation above, the length of the antennæ, and the form of the gnathopoda being all subject to considerable variations," remarks which would well apply to *Atyloides australis*.

Atyloides assimilis, n. sp. (Pl. LXXVII.).

Rostrum minute, lateral lobes of the head rounded, not very prominent; third pleon-segment having the postero-lateral angles produced, but only minutely. Animal closely resembling *Atyloides australis*, Miers.

Eyes situated close to the lateral lobes of the head, large, reniform, retaining their dark colour in spirits.

Upper Antennæ.—First joint thicker and a little longer than the second, second thicker and a little longer than the third, all three with groups of setæ on the lower margin, one at the apex being long and spiniform; flagellum of sixteen joints, several of

which have long setæ, spiniform and plumose like those at the apices of the peduncular joints; the one-jointed accessory flagellum as long, or nearly so, as the first of the principal, tipped with a long plumose seta and a shorter one. In those specimens of *Atyloides australis* which are comparable in size with the specimen here described, the proportions of the joints of the peduncle differ, and the present specimen has more groups of setæ than larger specimens of the allied species.

Lower Antennæ with the fourth joint shorter than the fifth; the flagellum of eighteen joints, the first longer than any of the others, showing within the markings of the new joints preparing for the next exuviation, an appearance not unusual, and observed also in specimens of the allied species.

Upper Lip.—The distal part shallower and more broadly rounded than in *Atyloides australis*.

Mandibles.—On the cutting plate of the left mandible there are two denticles outside the most prominent tooth, while *Atyloides australis* has apparently only one in that position.

First Maxillæ.—There are six plumose setæ on the oblique distal margin of the inner plate, the apical the largest, and eleven spines on the distal margin of the outer plate, similar in structure to those of the kindred species.

Maxillipeds.—On the outer plates there are five spine-teeth on the distal part of the inner margin, not set so closely together as the more numerous teeth in the other species; the finger is rather longer in proportion to the third joint, and has a long eilium on the back, set further back from the base of the nail than in *Atyloides australis*.

First Gnathopods.—Side-plates somewhat squared below; on the inner surface of the hand there are six small groups of spines in line, beginning near the base, the sixth being on the front margin not far from the apex; in the large specimens of *Atyloides australis* there are five groups rather differently arranged, and in the small specimens four groups; the palm in the present species is more oblique, the finger reaching just beyond it as in the adult male of the other species.

Second Gnathopods.—These, like the first gnathopods, have few setules on the front margin of the first joint instead of many as in *Atyloides australis*, and the palm more oblique and more groups of spines on the inner surface of the hand than in that species.

Peræopods all broken below the third joint, the remaining portions not showing any characteristic difference from those of *Atyloides australis*.

Pleopods.—Cleft spines two or three, joints of the rami ten or eleven.

Uropods similar to those of *Atyloides australis*, except that the rami of the second pair appeared to be subequal, the outer rather the longer; but as the tips were damaged, this is a little doubtful, the fewness of the spines on peduncles and rami of all the pairs might be due to the smallness of the specimen.

Telson shaped like that of *Atyloides australis*, but not longer than the peduncle of the third uropods.

Length.—The specimen, in the position figured, exclusive of the antennæ, measured something less than one-fifth of an inch.

Locality.—From the screw of the Challenger on December 18, 1873, a date which corresponds with Station 142, off Cape Agulhas; lat. $35^{\circ} 4' S.$, long. $18^{\circ} 37' E.$

Remark.—The specific name refers to the great likeness between this species and *Atyloides australis*.

Atyloides serraticauda, n. sp. (Pl. LXXVIII.).

Rostrum minute; first and second segments of the pleon with the postero-lateral angles forming a minute tooth; the second having about the middle of the so-called epimera or immovable side-plates a row of eight spines, the largest lowest, with an anterior row of four; third segment of the pleon having the postero-lateral angle toothed, with a rather larger tooth on the hind margin immediately above that at the angle; the lower margin having in its anterior half several submarginal spines singly and in groups. Surface hairy.

Eyes large, reniform, retaining colour in spirits, situated near the lateral lobes of the head, and with only a narrow space between them at the top of it.

Upper Antennæ.—First joint more than twice as long as broad, longer than the second and third together, its upper margin longer than the lower; second joint twice the length of the third joint, which is small, not twice as long as broad; flagellum with sixty-two joints remaining in the specimen examined, about five times as long as the peduncle; the accessory flagellum rudimentary, consisting of one conical joint, about half the length of the first joint of the primary flagellum, tipped with two or three small setæ, and having a small hair on the margin.

Lower Antennæ.—First three joints short, the first very little expanded, the gland-cone decurrent, and, like the first and third joints, with short setæ at the apex; the fourth joint equal in length to the preceding three united, a little shorter than the fifth, its upper margin produced in a small rounded projection; the fifth joint having like the fourth several groups of stiff setæ on the under or inner side; the flagellum of thirty-four joints, of which the first equals between three and four of those which follow it.

Upper Lip.—The outer plate rather narrowly rounded at the distal end, the central part of this margin closely set with microscopic teeth or spinules.

Mandibles.—Cutting plate with seven or eight teeth; secondary plate on left mandible widened distally, cut into five teeth; on the right mandible slight in structure,

distally divided into two long teeth, curved towards each other, a denticle projecting from the side of the inner and longer of the two; spine-row of about eight denticulate spines; molar tubercle close to the spine-row, with the denticles of the crown rather elongate; a small process between the molar tubercle and the palp; the palp is set over or a little in advance of the molar tubercle, the first joint short, the second with the outer rim slightly concave, having some spines along the surface towards the inner margin, the third joint a little shorter than the second, widening distally, the outer margin very convex, with a spine about a third of the way up it and another on the adjoining surface, also with a row of five long spines on the outer surface near the base, none on the inner margin, but some sixteen of various sizes on the broad, truncate, slightly oblique, distal margin.

Lower Lip.—Principal lobes rather deep and thick, little delhiscent, well ciliated on the inner margin.

First Maxillæ.—Inner plate rather large, with some sixteen plumose setæ along the inner and apical margins, that adjoining the actual apex being the longest and thickest; outer plate with eleven spines on the truncate distal margin, the denticulation of the spines being confined to the distal part of their inner margin and there having a prominent convex outline; the first joint of the palp longer than broad, with one or two spinules on the outer margin, the second joint wide, with one or two spinules on the convex outer margin, and eight or nine spine-teeth on the truncate distal margin, accompanied by several setæ or slender spines inserted on the surface below the spine-teeth.

Second Maxillæ.—The plates elongate, inner a little shorter than the outer, about equal to it in breadth, with a long row of plumose setæ on the surface, beginning low down on the inner margin, and spines passing round the apical and a little way down the inner margin; the outer plate with a similar arrangement of longer spines, also some short ones at the apical part of the outer margin, and two or three spinules near the base of it.

Maxillipeds narrow. Inner plates long, reaching to the distal end of the first joint of the palp, with several plumose setæ on the inner margin, three spine-teeth and some curved spines on the truncate distal margin; the outer plates not reaching to the distal end of the second joint of the palp, with fourteen or fifteen spine-teeth on the slightly concave inner margin, six curved setæ passing round the apical margin and distal part of the outer margin; there is a row of spines on the outer surface near the inner margin; first joint of the palp as long as the third; the second longer, bordered with not very numerous spines; the third with its distal margin as usual set round with spines, produced on the outer side over the base of the finger; the finger small, with a spine-like nail, near to which are three or four cilia; the dorsal cilium near the base very small. The figure of these maxillipeds shows the inner plates

gaping widely, as they happened to be drawn apart in mounting for the microscope, but it is of interest that in very few species could the inner plates have been thus drawn apart either accidentally or on purpose without fracturing the maxillipeds.

First Gnathopods.—Side-plates wider below than above, with two or three serrations at the hind corner of the convex lower margin. First joint reaching below the side-plate, with a few long setæ on the hind margin, and many spinules about both margins; second joint with a group of spines on the hinder apex, and spinules in other parts; third joint with groups of spines about the hind margin and near the pointed apex; the wrist not very much shorter than the first joint, considerably longer than the hand, with five groups of setiform spines on the front margin, and many groups of stronger spines along the hinder, and oblique part of the distal, margin; the hand parallel-sided, about three times as long as broad, armed like the wrist, with a group of short thick spines near the angle of the palm, within which, and not beyond it, the short finger closes over a convex palm set with setules. The numerous spines on the hind margins of the hand and wrist are of various lengths, all apparently with small accessory threads, and a great many, but not the longest, with broad bent tips and extremely fine pectination of the edges for some distance below the tips; the bent tip when seen broadside instead of in profile appears to be a distal expansion, somewhat paddle-shaped, with the convex edge presenting a slightly wrinkled look, and at the lower part broken into teeth; see the fig. *gn.2.sp.*

Second Gnathopods.—The side-plates longer than the preceding pair and of more even breadth. The branchial vesicles are shorter than the first joint of the limb, narrow oval, with a long neck. Marsupial plates much longer than the first joint, and of great breadth, with numerous setæ of moderate length. The limb in general similar to the first pair, but all the joints longer, the wrist with fewer spines, the hand equal in length to the wrist, with nine pairs of the broad-ended spines along the hinder margin, and five or six groups of spines on the inner surface adjoining.

First Peraopods.—Side-plates like the preceding pair, but larger. Branchial vesicles broader, as long as the first joint. Marsupial plates of great size. First joint reaching beyond the side-plate, with some spines on the hind margin, spinules on both margins; second joint with two groups on the hind margin; third joint longer than fourth, a little decurrent in front, ending obtusely, with slender spines at four points of the hind margin, and stouter ones at four or five points of the front; fourth joint with spines at six points of the hind margin, a few spinules in front; the fifth joint as long as the third, parallel-sided, with numerous groups of short spines on the hind margin, some setules on the front; finger curved, with a small projecting point of the inner margin adjoining the nail, and a small dorsal cilium near the base.

Second Peraopods.—Side-plates broader and longer than the preceding pair, not very deeply excavate behind. The branchial vesicles larger, a broader oval, the mar-

supial plates smaller than in the preceding pair; the limb in all material points resembling the first peraeopods.

Third Peræopods.—Side-plates not very deep, hind lobe a little deeper than the front. Branchial vesicles smaller than in the preceding pair. Marsupial plates narrow, not very long. First joint of the limb broadly oval, broader above than below; the front margin with spines, the hinder, which is the more convex, serrate, the lower lobe scarcely at all overlapping the short second joint; the third joint rather shorter than in the two preceding pairs, with spines at four points on each margin, the hinder a little decurrent, ending obtusely; the rest of the limb missing.

Fourth Peræopods.—Side-plates with a lobe behind, very decurrent. First joint similar to that of the preceding pair but larger; third joint also longer, with six groups of spines on the front, four on the hind margin. The rest of the limb missing.

Fifth Peræopods.—Side-plates small, not decurrent. Branchial vesicles not nearly as long as the first joint, narrow, with parallel sides, a short piece at the base being much narrower than the rest. The first joint larger than in the preceding pair; the third joint rather straighter than in the preceding pair, with spines at five points on each margin, the spines stronger. The rest of the limb missing.

Pleopods.—There are long and short spines on the side and apex of the peduncles; the coupling spines are small, so far as observed, with one strong lateral retroverted tooth in addition to the apical, and a row of denticles along one edge; the eleft spines appear to be four in number; the joints of the rami fourteen to sixteen.

Uropods.—Peduncles of the first pair a little longer than the inner ramus; the rami slender, with spines on the edges and the blunt tips, the outer ramus shorter than the inner; peduncles of the second pair longer than the outer, shorter than the inner ramus, reaching back to about the same point as the preceding peduncles; the rami rather broader, respectively shorter than those of the first pair; peduncles of the third pair shorter than the rami; the rami broadly lanceolate, subequal, with spines on both margins, and little teeth on the inner margin near the base of the spines; the inner and upper ramus has its inner margin pectinate; both have a nail-like termination, with a cilium near the tip.

Telson longer than the peduncles of the third uropods, broadest at the base, longer than its greatest breadth; eleft for nearly three-quarters of its length, not dehiscent, lateral margins convex or a little sinuous, the distal end emarginate, the end of each lamina being cut into five teeth, with small cilia in the interstices.

Length.—The specimen, in the position figured, measured, from the front of the head to the back of the third pleon-segment, a quarter of an inch.

Locality.—Station 161, off Melbourne; depth, 33 fathoms; bottom, sand. Two specimens.

Remarks.—The specimen described is a female. The specific name refers to the apical serration of the telson.

The species has some remarkable resemblances to *Amphithopsis longimana*, Boeck, from which however it is clearly distinguished by its cleft telson. It is also generically distinguished from *Amphithopsis* by the spine-teeth on the inner margin of the outer maxilliped plate, but it should be noticed that while Boeck gives to this part in *Amphithopsis* the generic character *spinis tenuibus instructa*, he states that the species *Amphithopsis longimana* has it furnished with teeth, “den ydre Plades hele indre Rand er vaebnet med taetstaaende, men korte Taender.”

Genus *Atylopsis*, n. gen.

Upper Lip with the distal margin more or less bilobed.

Mandibles with strong palp; the third joint as long as the second.

First Maxillæ with a few setæ on the distal margin of the inner plate.

Second Maxillæ with some plumose setæ on the surface of the inner plate.

Maxillipeds.—Outer plate without teeth on inner margin, not reaching the apex of the palp's second joint; third joint of palp apically produced over the base of the finger.

Antennæ with short peduncles.

First and Second Gnathopods similar in shape, the second larger than the first.

Uropods of the first and second pairs with the outer branch shorter than the inner; peduncles of the third pair short.

Telson subequal in length to the peduncles of the third uropods, cleft or emarginate.

The generic name points to the likeness between this genus and the *Atylinæ* of Boeck, although the upper lip is not apically rounded but incised.

From *Pontogeneia*, Boeck, which it closely approaches, it is further separated by having the third joint of the mandibular palp equal in length to the second, instead of much shorter.

From *Pherusa*, Leach, and its synonym *Amphithopsis*, Boeck, another near ally, it is distinguished both by the incised upper lip and by the telson being more or less divided; *Amphithopsis longimana*, indeed, has the apex of the telson a little incised, but that species disagrees with the generic definition both in this respect and in having teeth on the outer plate of the maxillipeds.

Had the type species of *Pherusa*, Leach, been anywhere described in detail, it might have been advisable to group the species of the present genus provisionally with it, but since the published descriptions of *Pherusa fucicola* only refer to the external characters, no advantage was to be gained by adopting a name which might afterwards prove more unsuitable than it seems at the moment. Boeck uses the shape of the distal margin of the upper lip as one of the characters by which he distinguishes his subfamilies; whether

it is in reality a mark of distinction on which great stress ought to be laid, is a matter still open to inquiry; in small specimens it does not lend itself very readily to the determination of the species, but its intrinsic importance cannot be judged by the student's convenience. But for the upper lip the present genus might be united with *Halirages*.

Atylopsis magellanicus, n. sp. (Pl. LXXIX.).

Head angled in front, with no proper rostrum; the first three segments of the pleon with the postero-lateral angles acute, a little outdrawn in the second, and more decidedly in the third, the hind margins sinuous.

Eyes rather large, reniform.

Upper Antennæ.—With the first joint longer and thicker than the second, but neither very long; the rest of these appendages was missing.

Lower Antennæ.—First three joints very short, the fourth shorter than the first of the upper antennæ; the rest missing.

Upper Lip with the distal end broadly and flatly rounded, with a slight tendency to be unequally bilobed. The figure in the Plate gives only a profile view; the description was made possible by the dissection of a second specimen after the Plate had been engraved.

Mandibles short and compact; the cutting plate short, divided into six or seven teeth, the outermost small, the two next considerably larger; the inner plate on the left mandible widening distally, the edge divided into five teeth, of which the lowest is the largest; the secondary plate on the right mandible was not well observed, but appeared to be as usual of slighter build than that on the left; spine-row of seven or eight serrate spines; the molar tubercle close to the spine-row, short but prominent, with the crown surrounded by long denticles; the process close above it is short and conical, and immediately succeeded by the palp, of which the first joint is short, the second broad, slightly concave behind, the surface near the front margin set with a few setæ or spines, those near the apex being long; the third joint is as long as the second, with the outer margin convex, with two spines on the outer surface near the base, the inner margin obtusely angled rather than convex, with three pairs of setiform spines near the centre, followed by five spines, pectinate strongly on two edges, of which the lower two are longer than those which follow, these five being succeeded by five more at the apex, of which the earlier two (especially the second) are stronger and more strongly pectinate than the remaining three.

Lower Lip.—Principal lobes little dehiscent, inner lobes short but rather thick; mandibular processes short, squared at the end.

First Maxillæ.—Inner plate oblong, the distal margin truncale, slightly oblique, carrying five plumose setæ, of which the innermost is not larger than the one next it,

and is succeeded on the apex by a small spine or spine-like cilium, of which there are three more along the inner margin; along this inner margin there is a hairy strip of the surface; the outer plate carrying on its truncate distal border eleven spines variously denticulate, the innermost the longest, the next much shorter, with the denticulation on the outer side; the second joint of the palp reaching beyond the outer plate, its distal margin cut into strong sharp teeth, between which are inserted six spine-teeth with serrate edges, the outermost the longest; four or five setiform spines are inserted on each surface just below the teeth.

Second Maxillæ.—The inner plate a little shorter and narrower than the outer, with a row of six plumose setæ on the surface, beginning below the centre of the inner margin; twelve or fourteen spines partially fringe the rounded apex and apical part of the inner margin; longer spines, plumose or pectinate, fringe the distal margin of the outer plate, increasing as usual towards the outer corner, and then followed by some short ones.

Maxillipeds.—Inner plates scarcely reaching so far as the distal end of the first joint of the palp, with plumose setæ on the inner margin, some small teeth (probably the usual three) and curved spines on the truncate distal margin; outer plates small, reaching beyond the middle of the second joint of the palp, inner margin slightly serrate, without teeth, with seven groups of slender, not acute, spines, inserted on the outer surface in pairs, except the lowest, which is solitary; beyond the rounded apex the distal border is armed with two plumose spines, followed by two plumose setæ; the first joint of the palp is short, with two setæ on the inner and one on the outer apex; the second joint, twice as long as the first, is fringed with setæ on its inner and oblique apical margin, with a group at the outer apex, and one on the outer margin below the apex; the third joint is longer than the first, being distally prolonged in a sort of triangular cap with ciliated edges over the base of the finger, the distal part of the inner margin is fringed with setæ, there is a small one in the middle of the hind margin, a group at the base of the cap, one near the tip of the cap, and some serrate spines near its base; the dorsal cilium of the finger is at some distance from its base; a group of three cilia is planted near the base of the long and large nail.

First Gnathopods.—Side-plates not very deep, wider below than above, slightly produced forwards, with some cilia along the lower margin, which is serrate towards the hinder angle. The first joint reaching beyond the side-plate, with some small spines along the margin; third joint rhomboidal, with two pointed apices, a group of spines on the lower margin, a few spines higher up, and the distal half of the hind margin lightly furred; the wrist as long as the hand, with groups of serrate spines on the hind margin and the free slope of the distal margin, the long front margin having spines at the apex; the hand more than twice as long as broad, widest at the palm, which is straight, slightly oblique, set with setules of various lengths, and defined by a group of stout spines of various lengths, and carrying a small plumose seta

close to the finger-hinge; there are five groups of spines along the hind margin of the hand, four near that margin on the inner surface, and other groups adjoining the front margin and its apex; the finger is short to match the palm, its inner edge divided into four decurrent teeth with cilia, the nail long and sharp, accompanied by cilia at the base; the dorsal cilium small, not far from the base of the finger.

Second Gnathopods.—Side-plates oblong, deeper than the preceding pair, a little wider below than above. Branchial vesicles a narrow oval, shorter than the side-plate. Marsupial plates broad oval, much larger than the branchiae, longer than the side-plates, with no setæ in our specimen, but indications of their places of attachment. The limb in shape and armature resembling the first pair, except that all the joints are longer; the hand longer than the wrist, with an extra group or two of spines, and the finger with an extra tooth on its inner margin.

First Peræopods.—Side-plates, branchial vesicles, and marsupial plates as on the preceding segment, but rather larger. First joint of the limb reaching beyond the side-plate, broader and a little longer than in the second gnathopods; the second joint short; the third more than twice as long as broad, with small spines or setules at three points on each margin, and a group at each apex; the front apex decurrent, sharp, with a strong spine close to the tip.

Second Peræopods.—Side-plates very broad, at the greatest breadth broader than deep, the excavation behind wide but not very deep. Branchial vesicles reaching as far as the side-plate, but much less broad. The marsupial plates longer and broader than the branchial vesicles. The first and second joints as in the first peræopods; the third rather longer than these; the fourth joint shorter than the third, with groups of spines at three points of the hind margin, of setules at two points of the front margin; the fifth joint subequal in length to the third or a little longer, with groups of spines at six points of the hind margin, of setules at four points of the front; the finger strong, slightly curved, the inner margin produced into a short point in advance of the short nail.

Third Peræopods.—Side-plates broad, the hinder lobe rather deeper than the front. Branchial vesicles about as long as the first joint of the limb. Marsupial plates a narrow oval, reaching a little below the side-plates. First joint broad oval, wider above than below, with spines on the front margin, the hinder serrate with small cilia in the serrations; the second joint with spines at the front apex, overlapped behind by the lower lobe of the first joint; the third joint with four groups of spines in front, five behind, those on the decurrent hinder apex being numerous and strong; fourth joint shorter than the third, like it widest distally, with three groups of spines in front, two behind; the fifth joint longer than the third, not widening distally, with five groups of spines on the front margin, three on the hinder, and a group of cilia at its apex; the finger as in the preceding pair.

Fourth Peræopods.—Side-plates with a lobe rather deeply decurrent behind. Bran-

chial vesicles a little smaller than in the preceding pair. The first joint larger than in the third pereopods, but similar in shape; the second and third also similar, the third rather larger; the rest of the limb missing.

Fifth Peraopods.—Side-plates broader than deep. Branchial vesicles smaller than the side-plates. First joint larger than in the preceding pair, much broader above than below; the third joint similar in shape and armature, but larger than there; the fourth joint like that of the third pereopods, but longer, with four groups of spines in front and three behind; the fifth joint in like manner with six groups in front and four behind, in addition to the apical group of cilia; the finger rather more than half the length of the fifth joint.

Pleopods.—There is a group of four spines near the distal end of the peduncles (at any rate in the third pair), one of which is very long and strong; there are others less conspicuous in other parts; the coupling spines are very small, their teeth small and seemingly not much retroverted; the cleft spines are three in number; the joints of the rami numbering from eleven to thirteen.

Uropods.—Peduncles of the first pair long, with many small spines on the edges; the rami broken, their basal portions narrow, suggesting that they would be in total length shorter than the peduncles; peduncles of the second pair longer than the outer ramus, with two large spines on one margin, and one spine at the apex of the other margin; the outer ramus with pectinate edges, four spines along one margin, and an apical group of three spines, the inner ramus broader and longer, the end broken; peduncles of the third pair shorter than the one remaining ramus, which is lanceolate, with pectinate edges, and has three spines along one margin, and four along the other.

Telson not longer than the peduncles of the third uropods, longer than the breadth at the base, narrowing a little distally, cleft for about two-thirds of its length, a little dehiscent between the two acute apices, from which the distal margin slopes upward, having on each side two serrations in each of which there is a small cilium.

Length.—The specimen, in the position figured, from the front of the head to the back of the third pleon-segment, measured one-fifth of an inch.

Locality.—Station 313, off Cape Virgins, Patagonia, January 20, 1876; depth, 55 fathoms; bottom, sand; bottom temperature, $47^{\circ}8$. Two specimens. Trawled.

Remarks.—The specimen examined and described was a female. The specific name refers to the place of capture. From *Iphimedia capensis*, Dana, renamed *Atylus capensis* by Spence Bate, which was taken at the Cape of Good Hope, the present species differs in having longer wrists, and the distal margin of the telson with fewer serrations. There are many points in which the imperfect state of the Challenger specimens on the one hand, and the brevity of Dana's description on the other, prevents

comparison. The likeness between the two species makes it probable that they belong to the same genus; the distance between the localities at which they were obtained adds a little to the probability that they are in fact specifically distinct.

Atylopsis dentatus, n. sp. (Pl. LXXX.).

Rostrum small, rounded, lateral lobes of the head not prominent, with sinuous outline; last segment of the pereon and first two of the pleon each dorsally produced backwards in a small tooth; first three segments of the pleon with the postero-lateral angles also produced in a small tooth, the lower border of the segment having a conspicuous spine; the integument rather hairy.

Eyes round, oval, near the front of the head, with slender ocelli.

Upper Antennæ.—First joint shorter than the head, longer than the second joint; second joint not much longer than thick; the rest missing.

Lower Antennæ.—First three joints short, gland-cone decurrent; fourth joint shorter than the first three united; the rest missing.

Upper Lip bilobed, very finely ciliated, one lobe more advanced and much broader than the other.

Mandibles.—Cutting plate divided into seven or eight teeth; secondary plate of the left mandible divided into five or six teeth, of which the lowest is the longest; on the right mandible the secondary plate is slighter, distally bifid, with two slender teeth conspicuous, the lower one the longer; spine-row of six plumosely serrate spines mixed with long cilia; close to the spine-row is the molar tubercle, the crown of which has several rows of strong denticles and a plumose seta; set just over the tubercle is the strong palp, the first joint a little dilated distally, the second rather stout, with a few spines near the front margin; the third joint as long as the second, with nine spines on the upper part of the front margin and the apex, of which the two actually at the apex are the slenderest, the others being broader and conspicuously pectinate on two edges; near the base, on the surface near the convex hind margin, are two pectinate spines, one much longer than the other, boldly pectinate in its lower part, and finely in the upper.

Lower Lip.—Principal lobes broad, distally somewhat narrowed and dehiscent, lightly ciliated; inner lobes short; mandibular processes short, blunt-ended.

First Maxillæ.—Inner plate small, with two setæ on the apex; outer plate carrying on the truncale distal margin ten spines, the three shortest of which are fureate, the others denticulate; the second joint of the palp reaching beyond the outer plate, broadest near the distal margin, which is dentate and has four spine-teeth of different lengths, besides two or three slender submarginal spines. Though only ten spines were seen on the outer plate, it is probable that the normal number is eleven.

Second Maxillæ.—The inner plate shorter and decidedly narrower than the outer, with two plumose setæ, one on the surface near the distal part of the inner margin, the other further from the inner and nearer the distal margin; on the distal margin there are six or seven spines, and rather more than that number on the outer plate, with the usual gradations.

Maxillipeds.—(These in dissection came away adhering to the first gnathopods.) The inner plates not reaching as far as the distal end of the short first joint of the palp, with a few plumose setæ on the inner margin, three small teeth and some slender curved spines on the truneate distal margin; the outer plates small, scarcely reaching beyond the middle of the second joint of the palp, the inner margin smooth, with a few submarginal spines on the outer surface near it, and four on the distal part of the inner surface; there are three curved spines in notches of the distal margin; second joint of the palp widening a little distally, not twice the length of the first, with a few slender spines on and near the front margin; the third joint rather longer than the first, produced in a short pointed ciliated cap over the base of the finger, the distal margin surrounded with spines; one spine near the middle of the hind margin; the finger small and slender, its inner margin sinuous, with a couple of cilia near the sharp spine-like nail; the dorsal cilium long, set not very close to the base of the finger.

First Gnathopods.—Side-plates short, oblong, but wider below than above, outdrawn at the lower front corner in a rounded angle. First joint of the limb reaching much below the side-plate, its margins almost naked; second joint short; third forming a sharp triangular tooth at the hinder apex, with a few pectinate spines near it, the front apex which rests on the wrist being also sharp; the wrist shorter than the first joint, equal in length to the hand, the front margin almost unarmed, the hinder armed at four points with pectinate spines; the hand a little widened distally, the front margin convex, longer than the hinder, carrying a few long setiform spines; the hinder margin straight, with a group of pectinate spines at the centre, and another at the apex, including a stout pectinate spine; the palm short, convex, quite distinct from the hind margin, yet not sharply defined, armed with a few setules, and having one that is plumose adjoining the hinge of the finger; the finger reaching with the nail beyond the palm, having a small decurrent tooth about the centre of its inner margin, and a few cilia near the nail; the dorsal cilium near the base, very small.

Second Gnathopods.—Side-plates small, oblong, both the lower corners rounded. The branchial vesicles as long as the side-plates, oval, flask-shaped. The first three joints of the limb as in the preceding pair, but longer; the wrist distally broader than in the preceding pair, not so long as the hand; the hand similar to that of the first gnathopods, but considerably longer and broader; the finger thicker.

First Peraopods.—Side-plates and branchial vesicles a little larger than in the preceding segment. First joint of the limb reaching much below the side-plate, broader

and longer than in the gnathopods ; the second joint short ; the third scarcely decurrent in front, a little longer than the fourth, shorter than the fifth joint, weakly armed, the longest spine being on the front apex ; the fourth joint with spines at three points of the straight hind margin, setules at two points of the convex front ; the fifth joint almost straight and of even breadth, with spines at four points of the hind margin, and three groups of setae in front ; the finger almost straight on the inner margin as far as the cilium at the base of the much-curved nail ; a small dorsal cilium near the base of the finger is followed by two others at intervals on the dorsal margin, which has a minutely pectinate appearance.

Second Peraopods.—Side-plates a little longer and broader than the preceding, the attachment narrow, the excavation behind being broad and shallow, the hind margin below the excavation sloping gently forwards. The limb missing below the third joint ; the upper part closely resembling that of the first pereopods.

Third Peræopods.—Side-plates broader than the preceding, the hind lobe a little deeper than the front. First joint broadly oval, rather wider above than below, with spinules at two points and spines at two points of the front margin, and six spinules in the serrations of the hind margin ; there is also a spine on the inner surface at the hinder apex within the wing ; the short second joint with a spine at the front apex ; the third joint with spines at three points on each margin, those on the squared slightly decurrent hinder apex forming a tolerably strong group ; the fourth joint a little expanded distally, shorter than the third joint, carrying spines at three points in front and on the hinder apex ; the fifth joint with spines at four points in front, and two behind ; the finger as in the preceding peræopods.

Fourth Peræopods.—Side-plates with a somewhat decurrent hind lobe. The branchial vesicles reaching a little below the hind lobe of the side-plate, and having apparently a small narrow accessory sac near the base. The first three joints of the limb resemble those of the third pereopods, but the first and third are larger ; the rest of the limb missing.

Fifth Peræopods.—Side-plates small, almost semicircular, but the front margin bent and flattened. Branchial vesicles minute, oval, pointing backwards. The first joint longer and much broader than in the preceding pair, much broader above than below ; the third joint similar to that in the preceding pair, but rather larger ; the rest of the limb missing.

Pleopods.—Coupling spines very small, seemingly with only one lateral tooth on each side below the apex ; of cleft spines I could only discover two even in the first pair, a short one with another much longer below it, having the arms long, nearly equal ; the inner ramus with seven joints, the outer with nine, the first joint in each as long as three or four together of those that follow.

Uropods.—Peduncles of the first pair shorter than the inner, longer than the outer,

ramus ; outer ramus much shorter than the inner, with two spines on the margin, and a group at the apex ; inner ramus with three on the margin and a strong group at the apex ; peduncles of the second pair a little longer than the outer, much shorter than the inner, ramus ; the outer ramus about half the length of the inner, with one spine on the margin and a group at the apex ; the inner ramus with three spines on the pectinate inner margin and a group at the apex ; peduncles of the third pair very short above, scarcely reaching back so far as the peduncles of the other two pairs, but below produced beyond them in a triangular apex ; the outer ramus narrower than the inner and about half its length, with three spines along its margin, the apex acute ; the inner ramus also with an acute apex, rather longer than the inner ramus of the first or second pair, its inner margin pectinate, carrying four or five spines, the outer margin four.

Telson as long as the peduncles of the third uropods, but not reaching back quite to the end of their produced tips, longer than broad, with a short, but definite, rather dehiscent, cleft, and the apices rounded ; the lateral margins converging slightly ; a cilium on either side near the margin, below the centre.

Length.—The specimen, in the position figured, measured under a quarter of an inch.

Locality.—Station 313, off Cape Virgins, Patagonia, January 20, 1876 ; depth, 55 fathoms ; bottom, sand ; bottom temperature, 47°·8. One specimen. Trawled.

Remarks.—The specific name refers to the dorsal dentation. A small specimen, remarkably like this species, so far as could be observed, but with the hands of the gnathopods more quadrate, the palms more oblique, was obtained at the surface, February 5, 1875, that is between Stations 212 and 213, at about lat. 6° N., long. 123° E., therefore at an enormous distance from the locality of the specimen described and figured. As in the second specimen the antennæ, peræopods, and uropods were broken, it does not seem worth while to go into fuller details about it.

The present species shows a very great resemblance to *Paramphithoë tridentatus*, Bruzelius, which Bocck has named *Halirages tridentatus* ; it is separated from it by the short outer branches of all three pairs of uropods, the somewhat different termination of the telson, as well as by the bilobed upper lip, and some other details of the mouth-organs. From its compatriot, *Atylopsis magellanicus*, it is distinguished by the dorsal teeth, and by the termination of the telson.

Atylopsis emarginatus, n. sp. (Pl. LXXXI.).

Rostrum small, with rounded point ; lateral lobes of the head sinuous, lower angle slightly produced, rounded ; first and second segments of the pleon postero-laterally angled but not acutely, third segment rounded.

Eyes indistinctly made out, seemingly large, reniform, colourless in spirits.

Upper Antennæ shorter than the lower. Peduncle short, first joint once and a half as long as broad, not equalling the length of the next two united; third a little shorter than the second; flagellum of thirty joints, the first longer than the next two united, carrying three groups of cylinders; many of the other joints with cylinders longer than the joints; the secondary flagellum one-jointed, minute, not half the length of the first joint of the principal flagellum, with a long seta inserted in the tip, and two or three cilia or hairs. In the young extracted from the mother's pouch, the flagellum of the upper antennæ consists of six long joints.

Lower Antennæ.—First three joints very short, subequal, gland-cone short, decurrent; fourth joint longer than the preceding three united; fifth joint rather narrower but longer than the fourth; flagellum of thirty-three joints, the first six rather thick, the first as long as two or three together of those that follow. In the young the flagellum is of eight or nine joints.

Upper Lip.—The distal border with a small non-central emargination, the cilia facing one another on either side of it rather stout and tooth-like, those more remote as usual hair-like.

Mandibles.—Cutting plate divided into seven teeth, of which the lowest three are the largest; secondary plate of left mandible distally widened and divided into five teeth, the lowest of which is the largest; secondary plate of the right mandible slight in structure, showing only two terminal teeth, the hinder of which is much the longer; spine-row on the left mandible of nine curved pectinate spines, the first broader than the rest, with oblique dentieulate apex; the right mandible showed only six spines, without a specially broad one; close to the spine-row is the molar tubercle with strongly dentate crown; above it a blunt-headed process, and above this the strong palp, the first joint a little expanded distally, as also is the second, which has on the surface near the inner margin about a dozen spines, slightly plumose, those near the apex the longest; the third joint is subequal in length to the second, the outer margin convex, with two long spines on the outer surface near the base, many short spines along the inner margin and four longer ones at the apex; the outer surface almost covered with adpressed cilia. In the young there appeared to be only three short spines at the apex of the third joint, with none along the inner margin.

Lower Lip.—Principal lobes rather broad and deep, little dehiscent, strongly ciliated round the distal and inner margins; inner lobes broad and thick and short; mandibular processes short, squared at the ends.

First Maxillæ.—Inner plate small, with five (in a second specimen only four) plumose setæ on the oblique distal margin, followed by four setules, two of which are upon the slightly produced apex, and two upon the inner side of it; outer plate carrying eleven spines on the truncale margin, the outermost long and straight, slightly dentieulate, set among some long cilia; the next shorter, with a long apical tooth on the inner side or

front, and a small denticle (on one maxilla two unequal denticles) behind it, the three following pairs consisting of a long slender slightly denticulate spine, and a shorter with from five to six radiated denticles near the apex, the longest lowest; the second joint of the palp reaching beyond the outer plate, its outer margin convex, the broadest part of the joint near the centre; the distal margin strongly toothed, with six or seven (longer or shorter) spine-teeth in the interstices, the outermost the longest; three slender submarginal spines attend the spine-teeth, and three are placed, not in line, on the surface near the middle of the outer margin.

Second Maxillæ.—Inner plate equal in breadth and almost in length to the outer, with a row of four plumose setæ beginning about the middle of the inner margin, and advancing but little on to the surface; the upper part of the inner margin and the apex fringed with short spines; the outer plate has long spines, plumose below and pectinate above, round the upper part of the inner margin and the apex, with some small spines on the upper part of the outer margin.

Maxillipeds.—Inner plates reaching a little beyond the first joint of the palp, with three spine-teeth on the trunate distal margin, several short enerved spines, and a slender submarginal spine-tooth close to the apex of the inner margin; the outer plates not reaching the distal end of the second joint of the palp, strongly ciliated on the outer surface near the outer margin, the inner margin serrate, devoid of teeth, with a row of slender spines on the outer surface, not far from the inner margin; round the distal margin and descending the outer are ten or more long curved spines and setæ, forming the usual gradation from one into the other; first joint of the palp short; second nearly twice as long, distally a little expanded, with several long spines on the straight inner margin; the third joint slender, equal in length to the first, produced in a small cap over the base of the finger, the edge of the cap appearing pectinate by the projection of adpressed cilia; the finger slender, with a sharp spine-like nail accompanied by a cilium at its base; dorsal cilium of the finger small, near the base.

Of the *triturating organ* of the stomach, all the spines appeared to be long and slender.

First Gnathopods.—Side-plates short and squared, slightly outdrawn at the lower front angle. First joint reaching much beyond the side-plate, longer than the next three joints put together, but shorter than the hand; second joint short; third a little longer, rhomboidal, with several spines about the distal margin; wrist triangular, distally wide, somewhat cup-like, with many pectinate spines on the hind margin; the hand broader than the wrist, more than twice as long as its own breadth, the long front margin convex, smooth, except at the apex, the shorter hind margin with four groups of pectinate or plumose spines; the palm oblique, sinuous, with a tooth process followed by a small erenate emargination near the hinge of the finger; the sinuous portion is cut into very numerous spinule-like close-set teeth; the strong curved finger has a small dorsal cilium near the

base, its inner margin cut into many adpressed teeth from base to nail; the nail projecting just beyond the palm, closing down between two rows of thick strong spines, of which the largest are innermost.

Second Gnathopods.—Side-plates small, oblong, a little longer than in the preceding pair, but distally rather narrower. Branchial vesicles oval or flask-like, broader below than above, about as long as the first joint. The limb closely resembling the first gnathopods in shape and armature; the first joint a little longer, the hand considerably longer, with six groups of spines on the hind margin. In the female specimen the gnathopods were slighter, especially as regards the hand, which in the first pair did not exceed the length of the first joint, in the second was shorter than it. Marsupial plates much longer than the first joint.

First Peræopods.—Side-plates rather longer and broader than the preceding pair. Branchial vesicles similar in shape, rather larger. Marsupial plates long and broad, the distal margin carrying nine or ten setæ. First two joints like those of the preceding pair; third joint rather longer than the fourth, with a very few spinules on the margins, of which the front one is slightly decurrent; the fourth joint spined at three points of the hind margin; the fifth joint longer than the third, slightly curved, with spines at five points of the hind margin; finger curved, considerably more than half the length of the fifth joint.

Second Peræopods.—Side-plates broader and longer than the preceding pair, excavate behind, the margin below the excavation sloping forwards to the lower margin. The first three joints of the limb as in the preceding pair; the rest missing.

Third Peræopods.—Side-plates with the hind lobe deeper than the front. The first joint little expanded, but rather wider above than below, its length twice its breadth; front margin nearly straight, with some small groups of spines, hind margin scarcely less straight, slightly serrate; second joint very short, partially overlapped by the hind lobe of the first; third joint rather broader and a little shorter than in the second peræopods, decurrent behind. The rest of the limb missing in this and the two succeeding pairs.

Fourth Peræopods.—Side-plates bilobed, the hinder lobe the deeper. Fig. *prp. 4.* represents the side-plate alone without its appendages. The limb like the preceding, but with the first and third joints longer.

Fifth Peræopods.—Side-plates with a single lobe. Branchial vesicles small. First joint like the preceding, except that it is larger, and that it is more expanded at the top than below; the second and third joints resemble those of the preceding pair.

Pleopods.—Coupling spines very small, with three or four retroverted teeth along each of two edges; clef spines apparently only three or four in number, with long unequal arms; joints of the rami numbering about thirteen or fourteen.

Uropods.—Peduncles of the first pair longer than the outer, shorter than the inner, ramus; the rami both long, pointed, with small spines on the margins; peduncles of the

second pair shorter than the rami; the outer ramus much shorter than the inner, which reaches nearly as far back as the inner of the first pair; these rami also have spines on the edges; peduncles of the third pair much shorter than the rami, which are long, the outer rather shorter than the inner, and in the female considerably so; the margins carry spines, more in the male specimen than in the female.

Telson longer than the peduncles of the third uropods, though not quite reaching the tips of them, a little longer than broad, very little narrowed distally, with a distal arched emargination, not as deep as wide, forming two triangular apices, a little serrate on the outer margins; the arch of the emargination is smoothly rounded in the female, but in the male is (perhaps accidentally) rather angular.

Length.—The specimen, in the position figured, measured exclusively of the antennæ, a little more than a quarter of an inch.

Locality.—Station 145A, off Marion Island, December 27, 1873; depth, 310 fathoms; bottom, volcanic sand. Two specimens, male and female. Dredged.

Remark.—The specific name refers to the shape of the telson.

Genus *Harpinioides*, n. gen.

Upper Antennæ longer than the lower, peduncle short, secondary flagellum minute.

Mandibles with elongated cutting-edge, the spines of the spine-row numerous, the second joint of the palp wide, the third equal in length to the second.

First Maxillæ with nine spines on the outer plate.

Maxillipeds with the inner plates reaching scarcely beyond the base of the first joint of the palp, the outer plates narrow, fringed on the inner margin with numerous slender spine-teeth; the finger of the palp narrow.

The First and Second pairs of *Gnathopods* alike, the wrist short, the hand long, tapering, subchelate.

The Third, Fourth, and Fifth Peræopods with the first joint in each broadly dilated; the *Fourth* longer than the *Third*, the *Fifth* than the *Fourth*.

In the *First and Second Uropods* the outer ramus shorter than the inner, in the third pair the rami lanceolate, subequal, longer than the peduncles.

The Telson not shorter than the peduncles of the third uropods, not eleft, slightly emarginate.

The generic name is derived from that of the genus *Harpinia*, Boeck, and *εἶδος*, likeness; it refers to the curious resemblance which the type-species shows in the form of the mandibles and maxillipeds to the genus in question; the gnathopods are peculiar, not indeed alien to *Harpinia*, but not attracting attention by any special resemblance to it. On the other hand the antennæ, peræopods, and pleon connect the genus closely with the Atylidæ.

Harpinioides drepanocheir, n. sp. (Pl. LXXXII.).

Rostrum minute, sub-depressed; back rounded; the first two segments of the pleon with the postero-lateral angles slightly rounded; the third segment, which is the longest, has the corners strongly rounded; there are some submarginal spines on the lower borders of these three segments.

Eyes not observed.

Upper Antennæ.—Peduncle short, the first joint longer than the next two united, and much thicker than either; the second longer and thicker than the third, which is nearly equal in length to the first two joints of the flagellum united; all the three joints have on the inner side apical groups of slender divergent spines, the second has also a group near the centre; the flagellum more than twice as long as the peduncle, of twenty-four joints, of which the first is the longest. Secondary flagellum one-jointed, very narrow, shorter than the first joint of the primary, the truncate end tipped with setules.

Lower Antennæ shorter than the upper, but with peduncles rather longer. The first three joints short, the first a little inflated, the gland-cone small, decurrent, the fourth joint not equal in length to the preceding three united, the fifth a little shorter and narrower than the fourth, like it having a group of small spines or setæ about at the centre, and two apical groups; the flagellum shorter than the peduncle, of fourteen joints.

Upper Lip with the distal border broad and flat, very slightly ciliated.

Mandibles.—The cutting plate in the left mandible with a long, nearly straight, very oblique edge occupied by about thirty-five minute denticles, closely set, with their points upwards, a large prominent tooth at the top, and at the lower end, which is very advanced, two or three large teeth; the secondary plate short, broad, especially at the distal margin, which is oblique, with a large tooth above and another below, the intermediate space showing seven little denticle-like prominences, of which the upper three are close together; spine-row of nine or ten dentieulate spines accompanied by cilia, the shorter spines at either end of the row, the arrangement somewhat fan-like; the molar tubercle small and slender, a little ciliated, but apparently without any denticulate crown; the cutting plate of the right mandible with only twenty-six denticles on the oblique edge, a prominent tooth at either end, and a third on the under margin some way to the rear of the lower apex; the secondary plate represented by a small straight spine, prickly at the distal end, shorter than the spines of the spine-row, which are ten in number; of the palp, which is set slightly in advance of the molar tubercle, the first joint is a little expanded distally, the second is stout, narrowest at the base and apex, carrying a row of five rather large spines on the inner surface, and one on the outer, near the very convex front margin; the third

joint is equal in length to the second, its surface covered with adpressed cilia, its apex armed with three small, lightly feathered spines.

Lower Lip.—Principal lobes broad, with a small group of spine-like cilia, some seven in number, with furcate tips, at the inner part of the distal margin; mandibular processes short, squared at the ends.

First Maxillæ.—Inner plate small, oval, with one plumose seta near the apex; outer plate with nine spines on the oblique truncale distal margin, the outermost the strongest, curved, smooth; of the others three are short, stout, smooth, the rest long, and very slightly denticulate; the second joint of the palp expanded a little distally, reaching beyond the outer plate, its distal border toothed, carrying seven or eight slender spine-teeth, accompanied by four or five submarginal spines. The comparative smoothness of the spines on the outer plate may be noticed as a rather unusual feature.

Second Maxillæ.—Inner plate a good deal shorter and narrower than the outer; near the middle of the inner margin is a long plumose seta, followed by a second on the surface, and then a third near the apex, at which there are two pairs of spines, succeeding three small spines at the top of the inner margin; the outer plate has seven or eight long spines at the narrowed apex, succeeding a row of five on each margin, the spine-bearing part of the outer margin being oblique.

Maxillipeds narrow. The inner plates scarcely reaching beyond the base of the first joint of the palp, with two long spiniform plumose setæ on the inner margin, two long spines much like them, but slightly curved, at the oblique outer end of the distal margin, at the inner truncate portion of which there are two spine-teeth and a slender submarginal spine; the narrow outer plates do not reach the distal end of the second joint of the palp; the serrate inner margin fringed with sixteen long spine-teeth, followed by six still longer on the oblique toothed distal margin; the first joint of the palp short, with a spine at the outer apex; the second broad, not nearly twice as long as the first, with nine or ten long spines spaced along the inner margin, and four or five about the distal border; the third broad, as long as the first, with a group of spines on the outer margin, several round the distal border, and several on the surface of different sizes, some very short but plumose like some of the long ones; the finger slender, about as long as the third joint, with a couple of cilia at the base of the nail.

First Gnathopods.—Side-plates large, much broader below than above, somewhat outdrawn in front, with the anterior angle rounded. The first joint reaching a little below the side-plate, its front margin sinuous, fringed with some setæ, and carrying two large spines near the distal end, the hinder margin slightly convex, with some long setæ near the centre and a spine at the apex; the second joint short; the third rhomboidal, with a few spines on the hinder and distal margins; the wrist short, triangular, distally eup-like, equal in length to the preceding joint, with an apical spine in front, the short free hind margin fringed with spines; the hand curved, shorter than the first joint,

about three times as long as the wrist, broad at the base, narrowing almost to a point at the hinge of the finger, the front margin smoothly convex, with short setæ at the apex, the hind margin gently sinuous, without any definite palm; the long, slender, slightly curved finger, about half the length of the hand, closes over the concave part of the hand's hinder margin, so as to leave a narrow cavity; its tip touches the margin between two pairs of setæ; between the lower of these two pairs and the hinge there are on the margin six setules and another pair of setæ.

Second Gnathopods.—Side-plates oblong, with the corners rounded, longer than the preceding pair, but not so broad below. The limb a rather elongated replica of that of the first gnathopods.

First Peræopods.—Side-plates in general like the preceding pair, but longer, the hind margin very straight, its lower corner scarcely rounded. Branchial vesicles small and narrow. Marsupial plates elongate, considerably exceeding the length of the first joint, narrow above, a little expanded below. First joint reaching a little beyond the side-plate, fringed along the front margin with many setæ, on the hind margin carrying a group of very long setæ at the centre, two groups of short ones below it, and spines at the apex; second joint short, a spine at the hinder apex; third joint longer than the fifth, much longer than the fourth, a little decurrent in front, with an apical spine, the hind margin having three groups of setæ; the fourth joint has a small apical spine in front, and at six points of the hind margin setæ, more or less plumose, of greater length successively towards the apex; the fifth joint narrowing a little distally, with spines at four points of the nearly straight hind margin, the front margin a little convex, with setules at the apex; the finger slightly curved, more than half the length of the fifth joint, the margins smooth, except for a very small dorsal cilium near the hinge.

Second Peræopods.—Side-plates broader than the preceding pair, not very deeply excavate, hind margin below the excavation sloping very slightly forwards. Branchial vesicles like those of preceding pair, but rather larger. The limb not materially different from that of the first peræopods.

Third Peræopods.—The hind lobe of the side-plates deeper but narrower than the front one. Branchial vesicles not reaching below the hind lobe of the side-plate. Marsupial plates also short and narrow. First joint almost as broad as long, and of nearly equal breadth throughout, the hind margin with a few serrations and cilia in the notches, the front margin carrying several setæ and spines, a long spine at the apex; a group of long setæ on the inner surface; second joint short, with an apical spine in front; third joint longer than the fourth, a little decurrent, with spines at four points in front, at three behind; fourth joint with spines at three points in front and at the apex behind; the fifth joint subequal in length to the third, with spines at five points in front; one group of setules at the apex of the hind margin, and another a little

higher up; the finger as in the preceding pair. In the specimen examined, the first joint of one limb of this pair was only half the size of the first joint of its fellow.

Fourth Peraopods.—Side-plates with a long decurrent hind lobe. Branchial vesicles narrow above and below, reaching a little beyond the side-plates. First joint of the limb resembling that of the preceding pair in shape, but exceeding it in size; the rest of the limb also similar to the preceding but longer.

Fifth Peraopods.—Side-plate small, rounded behind. First joint of the limb not longer, but broader, than that of the preceding pair, the expansion behind being longer than the front part of the joint; the rest of the limb very similar to the preceding pair.

Pleopods.—Coupling spines small, the base widened, three lateral retroverted teeth immediately below the apical; cleft spines three to four, with very unequal arms; joints of the rami numbering from nine on the inner to twelve on the outer.

Uropods.—Peduncles of the first pair reaching a little beyond those of the second, rather longer than the inner ramus, apically a little produced on the inner side, with a large curved spine issuing from the apex; the outer ramus shorter than the inner, with three or four spines on the inner margin, and a group, of which one is stout, on the blunt apex; the inner ramus similarly armed; peduncles of the second pair longer than the outer, shorter than the inner, ramus; the rami armed as in the preceding pair; peduncles of the third pair shorter than the rami, which are broad, lanceolate, equal in length, or the outer slightly the shorter, nearly as long as the inner ramus of the first pair, with three or four small spines on each margin.

Telson longer than the peduncles of the third uropods, reaching just as far back, its breadth at the base contained onee and a half in its length, the sides converging so that the distal end is half the width of the broadest part; a small triangular emargination is flanked on either side by an apex incised for the insertion of a spine; the place of insertion of a cilium was indicated on each margin a little above the apex, but the cilia were not present.

Length.—The specimen, in the position figured, measured, exclusively of the antennæ, a quarter of an inch.

Locality.—Kerguelen. Two specimens; the one examined and described was a female.

Station 149H, off Cumberland Bay, Kerguelen, January 29, 1874; depth, 127 fathoms; bottom, volcanic mud. One specimen. Dredged.

Remark.—The specific name, derived from the Greek words $\delta\rho\epsilon\pi\alpha\nu$, a sickle, and $\chi\epsilon\rho$, the hand, alludes to the peculiar sickle-shaped hands of the two gnathopods.

 1887. " Chevreux, Catal. Crust. Amph. Bretagne, p. 16.

For the definition of the genus, see Note on Boeck, 1876 (p. 454). The type species of the genus is *Atylus gibbosus*, Spence Bate; Boeck observes that *Dexamine brevitarsus* [*brevitarsis*], Grube, also belongs to it; it will further include the species *Dexamine antarctica*, Stebbing, and probably also *Atylus falcatus*, Metzger, and *Dexamine dolichonyx*, Nebeski. *Polycheria tenuipes*, Haswell, *Polycheria brevicornis*, Haswell, *Polycheria obtusa*, Thomson, are, I think, synonyms of *Tritæta antarctica*, Stebbing, and *Atylus uncinatus*, Sars, seems to be a synonym of *Tritæta falcata*, Metzger.

Tritæta kergueleni, n. sp. (Pl. LXXXIII.).

Rostrum minute, back of peræon broad, pleon carinate except on the front part of the first segment; animal globose when the head and tail are drawn towards one another, but with the legs remaining exserted. The first three pleon-segments with the lower margins spined, forming an angle with the hind margin, which is not acute or outdrawn; the three following segments by the dorsal processes of the fourth and sixth presenting the profile of an aged human face. (Compare Note on Rondellet, 1554, p. 3.)

Eyes round-oval, with numerous ocelli, situated near the slight lateral lobes of the head, dark in the specimens preserved in spirits.

Upper Antennæ.—First joint shorter than the head, not twice as long as thick, second joint twice the length of the first, not tapering regularly, but thicker in the basal than the distal half, the lower edge of this and the preceding joint having several setæ; the third joint very small, not much thicker than the proximal, nor much longer than the distal, joints of the flagellum; flagellum of twenty joints, increasing in length and decreasing in thickness, though not quite regularly, to the terminal joint which is short; each, the last excepted, carries a cylinder longer than the joint.

Lower Antennæ.—Peduncle longer than that of the upper antennæ; the first three joints very short, the gland-cone well developed, the third joint carrying several setæ on its lower margin; the fourth joint long, shorter than the second of the upper antennæ, which it resembles in shape; the lower margin armed with slender spines; the fifth joint straight and thin, a little shorter than the fourth, armed with slender spines, of which many are elongate; the flagellum of eleven slender joints, armed with slender spines, together shorter than the peduncle.

Upper Lip broadly and smoothly rounded, delicately ciliated.

Mandibles.—Cutting plate with the edge divided into six teeth, the outermost the largest; secondary plate on the left mandible similar to the principal, but smaller; on the right mandible this plate is slighter, and ends in two prominent teeth, which curve the one towards the other, the outer being the longer, and having two or three denticles on its side; the spine-row of three plumose spines on the left, and two on the right mandible; the molar tubercle large and strong, the crown of irregular shape, set with very many small denticles, and carrying at one corner a short plumose seta; it has on the forward margin a small protuberance; there is an articulating process, but no palp.

First Maxillæ.—Inner plate small, oval, with two plumose setæ on the inner margin, the larger close to the apex; the outer plate broad, with nine spines on the truncate distal margin, several of them long and denticulate, three short, denticulate on both edges near the apex; the palp reaching a little beyond the outer plate, the first joint short, the second long, with six slender spines on the oblique distal margin, and one some way from the apex on the outer margin.

Second Maxilla.—Inner plate narrower than the outer, carrying eleven plumose spines, seven on the distal, four on the inner margin; the outer plate with about sixteen spines round the distal margin, the outermost a small one.

Maxillipeds.—Inner plates short, not reaching so far as the distal end of the first joint of the palp, carrying five long plumose spines on the squared distal margin, two or three on the inner margin, and some transverse rows on the outer surface, in one of which two of the spines exceed all the others in stoutness; the outer plates very long, reaching beyond the middle of the third joint of the palp, the slightly concave inner margin armed with eighteen or nineteen small sharp spine-teeth, and the apex with one rather larger than the rest; first joint of the palp short, the second considerably longer, broad, armed on the inner margin, and the outer surface near it, with numerous groups of long slender spines; the third joint longer than the first, beset with numerous groups of spines; the finger very short, the sharp nail accompanied by a cilium.

First Gnathopods.—Side-plates short, sharply angled below in front, the point projected forwards. The first joint, as in all the legs, reaching much beyond the side-

plates, its length equal to that of the wrist and hand combined, carrying some long, distally serrate spines or spiniform setæ near the front margin; second joint very short, third longer than broad, carrying on most of the hind margin and along the squared distal margin many long spines, the wrist much longer than the hand, expanding behind and then again slightly contracting, the hinder part armed with many long spines; the hand longer than broad, narrow at the base, but presently expanding, beset on both margins and surfacees with numerous groups of spines of various lengths, and, like those on the preceding joints, finely pectinate; the palm border is finely pectinate, a little convex, with some defining spines; the finger reaching a little beyond the palm, the inner margin produced into a small tooth at the base of the nail, with a cilium; the dorsal cilium small, near the base.

Second Gnathopods.—Side-plates deeper than those of the preceding segment, front margin sinuous, its apex pointed forwards. Branchial vesicles large, simple, much longer and broader than the side-plates. Marsupial plates narrower, but longer than the branchial vesicles, with many long setæ along one margin and the apex, fewer and shorter on the other margin. The joints of the limb similar to those of the first gnathopods, but with the first, third, fourth, and fifth joints longer.

First Peræopods.—Side-plates shallow, produced downwards in front into a long tooth directed a little forwards. Branchial vesicles and marsupial plates as in the preceding pair. First joint of the limb broader, but not longer, than the third joint, armed with spines on both margins; the second joint short, with a group of spines at the apex; the third joint longer than the next two united, a little curved, with spines on both margins, those on the hinder margin, as in the first joint, the longer; fourth joint shorter than the fifth, with spines about the distal end; fifth joint with spines at two points on the front margin and a group of setæ at its apex, at the back expanding a little before the end, and forming a sharp tooth tipped with two spines, against which the finger impinges; between this tooth and the narrow distal end is a large, angular cavity; there are spines along the surfacee, and a group close to the hinge of the finger, one being incurved; the finger itself is much curved, making with the tooth of the hand a powerful grasper; it has a small dorsal cilium near the base, and a very small cilium on the inner margin near the root of the nail.

Second Peræopods.—Side-plates a little broader than in the preceding pair, otherwise scarcely differing; the limb and its appendages also in close agreement with those of the first peræopods.

Third Peræopods.—Side-plates as broad as the preceding and as deep as their hind margin, the front lobe the deeper and a little pointed. The branchial vesicles like those of the preceding pairs. The marsupial plates short and narrow, with only ten long setæ set round the lower part. The first joint longer than the third, with a small expansion confined to the upper part just below the side-plate, spined along both margins; the

second joint with spines in front; the third equal in length to the next two united, spined along both margins; the fourth longer than the fifth, with a few spines on the margins; the fifth shorter than in the preceding peræopods, but otherwise similar, facing backwards not forwards.

Fourth Peræopods.—Side-plates like those of the preceding segment, but considerably smaller. Branchial vesicles shorter than the first joint. Limb differing but little from the preceding pair; the first and third joints rather longer, the expansion of the first a little slighter; the spines on the front margin of the third, fourth, and fifth joints more pronounced.

Fifth Peræopods.—Side-plates smaller than those preceding them, but similar. Branchial vesicles smaller than the preceding pair. First joint very slightly expanded behind close to the base, the whole of the hind margin fringed with strong spines alternating in length, the joint much exceeding the length of the third joint, instead of being subequal to it as in the preceding pair; the third joint shorter than in the preceding pair; the limb otherwise similar.

Pleopods.—Coupling spines slender, with three or four retroverted teeth. Cleft spines three in number on the first two pairs, on the third pair only two; joints of the rami numbering seventeen to eighteen.

Uropods.—Peduncles of the first pair shorter than the rami; outer ramus a little longer than the inner, both with the margins fringed and the apices tipped with spines; peduncles of the second pair shorter than the rami, which are armed like the preceding pair, the outer rather shorter than the inner; peduncles of the third pair much shorter than the rami; the rami lanceolate, spined on both margins, the inner longer than the outer, reaching rather further back than the first pair, which reach much further back than the second.

Telson elongate, cleft nearly to the base, reaching far beyond the peduncles of the third uropods, a little dehiscent near the sharp spine-tipped apices, each plate bordered on the outer margin with six or seven spines, and much resembling the adjacent rami of the uropods.

Length.—The specimen, in the position figured, measured, from the front of the head to the back of the second pleon-segment, a fifth of an inch.

Locality.—Station 149H, off Cumberland Bay, Kerguelen, January 29, 1874; depth, 127 fathoms; bottom, volcanic mud. One specimen, female. Dredged (type-specimen).

Station 149D, Royal Sound, Kerguelen, January 20, 1874; depth, 28 fathoms; bottom, volcanic mud. Two smaller specimens. Dredged.

Remarks.—The specific name is taken from the place of capture.

In describing the subfamily Dexaminæ, to which he assigns his genus *Tritæta*,

Boeck says that the palp of the first maxillæ has but one joint, armed on the left maxilla with teeth, on the right with spines, and that the palp of the maxillipeds is devoid of the last unguiform joint; in describing the genus *Tritæta*, he says that the outer plates of the maxillipeds are armed with few but strong spines, and only on the upper half; in the present species it will have been noticed that the palp of the first maxillæ is two-jointed (though the first joint is rather obscure), and that it has spines, not teeth, on the apex both in the left and right maxilla; also that the maxillipeds have many small teeth along the greater part of the inner margin, and that the palp has a fourth unguiform joint. Notwithstanding these differences there can be no question of separating the present species from the genus *Tritæta*; the spelling of the name is not easy to explain, since Boeck himself derives it from *τριταία*, though he invariably spells it *Tritæta*.

From *Polycheria tenuipes*, Haswell, *Polycheria brevicornis*, Haswell, *Polycheria obtusa*, G. M. Thomson, which, as observed above, all belong to this genus, and are all possibly synonyms of *Tritæta antarctica*, Stebbing, the present species is at once distinguished by the very different side-plates. Haswell figures the maxillipeds of *Tritæta tenuipes* with a three-jointed palp; the palp is also, I think, three-jointed in *Tritæta dolichonyx*, Nebeski, unless the fourth joint be represented by one of the numerous spines at the apex of the third joint.

For the original definition of the genus, see Note on Leach, 1814 (p. 86). That this genus appears first in the Appendix to Leach's article Crustaceology is clearly due to the fact that the type species, Montagu's "*Cancer Gammarus spinosus*," 1813, was not available when the article was originally written or printed, a fact which corroborates the date 1813 for the article itself. Dana in 1852 (U.S. Explor. Exped., vol. xiii. pt. ii. p. 910, note) was inclined to include *Dexamine* in what he supposed to be Rathke's genus *Iphimedia*. Sars in 1882 (Oversigt af Norges Crustaceer, p. 26) places *Dexamine*, in the family Atylidæ, between *Lampra [Tritæta]*, Boeck, and *Atylus*, Leach. Schneider in 1885 inclines to uphold Boeck's "*Dexaminiæ*" as a family, for the two genera which Boeck assigns to the group. Boeck's definition of the genus is as follows:—

"Maxillipeds having the inner margin of the outer plate armed with spines; the inner plate carrying on the apex a few slender setæ."

"Side-plates large, rounded on the lower margin; the four front pairs much deeper than the fifth."

"Upper Antennæ longer than the lower."

"Peræopods all with the fourth and fifth joints elongate; the finger long, slightly curved."

Dexamine flindersi, n. sp. (Pl. CXXXVII. C).

Rostrum acute, small but clearly defined; the lateral lobes of the head convex, not projecting quite so far as the rostrum.

Eyes situated on the lateral lobes, having numerous small ocelli.

Upper Antennæ.—The first joint rather thick, about once and a third as long as broad, with a few spinules and cilia on the lower and apical margins; the second joint about once and a half as long as the first, with a slender spine high up on the under margin, below which the joint becomes thinner and carries a few spinules; the third joint more than a third the length of the second, much thinner, a little longer than the

first joint of the flagellum but resembling it in general appearance; the flagellum longer than the peduncle, consisting of twelve joints of various lengths, and, except the two end ones, all nearly of the same thickness.

Lower Antennæ shorter than the upper. The first three joints short, the gland-cone small but prominent; the fourth joint rather shorter than the second of the upper antennæ, narrowing a little distally, carrying two or three small spines; the fifth joint a good deal shorter and narrower than the fourth, widening distally, having a spine at the apex of each margin, and a small one in the middle of the upper margin; the flagellum shorter than the peduncle, tapering, of five unequal joints, the first longer than the second and third united, the fourth longer than either of them separately.

Upper Lip.—The distal margin convex, the central part with minute cilia, longer ones on either side of the centre pointing inwards as usual.

Mandibles.—The cutting edge divided into seven unequal teeth, the secondary plate into four short teeth in a row with a slender spine-like tooth facing them on the left mandible, into four irregularly grouped on the right mandible; the spine-row consisting on the left mandible of three, on the right of two, denticulate or plumose spines; on the right mandible the molar tubercle with the dentate crown irregularly four-sided; on the left mandible the molar tubercle presenting a rather flattened appearance, with eight or nine rather strong but irregular teeth round part of the margin; palp wanting.

First Maxillæ.—The spines on the outer plate seem to be eleven in number, with lateral denticles to the number of three or four on some of them; the first joint of the palp short, the second tolerably long but not reaching beyond the outer plates, carrying on the narrow apex two long uneven setiform spines.

Second Maxillæ.—The outer plate has two spines placed apart on the outer margin, as well as many on the apical margin.

Maxillipeds.—The inner plates, so far as could be made out, are very small, not reaching so far as the distal end of the palp's first joint; the outer plates very large, completely covering the palp, the inner margins smooth and not dehiscent for a considerable distance; on the distal half there are three small spines which closely interlock with those opposite; these are followed by a row of three or four stout spine-teeth, which also interlock, the margins then becoming dehiscent, serrate, with five long curved spines on each; the outer margins are convex, the greatest breadth of the plates nearer the distal end than the base; the first joint of the palp is short, carrying a long spine; the second joint with some long spines on the inner margin, chiefly on the distal half; the third joint about as long as the first, with some spines on the distal half of the inner, and on the apex of the outer, margin; the finger much shorter than the third joint, with a small nail, and a scutule at the base of the nail. The palps, as shown in the figure *mxp.*, were seen through the partially transparent outer plates.

First Gnathopods.—The side-plates much deeper than broad, the front and lower

margins being serrate or indented, the notches armed with spinules; the hind margin is nearly straight, a little bent in near the centre. The first joint reaches beyond the side-plate, is curved, and distally widened, the front margin concave, the hinder convex; the second and third joints are short; the wrist is triangular, shorter than the hand, longer than broad, with long spines at the apex of the hind margin as well as some higher up; the hand at its base is almost as wide as the wrist, and widens towards the palm, which is very slightly convex, making something more than a right angle with the hind margin, and something less than a right angle with the front; a row of four palmar spines is planted on the surface near the point where the palm begins; the finger is gently curved, nowhere very broad, the edges smooth, but with a dorsal cilium near the base, and a decurrent tooth formed by the inner margin near the base of the small acute nail, which seems to reach beyond the palm.

Second Gnathopods.—The side-plates rather larger than the preceding pair, the front margin more convex, smooth, the lower margin narrow, indented, carrying three or four spinules, the hind margin nearly straight. The limb very similar to the preceding, but with the first joint longer and more curved; the straight hind margin of the hand has two spines; the palm-margin is finely pectinate and fringed with spinules; but probably all these particulars apply also to the hand of the first gnathopods; the finger fits the palm.

First Peraopods.—The side-plates rather larger than the preceding pair, with the lower margin oblique, armed like the others. The branchial vesicles not quite as long or wide as the side-plate. The first joint attached a little above the middle of the side-plate and reaching a little below it, curved, widening a little distally, the hind margin convex, with one or two spinules, the front margin concave, with a spine at the apex. The second joint short, with a little spine on the hinder apex; the third joint a little longer and broader than the fourth, each with a spine near the middle of the hind margin and two or three at its apex; the fifth joint rather longer than the third, with spines at three points of the hind margin, and a couple of setules on the front; the finger three-quarters the length of the fifth joint, straight, except at the nail, with a small dorsal cilium near its base, and another at the base of the nail.

Second Peraopods.—The side-plates broader than the preceding pair, with five spinules on the nearly straight, slightly oblique lower margin, and one on the hind margin. The first two joints as in the preceding pair. The rest missing.

Third Peraopods.—The side-plates with convex front margin, produced below in a little lobe almost to the depth of the preceding plates, the lower margin beyond the lobe nearly straight and parallel with the upper, carrying spinules, the hind margin nearly straight, with one spinule near the rounded lower corner; these plates are much broader and not much less deep than the preceding pair. The branchial vesicles somewhat pear-shaped. The limb missing.

Fourth Peræopods.—The side-plates much smaller than the preceding pair, unequally bilobed.

The Fifth Peræopods and all the pleon were missing.

The minute fragment of which this specimen consisted was not measured before dissection, as from its condition it did not seem suitable for description. But as eventually it proved to be the only representative of the genus *Dexamine*, Leach, in the collection, it seemed worth while to take note of it, if only for the sake of the maxillipeds, and these are of interest, even if the reference to *Dexamine* should have to be set aside when the undescribed portions of the animal become known. The palp of the first maxillæ certainly appears to be two-jointed, which is contrary to the character assigned by Boeck to the genera *Dexamine* and *Tritæta*.

Locality.—Station 186, Flinders Passage, September 8, 1874; depth, 8 fathoms; bottom, coral mud.

Remark.—The specific name refers to the place of capture.

Genus *Stenopleura*, n. gen.

Mandibles with multidentate cutting plate, secondary plate on the left mandible, strong molar tubercle; palp robust, its second and third joints subequal in length.

First Maxillæ with the inner plate small, carrying one plumose seta on the apex.

Inner plate of the *Second Maxillæ* shorter, scarcely broader than the outer.

Maxillipeds with the inner plate not reaching beyond the base, the outer not beyond the apex, of the first joint of the palp; the palp's last joint long and sharp.

The Antennæ with short peduncles and long flagella, the upper longer than the lower.

The side-plates all shallow, the fifth as deep as the fourth.

The two pairs of *Gnathopods* alike, subequal, the hand as long as the first joint.

The first and third joints of the *First* and *Second Peræopods* not slender.

The first two pairs of *Uropods* with the outer rami much shorter than the inner; the third pair with short peduncles, long rami; the outer rather shorter than the inner.

Telson undivided, with sculptured end, not shorter than the third peduncles of the third uropods.

The generic name is derived from *στενός*, narrow, and *πλευρά*, side, in allusion to the shallow side-plates. The genus appears to be inosculant between the Atylidæ and Eusiridæ.

Stenopleura atlantica, n. sp. (Pl. LXXXIV.).

Rostrum inconspicuous, lateral lobes of the head small, somewhat pointed; the postero-lateral angles of the first three pleon-segments not drawn out to a point; the fourth pleon-segment with a dorsal depression.

Eyes high up on the sides of the head, longer than broad, large, with numerous very small ocelli.

Upper Antennæ.—The peduncle short, about as long as the head, the second joint thinner and shorter than the first, the third than the second; the flagellum of thirty-three joints, the first much longer than the third joint of the peduncle, carrying some cylinders, the next twelve joints short, not thick, the remainder again longer, filiform.

Lower Antennæ.—The first three joints of the peduncle very short, the first a little expanded, gland-cone inconspicuous; the fourth joint longer than the preceding three united; the fifth shorter and thinner than the fourth, like it having groups of cilia or setules along the upper margin; flagellum filiform, of thirty-five joints.

Mandibles.—Cutting plate short, with widened distal margin, not curved downwards, divided into nine teeth, of which the lowest three are the largest, the lowest but two larger than the others; the secondary plate on the left mandible also short and broad, distally divided into eight teeth, none large, the lowest larger than the rest; on the right mandible no secondary plate could be clearly made out; spine-row of three strong, not smooth spines, amidst a row of eilia; on the right mandible there were only two strong spines, a difference in number which, as well as the apparent absence of a secondary plate, might possibly be due to accident, but the same difference in the number of spines of the spine-row was observed in *Dexamine flindersi*, and is noticed by Schneider in *Dexamine thea*, Boeck; the molar tubercle with twelve or thirteen rows of rather strong denticles; the first joint of the palp short, with a narrow base; the second joint large, narrowest at either end, hind margin a little concave, front very convex, with five or six slightly plumose spines along its course; the third joint much thinner than the second, but of about the same length, with five or six spines on the front margin, three at the apex, one on the surface behind near the base, and many adpressed eilia on the surface near the apex and near the front margin, beyond which some of them project.

First Maxillæ.—Inner plate small, with a single plumose seta on the middle of the rounded apex; the outer plate with a small tuft of cilia at the distal end of the inner margin, the truncate distal margin carrying ten spines in two rows, five long and slender, minutely denticleate, in one row, in the other four that are shorter, but one that is long and stout, this being the next to the outermost; the spines in this second row appear to have but a single denticle or none; the second joint of the palp is long, overtopping the outer plate, with five slender spine-teeth, serrate on both edges, set

in the dentate distal margin; three of the spines are on the inward slope of the margin, with two short setæ on the surface near them, the remaining two on the outward slope, the apical point between being rounded, hairy or minutely serrate.

Second Maxillæ.—Inner plate shorter than the outer; eight or nine spines on the slightly oblique distal margin of each.

Maxillipeds.—Inner plates scarcely reaching beyond the base of the first joint of the palp, the distal margin sloping outwards, and armed on its outer part with two or three incurving spines; the outer plates not reaching beyond the distal end of the first joint of the palp, the inner margin unarmed, except for a few setæ which arise on the surface near it; round the distal border there are four curved spines or setæ, the hind-most the longest; first joint of the palp short, the second the longest, widening distally, with some spines of various lengths, not numerous, on the inner border; third joint rather longer than the first; finger as long as the third joint, with a sharp curved nail, and some cilia near the base of it.

First Gnathopods.—Side-plates very small, almost triangular, projecting the apex forwards. The first joint reaching much below the side-plate, rather shorter than the hand, the hind margin convex, the front nearly straight; the third joint almost without free front margin, with setæ or spines at two points on the hind margin, distal edge somewhat squared; the wrist much shorter than the hand, triangular, cup-shaped, very slightly produced behind, with groups of serrate spines at the apex and two other points of the hind margin; the hand oval, with the broader end at the base, the hind margin at intervals carrying spines of various lengths, none so powerful as the largest of those on the wrist; the front margin has a setule at the apex, and another at some distance from it; the finger is long and curved, probably antagonising with the strong spines of the wrist, as there appears to be no defined palmar margin on the hand; the nail is long and sharp, with a small eilium at its base; the dorsal eilium near the hinge of the finger is very small.

Second Gnathopods.—Side-plates a little larger and more squared than the preceding pair. Branchial vesicles scarcely so long as the first joint of the limb. The limb in general resembling the first gnathopods; the first joint a little longer and thicker, with some setæ on the hind margin near, as well as at, the apex; the other joints also slightly larger.

First Peræopods.—Side-plates very small and shallow, the short front margin almost straight, the longer lower margin convex. The branchial vesicles irregularly oval, the hind margin sinuous, rather longer than the first joint of the limb. The first joint extending much below the side-plate, broad except at the base, not twice as long as broad, front margin nearly straight, with one or two seta-like spines near the top, hind margin convex, with spines at the apex; second joint short; third shorter than the fourth or fifth, but broader, its hind margin straight, with two sets of spines, the front margin very

much bowed, with a couple of small spines at the apex, and another a little higher up; the fourth joint rather shorter than the fifth, slender, a little curved, with spines at four points of the hind margin; fifth joint as long as the first, slender, a little curved, with spines at three points of the hind margin; finger slender, much curved, acute.

Second Peræopods.—Side-plates like the preceding pair, but larger. Branchial vesicles considerably longer than the first joint of the limb, of nearly even width throughout, the margins irregular; the first joint extending less beyond the side-plate, because of the greater size of that plate; the limb scarcely distinguishable from that of the preceding pair except that the joints from the third to the sixth are rather longer.

Third Peræopods.—Side-plates bilobed, broader, and at the hinder lobe deeper, than the preceding pair. Branchial vesicles longer than the first joint of the limb. The first joint a broad oblong-oval, rather longer than the first joint in the preceding pair, with small spines at two points on the front margin and at its apex, and one or two spinules on the hind margin; second joint short, with its hind lobe not decurrent but pointing downwards; third joint shorter than the first, the breadth about half the width, spines at two points on the straight front margin and at its apex, and with a similar distribution on the convex hind margin; the rest of the limb missing. In a second mounted specimen the peræopods were all broken at the third joint, but the fragments indicated that the third and fifth pairs were probably similar to the fourth, the third shorter, the fifth longer.

Fourth Peræopods.—Side-plates with a decurrent hind lobe. Branchial vesicles scarcely so long as the first joint. First joint longer and broader than in the preceding pair, wider above than below; third joint longer than in the preceding pair, as long as the first joint, the breadth one-third of the length, spines at four points on each margin; the fourth joint a little longer than the third, slender, slightly curved, with spines at four points in front and two behind; fifth joint much longer than the fourth, slender, a little curved, with spines at five points on the front margin, some spinules at four or five points behind, the distal end rounded below the apical spines of the front margin; finger slender, sharp, curved, with some minute eilia on the inner margin.

Fifth Peræopods.—Side-plates small, not decurrent, the hind margin nearly straight. Branchial vesicles very small. First joint much larger than in the preceding pair, the hind margin nearly straight, much longer than the front, so that it descends below the second joint, having a little incision at the lower corner with a small cilium in it; there are spines at the apex of the front margin and at two points above it; the third joint nearly as long as the first, with spines at four points on the front, and five on the hind, margin; its breadth not a third of its length; the rest of the limb missing.

Pleopods.—Coupling spines very small, with four or five small teeth; eleventh spines few in number, apparently only two, with long arms, the inner nearly as long as the

outer; joints of the rami numbering from thirteen to fifteen, on the last pair twelve and fourteen.

Uropods.—Peduncles of the first pair subequal in length to the longer inner ramus; the outer ramus much shorter than the inner, both carrying numerous spines along the margins, and a group containing one long one at the apex; peduncles of the second pair much shorter than the outer, a little longer than the inner ramus; the rami armed as in the preceding pair; peduncles of the third pair very much shorter than the long, broad, sharply pointed, much spined inner ramus; the outer ramus missing in this specimen, in another seen to be rather shorter and more slender than the inner; the peduncles of the first and third pairs reach slightly beyond those of the second pair, the inner ramus of the third a little beyond the inner of the first, which again reaches a little beyond the inner of the second; all are minutely pectinate on the edges. By an accidental twisting of the third uropods the inner ramus in the figure *ur.3* has the appearance of being the outer.

Telson a little longer than the peduncles of the third uropods, reaching back equally far; longer than broad, with a triangular slightly serrate tip, the converging lateral margins forming small apices on either side less far back than the central and larger apex.

Length.—The specimen, in the position figured, measured, without the antennæ, three-tenths of an inch.

Locality.—The specimen figured was labelled as obtained on the 25th of August, 1873, in Mid Atlantic, whether at the surface or from any depth was not stated. Corresponding to this date is Station 106; lat. $1^{\circ} 47'$ N., long. $24^{\circ} 26'$ W.; depth, 1850 fathoms; bottom, Globigerina ooze; bottom temperature, $36^{\circ} 6'$.

A second specimen, a female with eggs, mounted in Canada balsam during the voyage, was labelled as taken in the "South Atlantic, 11. 10. 73," lat. $35^{\circ} 41'$ S., long. $20^{\circ} 55'$ W., belonging therefore to the neighbourhood of Tristan da Cunha.

Remarks.—I believe that the specimen from Station 106 is a female, as there were eggs apparently belonging to this specimen, but I did not discover any marsupial plates or other decisive indications of sex, so that the point is doubtful. The specific name refers to the place of capture.

Family EUSIRIDÆ.

Upper Lip distally symmetrical, or nearly so.

Mandibles with the cutting plate broad, dentate; the secondary plate on the right mandible less powerful than that on the left; the molar tubercle either weak or strong; the third joint of the palp elongate.

Maxillipeds with the inner and outer plates well developed, but small in comparison with the elongate palp.

Lower Antennæ with the peduncle elongate.

First and Second Gnathopods alike in form, the wrist cup-like, the hand ovate, robust.

Uropods biramous; in the first and second pairs the outer ramus generally shorter than the inner.

Telson elongate, more or less cleft, but sometimes to a very small depth.

The first pair of side-plates larger than the second.

Genus *Rhachotropis*, S. I. Smith, 1883.

1887. " Hansen, Oversigt over de paa Dijmphna-Togtet inds. Krebsdyr.

S. I. Smith in 1883 substituted the name *Rhachotropis* for Boeck's *Tritropis*, that being preoccupied, but gave no fresh definition of the genus. Carus in 1885 makes *Tritropis*, Boeck, a synonym of "*Amphitonotus*, Costa," but of the three species he places under the genus so named one belongs to *Dexamine*, a second to *Atylus*, and the third is undescribed. For what may be regarded as the original definition of *Rhachotropis*, see Note on Boeck, 1870 (p. 400), genus *Tritropis*.

1876. " *Helleri*, Boeck, De Skand. og Arkt. Amph., p. 513.

1883. *Rhachotropis aculeata*, S. I. Smith, Proc. U.S. Nat. Mus., pp. 222, 229.

According to Buchholz, who has given figures and a description, which clearly agree with the Challenger specimens, the form which Boeck has named *Tritropis helleri* is only the young of the older species, the absence of the carina from the earlier segments of the

peræon being a characteristic of youth and not of species. A specimen measuring, without the antennæ, more than three-quarters of an inch, had no trace of a carina on the first five segments of the peræon.

Locality.—Station 49, south of Halifax, Nova Scotia, May 20, 1873; lat. $43^{\circ} 3'$ N., long. $63^{\circ} 39'$ W.; depth, 85 fathoms; bottom, gravel, stones; bottom temperature, 35° . Thirteen specimens. Dredged.

Rhachotropis kergueleni, n. sp. (Pl. LXXXV.).

The Rostrum very long and narrow, depressed between the upper antennæ; the lateral lobes of the head narrow, prominent; segments of the peræon very short; the first four segments of the pleon long, carinate, dorsally produced into a small sharp tooth, that on the second segment the largest; on the first and second segments there is an additional less prominent denticle on either side of the central one; the postero-lateral angles of the first three pleon-segments are not acute or produced; in the third segment the lower margin is straight, with several small submarginal spines, the lower lobe of the hind margin is cut into fifteen upward turned teeth.

Eyes not perceived.

Upper Antennæ.—First and second joints long, subequal in length, the first thicker than the second, carrying some long plumose cilia; the second joint having many setules on the upper and some spinules on the lower margin, and an apical feathered cilium; the third joint not a third of the length of the second; the flagellum much longer than the peduncle, of thirty-four joints, those of the distal half being very slender.

Lower Antennæ.—The first three joints very short, the gland-cone short, decurrent; the fourth joint much longer than the preceding three united, longer than the first joint of the upper antennæ, fringed above with setules, below with spinules and long plumose cilia; the fifth joint much longer than the fourth, nearly as long as the peduncle of the upper antennæ, fringed above with setules, and having a few spinules on the lower margin; the flagellum very slender, longer than the peduncle, abruptly narrower, of thirty-seven joints, all slender, the first eleventh at the base within the socket.

Upper Lip.—The distal margin a little flattened, very slightly ciliated.

Mandibles.—The cutting plate is narrow, with a small denticle at the top, the lower end bidentate, although scarcely so in the left mandible of the specimen examined, perhaps through its being worn down by use; the secondary plate of the left mandible with the edge cut into six small teeth; the secondary plate on the right mandible is narrow, with a very irregular edge, perhaps regularly dentate in unworn specimens; there are two spines in the spine-row, of which, however, on the left mandible only the stumps remained; the molar tubercle small, its dentate crown roundly oval, fringed with strong sharp teeth, with rows of smaller denticles on the inner side, which do not appear

to cross the hollow centre of the crown ; there is a short seta accompanied by some cilia ; the palp is of great size, the first joint short, the second long and broad, with about a dozen spines of various lengths on and near the inner margin ; the third joint longer than the second, with the concave inner margin fringed for most of its length densely with spines, those about the narrow apex being more obviously pectinate than the rest ; the convex outer margin shows no spines.

Lower Lip.—The principal lobes distally rounded and ciliated, rather widely denticulate, the inner margins also ciliated ; the mandibular processes very short.

First Maxillæ.—The inner plate comparatively long, with a short setule and a plumose seta on the inner side of the rounded apex ; of the nine spines on the truncate distal margin of the outer plate five are long, and all except the outermost have five or six lateral denticles ; the other four are shorter, and have a single lateral tooth, unless this be wanting on the outermost ; the second joint of the palp is very long, much over-topping the outer plate, it is strongly ciliated, and has several long setæ near the apex and some long spines upon it.

Second Maxillæ.—The inner plate with the inner margin slightly concave, the outer very convex, spines round the narrowed apex, and a very little way down the inner margin ; the outer plate of more even breadth, not so broad as the greatest breadth of the inner plate ; the spines on the narrowed apex and a little way down the inner margin much larger than those of the inner plate.

Maxillipeds.—The inner plates not reaching far along the first joint of the palp ; the broad distal margin has three spine-teeth set close together on the inner part, and three curved spines on the serrate outer part ; the outer plates are narrow, not reaching the middle of the second joint of the palp ; about twenty long spines arm the inner margin, and five still longer ones pass round the narrow apex down the upper part of the convex outer margin ; the first joint of the palp is short, with a couple of spines on the outer margin just below the apex, and a small one lower down ; the second joint is elongate, not broad, with several spines on the inner surface and along the inner margin ; the third joint is long, shorter than the second, longer than the first, with many spines of various sizes, some pectinate, along both margins and on the surface ; the finger is long and slender, much curved, and sharply pointed. About the mouth-organs and other parts of this creature there are many conspicuous oval parasites.

First Gnathopods.—Side-plates narrow and tongue-like, directed towards the base of the lower antennæ. The first joint reaching much below the side-plate, proximally very narrow, then widening, concave, and channelled in front, with spines near the apex, the hind margin convex, with some small submarginal and one or two apical spines ; the second joint short, with an apical spine ; the third joint longer than broad, with two groups of spines on the hind margin, and a larger group on the squared apical border ; the wrist short, cup-like, with a small calx, having the hind margin serrate, the apex

dentate, both set with groups of spines, which, as in the preceding and following joints, are pectinate; on the inner surface there are five spines of very unequal lengths; the hand is large, oval, narrowest distally, the long front margin smooth except for the apical spines, one of which is pectinate, the hind margin almost absorbed by the long convex palm, which is defined by a row of five strong palmar spines on the inner surface, and three on the margin; of the five the outermost is the longest, of the three the lowest; the palm-border is striated as in the genus *Eusiroides*, and crowded with submarginal pectinate spines or spinules of various lengths; there are also scattered spines or groups of spines on both surfaces. The long curved finger closes over the whole palm, the inner margin smooth, probably channelled.

Second Gnathopods.—Side-plates small, rather broader than the preceding pair, with convex lower margin, not produced forwards. The branchial vesicles narrow, not so long as the first joint. The limb scarcely differing from that of the first gnathopods, except that the third joint, the process of the wrist, the hand, and the finger are rather longer.

First Peræopods very slender, as are all the peræopods. Side-plates like the preceding pair. Branchial vesicles longer than the preceding pair, widening a little near the distal end, as long as the first joint. First joint evenly narrow, with some small spines along the front margin and at the hinder apex; the second joint very short, with a spinule on the hind margin and spines at its apex; the third joint not quite two-fifths the length of the first, not decurrent in front, with small spines on the hind margin at five points; the remainder of the limb missing.

Second Peræopods.—Side-plates broader than the preceding pair, excavate behind to some depth, the lower margin straight, with a small tooth where it meets the curve of the hind margin. The branchial vesicles like the preceding pair. The limb defective as in the first peræopods; no spinule on the hind margin of the second joint.

Third Peræopods.—Side-plates as broad and not much less deep than the preceding pair, the front lobe rounded, the hinder more shallow and a little serrate. The branchial vesicles nearly as in the preceding pair, but a little more regularly oval. The first joint of the limb very small, the front margin very slightly convex, with one or two spinules, the hind margin toothed for four spines, apically acute, the lower margin with a small rounded lobe in front, the hinder part straight; the second joint very short, unarmed; the third joint long and slender, three times as long as the first, slightly curved, with small spines along the margins, the apex sharply decurrent behind, and carrying two larger spines. The rest of the limb missing.

Fourth Peræopods.—The side-plates with a hind lobe produced downwards, its lower corner serrate. Branchial vesicles smaller than the preceding pair. First joint similar in shape to that of the third peræopods, rather larger, with a few spines along

the front margin, and five in the notches of the hind margin ; the third joint two and a half times the length of the first, with many spines along the margins, two on the slightly concave front margin being long like those at the apex ; the fourth joint rather shorter, the fifth much longer than the third, both very slender and carrying numerous spines on both margins ; the finger missing.

Fifth Peræopods.—The side-plates as broad as those of the third peræopods, the lower margin somewhat lobed in front. The branchial vesicles very small. The first joint of the limb much larger than in the preceding pair, with several small spines on the nearly straight front margin, and nine small ones in the serrations of the convex hind margin ; the third joint longer and stouter than that of the fourth peræopods, similar in shape, carrying many spines, its length double of the first joint. The remainder of the limb missing.

Pleopods.—Coupling spines small, with a single lateral retroverted tooth close to the apex ; cleft spines six on the first pair, five on the second, three on the third pair, the arms long and very unequal ; above the cleft spines are several plumose setæ ; joints of the rami sixteen and nineteen in the first pair, eighteen and twenty-two in the two other pairs, the smaller number belonging to the inner ramus.

Uropods.—The peduncles of the first pair rather longer than the rami, with small spines along the margins ; the rami slender, acute, nearly equal, the outer a little the shorter, both with a few marginal spines ; the peduncles of the second pair longer than the outer, shorter than the inner ramus, with spines on the outer margin and at the acute apex of the inner ; the rami have few marginal spines ; the peduncles of the third pair much shorter than the rami, reaching back a little beyond those of the two preceding pairs, having some spines on both margins, those on the inner very slender, except one that lies beside the very acute apex ; the rami broad and long, nearly equal, the outer rather shorter than the inner, both with numerous marginal spines, and both narrowing rather abruptly to the acute apex.

The Telson long and narrow, reaching nearly to the apices of the rami of the third uropods ; the greatest breadth not one-third of the length, the sides converging very slightly till near the apex, which is almost acute, although divided by a very short slightly dehiscent slit ; the surface carries many spinules at a little distance from the lateral margins, and near the top of each of these margins a long feathered cilium or seta with a short spine beside it ; the margins show some pectination especially near the apex.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the apex of the third uropods, nine-twentieths of an inch.

Locality.—Two specimens were obtained at Kerguelen ; depth not specified.

Remarks.—The specific name refers to the place of capture.

Genus *Cleonardo*, n. gen.

Near to *Rhachotropis*, S. I. Smith.

Antennæ subequal, the upper longer than the lower.

Upper Lip with the distal margin convex.

Palp of the *Mandibles* long and slender, the third joint longer than the second.

The outer plate of the *First Maxillæ* carrying eleven spines; the two-jointed palp very long.

The inner plate of the *Second Maxillæ* much broader than the outer.

The ealk of the wrist in the two pairs of *Gnathopods* not much produced.

The Peræopods all very long and slender, especially the fingers, which have setæ on the outer margin.

The outer ramus shorter than the inner in each pair of *Uropods*.

The Telson long and deeply cleft.

The trunk without earina or proesses.

The generic name is taken from a personal name in Don Quixote.

From the species that have been assigned to *Rhachotropis* (under the name *Tritropis*), the species on which the present genus is founded differs in some particulars not included in the generic character; thus the side-plates of the first four peræon-segments are not so small, nor is the first pair produced forwards; the third joint in the first and second pairs of peræopods is not short, but elongate, while it is comparatively short in the three following pairs.

Tritropis appendiculata, G. O. Sars,¹ must no doubt be referred to this genus. That species was obtained in the sea north-west of Finmark, at the depth of 1287 fathoms, at a station located in the cold area. In 1885 Sars remarks upon it, "the form treated of here exhibits in some respects a rather striking deviation from the other species referred to the genus *Tritropis*, and may possibly be found to constitute a separate genus."

Cleonardo longipes, n. sp. (Pl. LXXXVI.).

Rostrum short and broad but well pronounced, sides of the head with broadly rounded lobes. The skin microscopically furred.

Eyes not perceived.

Upper Antennæ.—First joint of the peduncle much stouter than the second, outdrawn below into a blunt point, tipped with one very short and one rather longer spine, and two feathered spine-like cilia; the second joint rather longer than the first, distally outdrawn to a point above and below, with feathered cilia preceding the outdrawn parts;

¹ Crust. et Pycnog. nova, No. 27, p. 451, 1879, and Den norske Nordhav-Expedition, p. 194, pl. xvi. fig. 3, 1885.

third joint very short and (especially at the centre) narrow ; there is a calceolus at the end of this, and two near the end of the preceding joint ; flagellum stout, with forty-six joints, the first as long as five or six of the following, with three calceoli, the following joints having each one, till near the end, cylinders on several of the distal joints.

Lower Antennæ.—The basal portion of the composite first and second joints not much expanded below, the distal part concave above, with a small, not prominent, gland-cone below ; the third joint short, with long, fine, feathered setæ at the apex ; the fourth elongate, with distally feathered setæ and slender spines in groups along its inner margin ; the fifth joint elongate, but shorter and much narrower than the fourth, with ten calceoli along it, and setæ as on the other joint ; the flagellum slender, of about thirty-five joints, with calceoli on those of the upper half. The calceoli are large and striking, especially in the middle part of the flagellum of the upper antennæ ; a short broad stalk supports an unusually large circular cup with radiate markings, from the centre of which, and connected with it at the back, rises the usual oval piece shaped like the bowl of a spoon, crossed by concentric lines, which are in this species very strongly marked.

Upper Lip.—The outer plate broadly rounded, the prominent convex central part of the distal margin fringed with small hairs and prickles ; the sides, which are also convex, but somewhat drawn back from the centre, are as it were whiskered with long cilia directed towards the centre, an arched row of such cilia crossing the whole breadth of the plate.

Mandibles.—The cutting edge long, incurved, much down-drawn, ending below in two or three strong teeth ; the secondary plate on the left mandible strong, bent so as to follow the curve of the principal plate, its long border divided into some eight strong teeth ; the secondary plate on the right mandible small, narrow, with a long apical tooth below and one or more short ones above ; the spine-row on the left mandible consisting of eight long spines with some cilia attending them ; on the right mandible the spines in the spine-row appear to be fewer ; the molar tubercle prominent, the roughly-oval dentate crown (as seen in the left mandible) set with some two dozen rows of denticles, and carrying a small plumose seta at the upper corner ; there is a process between the molar tubercle and the palp ; the first joint of the palp is concave on the inner side, the second joint long, abruptly narrowed on the inner side about midway, furnished with numerous setæ of different lengths, more or less feathered, along the inner margin, and a row which have their origin on the surface extending over more than the upper half ; the third joint rather longer than the second, crowded with spines of different lengths, the longer ones pectinate, the longest at the apex differing from the others in having the apical third unpectinate.

Lower Lip.—The forward lobes, both inner and outer, rounded, rather strongly ciliated ; the mandibular processes short.

First Maxillæ.—Inner plate oval, with one plumose seta on, and another a little below, the apex; outer plate not reaching much beyond the inner, with eleven slender spines on the moderately oblique apical margin, the innermost spine the longest, nearly straight, denticulate, the five following long, curved, with several lateral denticles, except the last, which has only two; on the inner row of five shorter spines each has two lateral denticles, except the central, which has only one; the palp reaching considerably beyond the outer plate, the first joint long, more than half the length of the second; the second joint carrying half-a-dozen seta-like spines on the inner margin near the top, four on the apex, and three at intervals on the hind margin.

Second Maxillæ.—The inner plate rather broader and very little shorter than the outer; the outer part of the apex unarmed, the remainder fringed with pectinate spines, of which the series descends the inner margin, closing with two long plumose setæ and three quite short simple ones; the outer plate having the apical and upper part of the inner margin fringed with curved, setiform spines, five short ones descending the outer margin.

Maxillipeds.—Inner plates not reaching the apex of the first joint of the palp, having three teeth on the apical margin, two close together, a seta intervening between them and the third, which is followed by three or four more setæ; a few setæ pass from the inner towards the centre of the apical margin; the outer plates not very broad, not nearly reaching to the apex of the second joint of the palp, with very numerous spines (not dentiform) along the inner margin, two at the apex longer than the others, and five or six long plumose setæ round the upper half of the outer margin; besides the spines there are on the surface within the inner margin setæ as stout as the spines, but longer; the second joint of the palp is much longer than the first, widening distally, provided with numerous long marginal setæ and a surface row near the apex; the third joint is longer than the first, crowded with setæ and spines of various sizes, many pectinate, some of those adjoining the finger straight, others curved; the finger a little curved at the tip, its inner edge prior to the tip being set with ten short setæ or seta-like spines.

First Gnathopods.—Side-plates short, bowed out in front, not much longer than broad, with a spine and some spinules on the upper part of the nearly straight hind margin. First joint reaching much beyond the side-plate, fringed in front with long setæ which start from the surface, and having two or three tufts on the hind margin; the second joint short, with an apical tuft behind; the third oblong, short, with setæ on the lower part of the hind margin and the squared apex; the wrist has three rows of setæ on the front margin, and seven or eight rows on the curved lobe behind, this lobe giving the wrist, seen from the outside, a cup-shaped appearance, whereas on the inner side it has a lozenge-like shape, the lower and hinder margins of the lozenge carrying setæ; the hand is broader at the base than the wrist, which it greatly exceeds in length and in size generally; the convex front margin carries several tufts of setæ of different

sizes ; the hind margin, with two small tufts, extends but a short distance before forming a slightly recessed angle which marks the beginning of the long convex palm ; in the recess is planted a group of spines, one of which is much longer than the rest, while recessed in the inner surface of the hand is a second neighbouring group of spines, seven in number, seemingly all of different lengths ; the palm margin carries four spines distributed along the earlier part of its course, cilia of different lengths fringing it right up to the finger-joint ; there are also some setæ projecting from the surface of the hand ; the finger is slender, curved, and of great length in correspondence with the palm ; it has some minute hairs on the inner margin.

Second Gnathopods.—Side-plates moderately broad in comparison with their length, not so broad as those of the preceding segment, with two or three spines on the straight hind margin, which is nearly parallel to the front one, lower margin convex. Branchial vesicles as long, but not so broad, as the side-plates. The limb strikingly resembles that of the first gnathopods, the joints being rather longer, and the hand a little more tapering, with the long palmar spine and the four marginal spines somewhat more pronounced.

First Peræopods.—Side-plates rather narrower than those of the preceding segment. Branchial vesicles small, oval. The whole limb very narrow and elongated ; the first joint reaching much beyond the side-plate, with eight or nine rows of setæ near the convex front margin, the slightly concave hind margin fringed with setæ, more or less plumose, of different lengths, some of them very long ; the second joint as usual short ; the third shorter than the first, but very long, curved, and little produced below, with four very long thin setæ and some setules on the convex front margin, and a variety fringing the concave hinder margin ; the fourth joint is shorter than the fifth, the fifth a little shorter than the third, but both are long and slender, nearly straight, with thin setæ and setules at various points ; the finger is slender, very slightly curved, as long as the fifth joint, or a little longer, with a small dorsal cilium near the base, and at a short distance from the apex a row of three or four dorsal setæ, the tip forming a very thin nail with a cilium at its base. The finger in each of the pereopods of this species bears a similarity to the finger of the fifth peræopods in the *Ediceridæ*.

Second Peræopods.—The side-plates not much longer than their greatest breadth, which is above the centre, the hind margin below the excavation running very obliquely forwards, with some slight serrations. The branchial vesicles not as long as the side-plates. The limb closely resembles the first pereopods.

Third Peræopods.—Side-plates small, bilobed, broader than the first joint of the limb, which is oval, but with the hind margin straightened, edged with spinules, the front margin carrying a couple of setules at the top, and small spines round the rest of its course ; the second joint short, overlapped behind by the first ; the third joint shorter than the first, a little longer than the fourth, narrowest at the base, and broadest

near it, a little decurrent behind, with spines on both margins, none of them strong; the fourth joint with four groups of spines on each margin; the fifth joint considerably longer than the third or fourth, with numerous spines on both margins, especially on the front; the finger very long and thin, longer than the third or fourth, subequal to the fifth joint, with a dorsal cilium and two dorsal setules, as in the preceding peræopods; which in all but the first joint it nearly resembles, but having the fifth and sixth joints much longer.

Fourth Peræopods.—Side-plates with the hinder lobe much larger than the front one. Branchial vesicles small, expanded below on either side of the narrow upper part. The limb nearly as in the preceding pair, rather longer in respect of the first and third joints, the first joint being a little more expanded above than below, while in the third peræopods the reverse is the case.

Fifth Peræopods.—Side-plates not bilobed, much deeper behind than in front. Branchial vesicles small. Limb similar to that in the two preceding pairs; first joint produced a little upwards in front, and considerably downwards behind, broader above than below; the third joint not longer than the fourth.

Pleopods.—The peduncles have a row of about a dozen setæ near the outer margin, and two groups near the top of the inner, and some also on the lower margin. The two coupling spines are very small and crooked, with only one lateral retroverted tooth, which is placed a long way below the terminal hook; there is a setule or small simple spine close by; the cleft spines appear to be six in number on the first and second, and five on the third pleopods, with an uncleft plumose seta above; the joints number twenty on the inner ramus to twenty-three on the outer.

Uropods.—The peduncles of the first pair longer than the rami; the rami stiliform, the inner somewhat longer than the outer, peduncles and rami bordered on the upper or inner margins with numerous spines and having their edges finely pectinate; the peduncles of the second pair equal in length to the inner ramus, which is broader and longer than the outer and more closely set with spines; peduncles and rami all fringed with spines and pectinate; peduncles of the third pair subequal in length to the outer ramus; rami broad, lanceolate, rather strongly serrate on the inner edges, the inner broader and considerably longer than the outer, with some plumose setæ besides its numerous spines; the peduncles with few spines, the rami with many, the edges of all pectinate.

Telson elongate, tapering, extending beyond the peduncles of the third uropods almost to the end of the rami, cleft for more than three-quarters of its length, not dehiscent, apices acute, all the margins except the basal finely pectinate, a couple of cilia not far from the base and outer margin on either side, and some others at other points, but scarcely perceptible even with a high power.

Length.—The specimen, in the position figured, measured, without the antennæ, two-fifths of an inch.

Locality.—Station 297, south-west of Juan Fernandez, November 11, 1875; lat. $37^{\circ} 29' S.$, long. $83^{\circ} 7' W.$; depth, 1775 fathoms; bottom, Globigerina ooze; bottom temperature, $35^{\circ}.5$. One specimen, male (as shown by the appendages at the seventh segment of the peraeon). Taken in the tow-net at the trawl.

Remark.—The specific name refers to the elongate character of the peraeopods. There are many points of similarity between this species and its Arctic congener, in spite of the vast interval between the localities at which they were respectively met with.

For the original definition, see Note on Kröyer, 1845 (p. 213); Boeck gives the following:—

"Mandibles apically only a little dentate, the molar tubercles robust.

"First Maxillæ with the palp elongate, acuminate, setose, the first joint more than half the length of the second.

"Upper Antennæ longer than the Lower, the third joint of the peduncle very small, almost rudimentary; the accessory flagellum very little.

"First and Second Gnathopods with the hands alike in size and shape; the wrist elongate, with a spur behind (postice calcarato), narrow, and attached at the middle of the front margin of the ovate inflated hand.

"The Third, Fourth, and Fifth Peraeopods very elongate, slender.

"The Third Uropods with the rami equal in length, laminar, setose on the margin.

"The Telson elongate, only a little apically eleventh."

Gerstaecker says that the telson is "nicht gespalten," but this is not accurate.

Eusirus longipes, Boeck (Pl. LXXXVII.).

1860. *Eusirus longipes*, Boeck, Forh. ved de Skand. Naturf. 8de Møde, p. 656.
 1870. " " Boeck, Crust. amph. bor. et arct., p. 77.
 1876. " " Boeck, De Skand. og Arkt. Amph., p. 504.

Rostrum small, lateral lobes of the head not very prominent; the seventh segment of the peraeon carinate, with a small postero-dorsal tooth; the first three segments of the pleon also carinate, the first two with a postero-dorsal tooth, and the postero-lateral angle produced in a small sharp point; the third segment with the long lower lobe of the hind margin serrate, the upper serratures pointing downwards, the lower upwards, the postero-lateral corners rounded, the serration continued a very little way along the lower margin; the fourth segment with a slight transverse dorsal depression; the sixth segment with the postero-lateral angles tri-denticulate.

Eyes large, reniform, close to the lateral lobes of the head, with numerous small ocelli, of about equal length and breadth.

Upper Antennæ.—The first joint much broader and a little longer than the second, each of them distally cut into four sharp points; the third joint narrower than the second and one-fourth its length, distally serrate; flagellum shorter than the peduncle, of nineteen joints, of which the first is much the longest, equalling the third joint of the peduncle; a calceolus, a cylinder, and some setules form the apical appendages of nearly every joint; the secondary flagellum of one long slender joint, pectinate on the outer edge, and a second minute joint, the two together nearly as long as the first of the primary. A specimen seemingly of the same species from Station 150 has thirty-eight joints in the flagellum.

Lower Antennæ shorter than the upper. First joint a little expanded, gland-cone well developed, decurrent; third joint short, distally toothed; the fourth joint as long as the second of the upper antennæ, rather longer than the fifth, with setules and spines on both margins, and distally toothed; the fifth joint much thinner, with many tufts of setules on the upper margin, distally denticulate and armed with spines and setæ; the flagellum much shorter than the peduncle, of seventeen joints, the first the longest, each with an apical group of setules.

Upper Lip distally broad, with a slit at the centre, a group of long cilia on either side, curving the one group toward the other; the surface also set with numerous long cilia over the whole breadth.

Mandibles.—The cutting plate on the left mandible elongate, scarcely toothed, with an indication only of a tooth above, and of a division of the large, blunt, tooth-like end below; the secondary plate divided into eight clear teeth, the general shape of the plate corresponding to that of the principal; on the right mandible the principal plate has no indication of a tooth above, but below is divided into two strong teeth, the lower of which while in preparation is seen to possess two sharp points; the secondary plate is of slighter construction than on the other mandible, distally forming two spear-head teeth, with

serrate edges, and having some smaller denticles on the sides; the spine-row consists of four elongate denticleate spines; the molar tubercle prominent, without being very large, its transversely elliptical crown set with many denticles; the palp set just over the molar tubercle, its first joint short, the second decidedly shorter than the third, with some seven long setæ along the outer surface, and some short ones on or near its convex inner margin; the long slender third joint with a group of four setæ on the outer surface near the base, and not far from the convex outer margin; the inner margin not convex, fringed for most of its length with pectinate spines, of which the narrow apex has five, two long and three short.

Lower Lip.—The principal lobes distally rounded, dehiscent, much ciliated; the inner lobes distally broad in proportion to their depth; the mandibular processes short, apically rounded.

First Maxillæ.—The inner plate almost oblong, with one plumose seta on the distal margin; the outer plate with eleven elongate spines, the innermost taking its rise lower on the plate than the rest, long, very thin, with seven small lateral teeth, the next four with four or five long lateral teeth, the next which is stouter and more curved with only one or two lateral teeth, the outermost with three, the remaining four in the parallel row are long and slender, with from four to six small denticles apiece; the first joint of the palp fully half the length of the second; the second reaching beyond the outer plate, its inwardly sloping apical border fringed with eleven slender spines or setæ.

Second Maxillæ.—The inner plate broader and shorter than the outer, the fringing setæ neither numerous nor long, reaching about halfway down the inner margin, and halfway across the broad distal margin; some being submarginal in origin; the outer plate has the apex somewhat narrowed, with spines of some length, the series passing a little way down the inner and outer margins, the three spines on the outer margin being, however, short and seta-like.

Maxillipeds.—The “prismatic” inner plates are short, scarcely reaching the centre of the first joint of the palp, with two short spines close together near the inner apex, the distal border trunecate, carrying at the inner corner a setiform spine, three strong spine-teeth close together on the margin, followed on the outer slope by three slender curved spines; the outer plates reach the middle of the second joint of the palp, the inner margin bordered with twenty spines, the pectinate distal half of which is abruptly narrower than the proximal; two more, rather longer than the rest, occupy the apex, beyond which on the curve of the outer margin are four long slightly feathered spines or setæ, much more widely apart than the spines of the inner margin and apex; there is also on the outer surface near the inner edge a submarginal row of slender spines; the first joint of the palp has the outer apex acute; the second joint much longer, widening distally, with a few setæ and setules on the upper half of the outer margin, many setæ or spines along the inner margin, and some on the surface, especially near the apex; the third joint rather longer than the first, with spines on the distal part of the inner edge, and on the surfaces

within it, besides strong transverse groups on the inner surface and round the apical margin; the inner margin of the finger armed with three or four graduated spines, each having an accessory thread, the largest spines nearest the slender curved nail, at the base of which there is a cilium and a small decurrent spine; the finger has a dorsal cilium near the base of the nail.

First Gnathopods.—Side-plates much broader below than above, extending forwards to the base of the lower antennæ, the rounded front angle having a little indent, not a tooth, the hinder angle forming a sharp tooth, the slightly convex lower margin fringed with some setules; the first joint reaching much beyond the side-plate, the front margin a little concave, armed below with some long and strong spines, the hind margin convex, nearly smooth; the second joint with some small spines at the apex of the hind margin, the apex in front on either side forming an angle; the third joint short and broad, with spines along the lower part of the hind margin and the hind part of the squared distal border; the wrist with a very long front border, fitting when bent upwards into the channelled front of the first joint, the hind border very short, covered with a brush of serrate spines, not produced into a heel; the distal margin forming a large unsymmetriical cup, with a few spines at the hinder part; in this cup the great egg-like hand is seated, attached to the antero-distal end of the wrist; the front margin of the hand is smoothly convex, much shorter than the palm, but much longer than the free portion of the hind margin; the hind margin ends in a group of nine or ten very unequal but strong palmar spines, the integument near them showing some small scale-markings; the palm margin is smoothly convex, with another border within it on either side, these inner borders being fringed with spines or spinules abruptly narrowing at the distal portion, and being there pectinate; on the outer surface these spines are set obliquely, alternately larger and smaller, but nearly all the same size, on the inner surface they stand straight, and the sizes differ much; the long thin finger fits closely round the whole palm-margin, for which its inner edge appears to be channelled; it is smooth except for some very small hairs on the inner margin, and a small dorsal cilium near the hinge.

Second Gnathopods.—Side-plates a little deeper than the preceding pair but narrower, a little wider above than below, with a small tooth at each end of the lower margin, the hinder one being the stronger. The large branchial vesicles of this and the four following pairs have a slender accessory vesicle springing from the same base as the principal sac, but not attaining the same length. The limb in most respects resembles that of the first gnathopods; the first joint rather longer, without the great spines near the lower front angle; the third joint rather longer, with fewer spines on the hind margin; the wrist rather larger.

First Peræopods.—Side-plates a little larger than the preceding pair, sides nearly parallel, the lower margin with some setules and with a tooth at each corner. Branchial vesicles larger than the side-plates, much inflated. Limb slender; first joint reaching

much below the side-plate, fringed with setules; third joint longer than the fifth, much longer than the fourth, with spinules and setules along both margins; the fourth joint with larger spinules, and at the hinder apex carrying a spine; the fifth joint straight, fringed behind with slender spines, and having a few spinules in front; finger curved, acute, scarce half the length of the fifth joint, the edges finely pectinate; a dorsal cilium not far from the base of the nail.

Second Peræopods.—Side-plates with the front margin nearly straight, ending in a tooth, excavate behind, the hind margin below the excavation serrate and sloping forwards to join the convex lower margin. Branchial vesicles larger than in the preceding segment. The limb like that of the first peræopods.

Third Peræopods.—Side-plates broad, bilobed, the hinder lobe rather deeper than the front, its hind margin ending in a small tooth. The branchial vesicles nearly as large as the first joint. The first joint pear-shaped, the front margin convex, fringed with spines, the hind margin deeply serrate, the lower part straight, rounded at the lower angle; the second joint very short; the third scarcely longer than the fourth, much shorter than the fifth, its hind margin convex, decurrent, a little longer than the front, both margins armed, but as in the two following joints not strongly; the finger very slender, curved at the nail, not half the length of the long straight fifth joint, its margins pectinate.

Fourth Peræopods.—Side-plates with a deep hinder lobe; the branchial vesicles contorted. The first, second, and third joints of the limb similar to those of the preceding pair, but the first and third larger, the rest of the limb missing.

Fifth Peræopods.—Side-plates small, deepest in the middle. Branchial vesicles small and irregularly shaped. The limb resembling the third pair and the fourth so far as observed; the first joint larger than in the latter, the hind margin more sinuous; the third joint longer, the apical pointing of the hind margin of this and the following joint here becoming conspicuous, the armature of all the joints of more considerable strength; the superiority of size over the corresponding joints of the third pair is greater in the third and fourth joints than in the fifth and sixth.

Pleopods.—Coupling spines small, with three or four lateral teeth; there is a setiform spine close to the coupling spines, and there are also several other spines on the peduncles, especially about the apex; cleft spines five in number on the first pair, four on the other two; joints of the rami seventeen to eighteen.

Uropods.—Peduncles of the first pair shorter than the inner ramus, with some long spines on the inner margin and apex; the outer ramus shorter than the inner and than the peduncle, both rami with pectinate edges, marginal spines, acute apices; peduncles of the second pair much shorter than the inner ramus, apically dentate; the outer ramus as long as the peduncle, the inner much longer, longer than any of the other rami, the armature as in the preceding pair; peduncles of the third pair shorter than the rami,

with apical teeth of various lengths; the rami broad, lanceolate, with spines on both margins, which are pectinate; the outer ramus rather shorter than the inner.

Telson long and narrow, rapidly tapering, reaching much beyond the peduncles of the third uropods, cleft for about two-fifths of the length, the apices separate by a small triangular dehiscence for about one-third the length of the cleft, with the place of insertion for a spine or spinule a little above each apex on either side of it.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the dorsal apex of the third pleon-segment, three-tenths of an inch.

Locality.—Kerguelen, no depth specified. One specimen.

Station 150, Heard Island, February 2, 1874; lat. $52^{\circ} 4'$ S., long. $71^{\circ} 22'$ E.; depth, 150 fathoms; bottom, coarse gravel; bottom temperature, $35^{\circ}\cdot 2$. One specimen.

Remarks.—I cannot find any points of difference that would justify the separation of this southern species from the northern *Eusirus longipes*, Boeck, which Boeck identifies with *Eusirus helveticae*, Spence Bate, and *Eusirus bidens*, Heller. From *Eusirus cuspidatus*, Krøyer, it is distinguished among other things by the absence of the spine-teeth from the apex of the second joint of the maxillipedal palp.

A specimen dredged at Station 3, lat. $25^{\circ} 45'$ N., long. $20^{\circ} 14'$ W.; depth, 1525 fathoms; bottom, hard ground; temperature of the water at the bottom, $37^{\circ}\cdot 0$, at the surface, $65^{\circ}\cdot 0$, has the first three segments of the pleon carinate, but the seventh of the peræon neither carinate nor dorsally toothed; the specimen measures three-fifths of an inch from the rostrum to the extremity of the uropods, not quite outstretched; the fifth joint of the lower antennæ is rather longer than the fourth, and is fringed with calceoli.

Genus *Eusiroides*, n. gen.

First Maxillæ with ten spines on the outer plate.

The Gnathopods with large hands attached in the ordinary manner, that is, by the base, not by the front margin, to the short cup-like wrists.

The Peræopods stout.

The other characters agreeing with the genus *Eusirus*.

Besides the three closely related species, respectively from three different localities, for which the genus has been instituted, it is probable that *Atylus monoculoides*, Haswell, and *Atylus lippus*, Haswell, both from Clark Island, Port Jackson, ought to be transferred to it.

The characters distinguishing this genus from *Eusirus* might, as a rule, be considered insufficient to warrant the introduction of a new generic name, but had the new species been included in the old genus *Eusirus*, the definition of that genus must have been deprived of one of its most salient points, the peculiarity of the attachment of the hand

and wrist. Kröyer in describing *Eusirus cuspidatus*, says that there are half a score of spines on the outer plate of the first maxillæ; in the form which I have considered to be *Eusirus longipes*, Bocck, there are eleven spines, but in each of the three species of *Eusiroides*, after careful examination, I can only count ten. In *Pleustes*, if I may judge from *Pleustes abyssorum*, which has some other points of resemblance to the genus *Eusiroides*, there are also only ten spines on the outer plate of the first maxillæ.

Eusiroides cæsarialis, n. sp. (Pl. LXXXVIII.).

Rostrum small, carinate underneath, lateral lobes of the head rather prominent, flat in front, rounded below, separated by an incision from the short straight remainder of the lateral margin; the first two segments of the pleon dorsally produced backwards, each in a small sharp tooth, their postero-lateral angles produced in very small denticles, those of the third segment not produced, the lower lobe of the hind margin denticulate, the upward pointed denticles reaching almost to the top of it; the first segment distally and the second and third segments show only a suspicion of compression along the dorsal line, the back of the animal in general being broadly rounded; the fourth segment of the pleon with a transverse dorsal depression; the integument showing in many parts a strong striation.

Eyes large, reniform, not coming so near to one another at the top of the head, nor retaining so dark a colour in spirits, as the eyes of the next species, *Eusiroides pompeii*.

Upper Antennæ.—First joint longer than the next two united, twice as long as broad; the second joint much narrower than the first, and broader than the third, which is nearly half its length; the first joint has some groups of stout spines on the surface, and some mixed groups on the irregular apical margin; the second and third joints have some calceoli besides various groups of setules; the flagellum thick at the base, of seventy-four joints, is much longer than the peduncle; the earlier joints are broader than long, each having a large calceolus with attendant cilia and cylinders, the margins of the joints assuming a sort of spiral arrangement which is followed by the calceoli, for which there would not be room in single file; on the later joints their size diminishes, and from the slender terminal joints they are absent; the secondary flagellum, consisting of a single narrow joint, is not so long as the short first joint of the primary; its rounded apex is tipped with four setules.

Lower Antennæ not so long as the upper; the first three joints short, the first not expanded, the gland-cone inconspicuous, the second and third both more or less armed with spines; the fourth joint longer and broader than the fifth, carrying several groups of setae and spines; the fifth somewhat longer than the second of the upper antennæ, armed like the fourth, but also having calceoli; the flagellum of fifty-five or more joints is thick at the base, most of the joints being much broader than long, armed as in the upper antennæ, the first joint about as long as its breadth.

Upper Lip.—The front margin rounded, the hairs at the centre standing out straight, while those on either side converge towards them; outside of the hairy tract are spiny cilia on either side, forming a curved band across the surface. In the figure *l.s.*, the inner plate is drawn protruding beyond the outer, not in its natural position.

Mandibles.—The cutting plate on the left mandible forming a single tooth with a strong, sharp, curved edge, bending round the secondary plate; in the unworn condition this edge has a triangular tooth lying upon it at the top, and is interrupted so as to form a small tooth before reaching the apex; the secondary plate has its margin divided into five strong teeth; on the right mandible the cutting plate has a strong process above, and is apically divided into two teeth; the secondary plate in profile appears to resemble that on the left mandible, but to be slighter, and to have the upper teeth smaller; the spine-row is composed of six long, curved, denticulate spines; the molar tubercle is prominent, with a small sharply-toothed crown, of almost triangular outline, set about with many cilia; there is a blunt-headed process between the molar tubercle and the palp; the first joint of the palp is short, the second much shorter than the third, its hind margin nearly straight, the front convex, with thirteen spines upon it or the adjoining surface; the third joint very long and narrow, with the hind margin smooth, convex, the front margin except near the base closely fringed with spines, those near the narrow apex of increased length.

Lower Lip.—The rounded distal margins of the principal lobes lightly ciliated, the inner margins delinquent, each having near the top a projecting line of eight or ten spines, the roots of which are grouped on the surface; the rounded distal margins of the short thick inner plates are closely furred; the mandibular processes are short, apically rounded; their inner margin is continuous with a curved fold of the principal lobes, which is strongly ciliated with spiny cilia, especially where it approaches the group of spines above-mentioned.

First Maxillæ.—The inner plate much longer than broad, the apex sloping inwards with two slender spines or short setæ on the sinuous margin; the outer plate with ten spines on the truncaate margin, the lateral teeth varying in number from two to seven on the different spines, but in all long and slender; the first joint of the palp more than half the length of the second, with two spines on the outer margin; the second joint with five setiform spines on the outer margin, five on the narrow apex, and ten on the oblique margin below it, which may be reckoned either as part of the apex or of the inner margin; there is one seta on the outer margin of the trunk below the palp.

Second Maxillæ.—The inner plate as long as and a little broader than the outer, with spines on the rounded distal margin and halfway down the inner margin; the outer plate with spines round the distal margin, the longest at the most advanced point, followed by four shorter ones on the outer side, the outer border having three long plumose setæ on the upper half, and a short seta or spine below.

Maxillipeds.—The inner plates distally widened, scarcely reaching beyond the base of the first joint of the palp, with three pectinate spines high up on the inner margin, followed by one or two on the inner surface and four on the distal part of the outer margin; the truncate distal border being filled by three strong spine-teeth, attended by two or three feathered submarginal spines on the outer surface; the outer plates not reaching the distal end of the first joint of the palp, the inner margin fringed with numerous slender spines of various lengths, distally pectinate, the series continued at the apex and some way down the outer margin by long plumose setæ, six on the outer margin not closely set; the first joint of the palp rather long and narrow, with three groups of spines on the outer margin and narrowed apex; the second joint not greatly longer than the first, distally very wide, the front margin and apex fringed with many spines, the hind margin having two small groups and its apex a large one, together with a small group and a solitary spine on the inner surface below it; the third joint shorter than the first, the apical margin broad and flat, surrounded by strongly pectinate spines, the inner surface set with various groups of spines, the apical part on the outer side closely furred; the finger short, with three spines on the inner edge, and two or three eilia at the base of the nail, which is short and curved; a dorsal cilium near the centre.

First Gnathopods.—Side-plates deeper than broad, advanced in front to the base of the upper antennæ, the broad convex lower margin slightly notched for eilia. The first joint reaching below the side-plate, distally widened, rather longer than the hand, channelled in front, the front margin concave, armed with long setæ and spines, the hind margin convex, with numerous groups of short stout spines on the surface just within it; the second joint short, with a group of spines on the hinder apex; the third joint short and broad, produced into a sharp point behind and in front, much of the hind margin fringed with groups of pectinate spines; the wrist short, broad, distally eup-like, the hind margin apically toothed, fringed like that of the third joint, the surface and the front margin also carrying a few groups of spines; the hand large, a broad oval, narrowest at the hinge of the finger, with a transverse groove on the outer surface near the base, the convex front margin not much longer than the hind margin and palm, having a few small groups of spines on the surface near it; the hind margin as distinguished from the palm very short, not free from the wrist, armed with three groups of plumose setæ; the long convex palm defined by several strong palmar spines in transverse line on the inner surface; the palm border itself is strikingly striated at right angles to the outer edges, the multitudinous fine rods of the striations being themselves transversely striated; at the base of the striated border runs a fringe of spines and spinules on the outer side, and near the base on the inner side another fringe of slender spines or setæ, beyond which are some more scattered groups on the surface; on the outer side just below the spines and spinules is a series of seven or eight great spines, each with a sort of lobe or tooth over

its base, and an accessory thread lying alongside of the stout apex; the large curved finger closes over the palm with its channelled inner margin, smooth except for a series of small hairs; the dorsal cilium near the base is quite small.

Second Gnathopods.—Side-plates oblong, rather narrower and but little deeper than the preceding pair, the convex lower margin similarly notched. The branchial vesicles longer than the first joint, very broad except at the base. The marsupial plates as long as the branchial vesicles, but much narrower, fringed with many setæ. The limb closely agrees with that of the first gnathopods; the first joint is longer, the third has fewer spines on the hind margin, and a more acute apex, the hand is larger.

First Peræopods.—The side-plates similar to the preceding pair, but rather larger. The branchial vesicles rather broader than the preceding pair. The first joint reaching beyond the side-plate, the front margin fringed with slender spines, the hind margin with mixed groups of stiff spines and setæ or slender spines; the second joint short, with apical spines on the hind margin, and, as in the preceding limbs, some spinules higher up, the front lobe flattened; the third joint much longer than the fourth and a little longer than the fifth, with spinules on the front margin and spines at its somewhat decurrent apex, and spines at six points of the front margin; the spines of the next joint are stronger, at five or six points of the hind margin, and at the apex of the front; the fifth joint has nine groups of spines along the hind margin, six spinules at four points of the front margin, and a group at its apex; the finger is short, about half the length of the fifth joint; the dorsal cilium very plumose, close to the base; there is a smaller cilium near the base of the nail.

Second Peræopods.—Side-plates broad, excavated behind for less than half the depth, and less than a third of the width, the hind margin below the excavation sloping gently forwards. The branchial vesicles very broad, longer than the first joint. The marsupial plates as long as the first joint, but not quite so broad. The limb like that of the first peræopods.

Third Peræopods.—Side-plates as broad as the preceding pair or broader, the hind lobe deeper than the front. The first joint of the limb broadly oval, subequally wide at the basal and distal ends, the front margin fringed with spines, the hind margin serrate, but not deeply; the second joint with flat hind margin and pointed apex, and having two groups of spines on the front; the third joint but little longer than the fourth, not longer than the fifth, all three stout, with serrate front margins, the third joint with six, the fourth with four, the fifth with seven groups of spines in front, each with an apical group behind, and some smaller groups on the hind margin; the finger small, curved, not half the length of the fifth joint.

Fourth Peræopods.—Side-plates with a deep hind lobe and a very small front one. The branchial vesicles of great breadth, longer than broad, with a small accessory lobe near the base. The limb similar in structure to that of the third peræopods, but con-

siderably larger and longer, the first joint not regularly oval, broader at the basal than the distal end, the front margin very convex, and the hinder nearly straight.

Fifth Peraopods.—The branchial vesicles small and irregular in shape. The first joint of the limb larger than in the preceding pair, much broader above than below; the third joint also larger than in the preceding pair, like it having spines at seven points in front and at five on the hind margin, which is a little decurrent. The rest of the limb missing.

Pleopods.—Coupling spines short but strong, with apical hooks and serrate sides; the peduncles have also some lateral groups of setæ and apical rows of spines; the cleft spines appear to be seven, six, and five in the series on the first, second, and third pairs respectively; the joints of the rami number from eighteen to twenty.

Uropods.—Peduncles of the first pair rather longer than the rami, spined along two margins, one of which is produced in a blunt process tipped with a large spine; the outer ramus rather shorter than the inner, both spined along the margins, and having a group of spines at the blunt apices; peduncles of the second pair scarcely as long as the outer ramus, which is considerably shorter than the inner; the margins of the peduncles apically sharp; the rami with spines along the margins, and a group on the blunt apex; peduncles of the third pair shorter than the rami, which are subequal, apieally acute, with spines and plumose setæ along the margins.

Telson long and narrow, reaching beyond the peduncles of the third uropods, cleft beyond the centre, slightly dehiscent, the apices narrow but double, the outer point reaching a little beyond the inner, the interstice occupied by two or three cilia or setæ; on the sides near the base there are some minute setules, on the surface near the outer margin above the top of the cleft there are a pair of cilia, and some way below the top of the cleft a spine-like seta attended by a cilium.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the back of the third pleon-segment, rather more than half an inch. Another specimen measured, within the same limits, over three-fifths of an inch.

Locality.—Station 161, off Melbourne, April 1, 1874; depth, 33 fathoms; bottom, sand. Two specimens, one of them female.

Remark.—The specific name is derived from a character well known in the history of Rome.

Eusiroides pompeii, n. sp. (Pl. LXXXIX.).

Rostrum small, lateral lobes of the head with the front margin straight; the postero-lateral corners of the first two pleon-segments forming right angles, of the third segment rounded, denticleate, the upward-pointed denticles reaching halfway round the lower

lobe of the hind margin; the fourth segment with a slight transverse dorsal depression.

Eyes large, reniform, almost meeting at the top of the head, situated very near the front margin, with numerous small ocelli; dark in spirit-preserved specimens.

Upper Antennæ.—The first joint as long as the next two united, its length twice its greatest breadth, with one or two apical teeth, and two or three apical groups of spines; the second much narrower than the first, more than twice as long as the third, with some small groups of spines along the surface and on the bluntly toothed apex; the third joint armed in like manner; to a not quite complete flagellum there were fifty-three joints, the first broad, not quite so long as the third joint of the peduncle, showing within it eleven very short joints in preparation; almost every joint was armed with a calceolus and setules, many had also cylinders, these joints being distally more dilated than the others, and occurring at first alternately, then at intervals of two, and towards the end of two or three; the secondary flagellum consisting of a single slightly tapering joint, almost as long as the first of the primary, tipped with four setules.

Lower Antennæ shorter than the upper; first three joints short, gland-cone closely decurrent, third joint carrying some spines; fourth joint a little longer than the fifth, both carrying several groups of spines; the fifth joint about equal in length to the first of the upper antennæ; the flagellum thick at the base, with fifty-two or more short joints, the calceoli small.

Upper Lip so far as observed like that of *Eusiroides cæsar*.

Mandibles.—These differ from those of the species just mentioned in the following points; the secondary plate on the left mandible has seven teeth, on the right mandible is thin and straight, drawn out into four teeth at different levels, the principal plate on this mandible being broad and massive; the spine-row has nine spines on the left, seven on the right, mandible; the long third joint of the palp has a rather broader apex, and besides the thick fringe of spines on the front margin, has near the centre of the convex hind margin a single short spine or seta.

Lower Lip as in *Eusiroides cæsar*.

First Maxillæ.—Inner plate long oval, having on the inner slope of the apex two spines or short setæ, of which the upper part is slightly feathered; the outer plate carrying ten spines as in the species just mentioned, but with the lateral denticles less elongate, the innermost spine with many small denticles, the two outermost with but one denticle apiece; the first joint of the long and slender palp not more than half the length of the second, with two long spines on its outer margin; the outer margin of the second joint straight, smooth, the apex with three slender spines, eleven more fringing the oblique line running from the apex to the straight part of the inner margin; the spines are in two rows, longer in the one than the other; there is no seta on the outer margin of the trunk in our specimen.

Second Maxillæ.—The inner plate much broader and a little longer than the outer, the spines short, passing some way down the inner margin, but not nearly all round the broad distal border; the spines of the outer plate are much longer, passing a little way down the inner margin, and followed by some shorter spines not halfway down the outer margin.

Maxillipeds.—Differing in few points from those of *Eusiroides cæsarisi*; the inner plates less expanded distally, with a row of six pectinate spines at the top of the outer margin; one of the plates had four, the other three, spine-teeth on the distal border; six slender widely-spaced plumose setæ descend far down the outer margin of the outer plate; the first joint of the palp has the apical spines, but not the groups on the outer margin; the second joint has the outer margin free except for a large apical group; there are also on one palp two, on the other three, rows at a little distance within it; on the inner surface of the third joint there are two long lines of spines; the finger on one palp had three, on the other palp four, slender spines on the inner margin, the larger number being on the opposite side to that which showed the larger number of spine-teeth on the inner plate.

First Gnathopods closely resembling those of *Eusiroides cæsarisi*, except that the first joint has much of the lower part of both front and hind margin free from spines and setæ; the striated border of the palm is less deep and conspicuous.

Second Gnathopods closely resembling those of *Eusiroides cæsarisi*. The front margin of the side-plates is less rounded at the lower corner, the teeth at the lower corner of the hind margin are more marked. The branchial vesicles are broad but not so long as in the other species, while the marsupial plates are broader and longer. The second joint of the limb has spines at the apex behind, but no spinules higher up on the hind margin; the hinder apex of the third joint is bidentate, with a spine in the interstice.

First and Second Peræopods.—These with the side-plates differ but little from those of *Eusiroides cæsarisi*. The branchial vesicles are shorter, the marsupial plates wider, the joints perhaps scarcely so stout. In the side-plates of the second pair, the angle below the excavation is sharper than in the other species, and in the limb the third joint is rather shorter than that of the first peræopods, instead of being equal to it.

Third, Fourth, and Fifth Peræopods.—Between these and the corresponding limbs of *Eusiroides cæsarisi* the difference depends chiefly on the first joint, which in the present species is comparatively narrow, a not very broad oval in the third peræopods, longer in the fourth, with the top widened, in the fifth still longer, with the front and hind margins nearly straight, converging a little downwards; the short second joint has a single group of spines on the hind margin, at its apex.

Pleopods almost as in *Eusiroides cæsarisi*, but the coupling spines have a very strong lateral tooth, of which no trace was seen in the companion species; on the other hand, here the peduncles, though with many lateral setæ, appeared to be without the apical group of spines.

Uropods and *Telson* in all material respects like those of *Eusiroides cæsar*s, but the cleft of the telson not quite reaching the centre instead of extending beyond it, and the apical part of the telson slightly less acute.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the dorsal extremity of the third pleon-segment, barely half an inch.

Locality.—Station 151, Heard Island, February 7, 1874; lat. $52^{\circ} 59' 30''$ S., long. $73^{\circ} 33' 30''$ E.; depth, 75 fathoms; bottom, volcanic mud. One specimen, female.

Remarks.—The specific name is derived from Pompeius, the colleague of Cæsar in the celebrated Roman triumvirate. In addition to other marks of difference, this species shows none of the very striking striation of the integument which attracts attention in the preceding species.

Eusiroides crassi, n. sp. (Pl. XC.).

Rostrum small, lateral lobes of the head rather broad, irregularly rounded; postero-lateral angles of the first two pleon-segments produced in small teeth, those of the third segment almost right-angled, the hind margin not serrate; the fourth segment with a transverse dorsal depression.

Eyes very large, coming very near to one another on the top of the head, the inner margin concave, close to the front of the head, the ocelli numbering nearly two hundred.

Upper Antennæ very similar to those of *Eusiroides pompeii*; fifty-nine joints were counted of an incomplete flagellum.

Lower Antennæ as in the species just named; the gland-cone decurrent, well defined; fifty-two joints were counted of an incomplete flagellum.

Upper Lip with a broad distal margin, almost straight, and with the centre quite smooth, unless this appearance be due to the accidental turning back of the furred obtusely angled true margin; on either side is a tuft of spiny cilia, which seem to be confined to the margin, and not to form any curved band across the surface.

Mandibles differing from those of *Eusiroides cæsar*s in the following points—the cutting plates slighter in structure, the secondary plate on the left mandible having the terminal tooth much larger than the others, the spine-row consisting of six larger spines, with six much more slender; the teeth of the molar crown small; the palp much more massive, especially the long and broad third joint, of which the outer margin is quite smooth, extremely convex, while the inner margin is sinuous, bordered with a crowd of pectinate spines, and near the base with a few setæ; the apex, though narrow, has many long spines.

Lower Lip as in *Eusiroides cæsar*, the lateral margins well rounded, so that the apices of the mandibular processes are directed a little inwards.

First Maxillæ.—The inner plates long and narrow, with three spines or setæ on the inner side of the apex ; of the ten long spines on the truncate margin of the outer plate, the innermost has six lateral denticles, a shorter one beside it has three, the next beyond it four, the remainder being apparently content with two or one, the denticles being in most cases long ; the first joint of the palp half the length of the second, with one spine on the outer margin ; the second joint widest at the middle, where it has one spine on the convex outer margin ; two rows of slender spines, longer and shorter, fifteen in number, fringe the oblique line from the apex to the point on the inner margin where the plate is widest.

Second Maxillæ similar to those of *Eusiroides pompeii*.

Maxillipeds very similar to those of *Eusiroides pompeii*, but the inner plates have a series of five or six plumose setæ beginning on the inner margin and passing on to the surface some way short of the apex, the apical border having three curved spines on the outer part, and on the inner four spine-teeth all less stout, and one much less so, than in the other two species of *Eusiroides* ; the setæ on the outer margin of the outer plate do not descend so low as in either of those species ; the first joint of the palp is apically acute, with spines on both sides of the point, the broad second joint has no spines on or near the outer margin except the apical group ; the finger is more elongate, with a longer and sharper nail than in the other two species, with a single spine on the inner margin, and this in our specimen present only on one palp.

First and Second Gnathopods like those of *Eusiroides pompeii*, but the hinder apex of the third joint apparently not bidentate ; the hands are rather more swollen at the middle, compared with the two extremities, than in either of the two preceding species, so that especially in the second gnathopods there is a more definite separation of the palm from the hind margin, yet not quite so marked a distinction as in the figure *gn.2*.

First and Second Peræopods similar to those of *Eusiroides pompeii* ; the branchial vesicles shorter ; the fifth joint of the limb with only seven groups of spines on the hind margin instead of nine.

Third Peræopods.—Side-plates with the hind lobe much deeper than the front. Branchial vesicles narrowly oval, much smaller than the first joint. First joint more oblong than oval, very broad, with a tuft of setæ near the top of the front margin, spines at four or five points below, the hind margin nearly straight, with few not deep serrations, the lower margin broad and rather flat, to a great extent overlapping the short second joint ; the third joint broad, decurrent behind, longer than the fourth ; the fifth and sixth joints missing.

Fourth Peræopods.—Side-plates with a deep hind lobe and a very small front one.

Branchial vesicles as in the preceding pair. First joint of the limb longer than in the third pereopods, more convex in front, the hind margin long and nearly straight, with few serrations, the lower margin more deeply overlapping the second joint; the third joint longer and larger than in the preceding pair, with spines at five points on the straight serrate front margin, and at four of the hind margin, which is convex above and straight below.

Fifth Peraopods.—Side-plates deeper behind than in front, but not lobed. The first joint like that of the fourth pereopods, but less convex in front; the fourth joint shorter than the third, with four groups of spines on the straight serrate front margin, and an apical group behind; the fifth joint about as long as the third, with six groups of spines along the serrate front margin; the finger much curved, about half the length of the fifth joint.

Pleopods.—Coupling spines not examined; cleft spines four in the series on the third pair; the joints of the rami on the same pair numbering eighteen.

Uropods similar to those of *Eusiroides pompeii*; telson comparatively shorter than in that species, the apices simple, but as these have a worn appearance in the specimen, this mark of distinction cannot be relied on; the lateral margins are without the slight sinuosity observable in the two preceding species; in fig. *ur.3*, the telson being removed, the acute apex of the ventral side of the sixth pleon-segment is seen.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the dorsal extremity of the third pleon-segment, about half an inch. The specimen was dissected unfortunately before the line of measurement had been drawn.

Locality.—Station 320, off Monte Video, February 14, 1876; depth, 600 fathoms; bottom, green sand; bottom temperature, $37^{\circ}2$. One specimen.

Remark.—The specific name is derived from Crassus, the colleague of Cæsar and Pompey (or Pompeius) "in the first triumvirate" of Roman history. The name was chosen with a view to calling attention to the close alliance between this and the two preceding species. It may be convenient to compare the localities from which the three were respectively obtained: *Eusiroides cæsaris* came from Station 161, lat. $38^{\circ} 22' 30''$ S., long. $144^{\circ} 36' 30''$ E.; *Eusiroides pompeii* from Station 151, lat. $52^{\circ} 59' 30''$ S., long. $73^{\circ} 33' 30''$ E.; and *Eusiroides crassi* from Station 320, lat. $37^{\circ} 17'$ S., long. $53^{\circ} 52'$ W., so that, though not very remote from one another as regards the latitude, in respect to longitude the three species cover an enormous space.

For an account of *Iduna* see Note on Boeck, 1860 (p. 324). *Iduna* being preoccupied has been superseded by *Liljeborgia*, for the original definition of which see Note on Spence Bate, 1862 (p. 333). In 1865, Lilljeborg, unaware of the identity of Spence Bate's genus with Boeck's, changed *Iduna* into *Microplax*, which he placed in his third subfamily "Gammarina, Dana," and defined as follows:—

"Antennæ superiores flagello appendiculari præditæ. Caput antice non productum. Pedunculus antennarum superiorum medioeris et segmenta ejus ultima duo elongata.

"Pedes maxillares laminis interioribus prædicti, laminaeque hæc et exteriore minimæ et interiores vix basin palpi assequentes. Mandibulæ inter se similes."

Boeck in 1876 gives the following definition of *Liljeborgia*, for which in the list of errata he substitutes the erroneous spelling *Lilljeborgia*:—

"Mandibles apically strongly dentate; molar tubercles obsolete.

"Upper Antennæ shorter or little longer than the peduncle of the Lower; the accessory flagellum very long.

"First Gnathopods with the hand a little smaller than that of the Second pair, but of similar shape; the wrist rather short, produced into a heel behind and downwards.

"The Fourth Peræopods longer than the Third, and the Fifth than the Fourth.

"The Telson cleft to the base."

The last character must be modified as at any rate not applicable to all the species within the genus; it may be changed into—Telson more or less cleft. Lilljeborg's statement that the mandibles are alike is not entirely accurate, since the secondary plate on the right mandible is very different from that on the left.

Liljeborgia consanguinea, n. sp. (Pl. XCI.).

Rostrum narrow, sharply pointed, not half the length of the first joint of the upper antennæ, lateral lobes of the head narrow, distally rounded, outdrawn between the upper

and lower antennæ; the first segment of the peræon the shortest, the seventh the longest; the pleon carinate, each of the first five segments dorsally produced backwards in a small but pronounced tooth, with a cilium attached to the under side; the first three segments of the pleon long, the postero-lateral angles produced in a small sharp tooth, larger on the third segment than on the others, and on that segment upturned; the hind margin of the third segment is sinuous on each side below the dorsal tooth.

Eyes themselves not perceived, but from traces on the integument of the head it may be inferred that they were present, and of considerable size.

Upper Antennæ.—First joint considerably longer than the two following united, the second more than half the length of the first, with three groups of setæ on the inner side, distally produced into two sharp points, the third joint not longer than broad; the flagellum of thirteen joints, the first nearly twice as long as the third joint of the peduncle, all together rather longer than the whole peduncle; the secondary flagellum of nine (on one antenna of eight), joints, equal in length to the first five of the primary.

Lower Antennæ longer than the upper, the first joint little expanded, the second more than usually distinct from the first, with a blunt inconspicuous gland-cone, the third much longer than the second, with some small spines at the lower apex; the fourth joint more than twice as long as the third, with some spines along the margins, the fifth rather longer, also set with spines or short setæ; the flagellum of thirteen joints, not nearly so long as the peduncle.

Upper Lip.—The distal plate somewhat of a transverse oval in shape, its distal margin insinuate in a very slight almost imperceptible degree, furred in the usual manner. (This description is given from the Heard Island specimen.)

Mandibles.—The cutting edge angled, divided into six teeth, the four uppermost being small, the next the most prominent, the lowest as large as this or larger; the secondary plate of the left mandible is almost as large and powerful as the principal, its edge less oblique, divided into five teeth, of which the lowest is the largest, the uppermost the smallest, with two small denticles on its side; on the right mandible the secondary plate is much feebler, the edge denticulate with seven or eight little denticles and two moderately strong teeth at the lowest part; the spine-row consists of six spines, those nearest the cutting edge being the strongest; from the bluntness of these spines in actual use compared with their sharpness in preparation, it may be inferred that they are by no means merely ornamental appendages; beyond the spine-row, doing duty apparently for the molar tubercle, is a second row of five or six spines, set closely together, the first one or two short, the rest long, the furthest back being much the longest; the slender palp, exceeding the length of the trunk of the mandible, is fixed on a projection over the space between the two spine-groups, and has three almost equal joints, the second a very little longer than the first, and the first than the third; some four slender spines or setæ

high up on the inner margin of the second, the third with some twelve or thirteen similar spines or setæ on the margin and apex.

Lower Lip.—The lobes capable of wide dehiscence, ciliated on the narrow top and the inner margin; the mandibular processes short and divergent. The figure *l.i. A* was drawn from the Heard Island specimen, and seems to show the extreme dehiscence of which the lobes are capable, causing the generally very divergent mandibular processes to assume a position parallel to one another. For what is probably the more normal position and appearance the figure of the lower lip of *Liljeborgia haswelli* may be consulted. On the inner margin near the apex there seems to be in both species a small spine among the cilia.

First Maxillæ.—Inner plate small, almost oblong, with a plumose seta at the apex and a shorter one below it; the outer plate with ten spines of various lengths, two short, with only a single lateral tooth apiece, several long and slender and much denticulate, the strong outermost spine with a little denticle on each side; the second joint of the palp reaching far beyond the outer plate, carrying five or six spine-teeth on the apical margin, and several spines on the inner margin and near the apex, besides two on the outer margin.

Second Maxillæ.—The inner plate short and broad, shorter and much broader than the outer, with plumose spines round the apical and a little way down the inner margin, the latter having some strong cilia below; the inner plate has several spines on the apex, and two or more small ones on the outer margin.

Maxillipeds.—The inner plates narrow, not reaching much beyond the base of the first joint of the palp, with two long spines on the inner margin, three spine-teeth and four slender spines on the apical margin; the outer plates narrow, reaching a little beyond the first joint of the palp, fringed on the inner side with ten or eleven spine-teeth, the two longest completely occupying the apex; there are besides some submarginal slender spines on the outer surface; the first joint of the palp is short, with two spines on the outer margin near the rounded apex, the second joint is very long, widening distally, fringed with spines on the inner margin and outer apex; the third joint is also long, yet shorter than the second, like that having many spines; the finger is long and broad, shorter than the third joint, the nail minute, the inner margin not much curved, pectinate, the dorsal cilium small, near the base.

First Gnathopods.—The side-plates narrow at the base, very broad below, the front margin running obliquely forward to the lateral lobes of the head, bending abruptly downwards, and forming a small tooth before bending round to join the long lower margin; the hind margin nearly straight, forming a small tooth at its juncture with the lower margin. The first joint of the limb reaching much below the side-plate, slightly longer than the hand, and much narrower, with short spines standing out from the front margin, and many long setæ on the hind margin; the second joint short; the third not much

longer, oblong, with three groups of spines on the hind margin and one on the rounded apex; the wrist in front scarcely longer than the third joint, with an apical spine, distally cup-like, prolonged behind, and there set with many groups of spines of various lengths, the apical groups the largest, many, if not all, of the spines being pectinate; the hand large, oval, the front margin smooth, with a few spines at the apex, the hind margin also smooth, short, almost covered by the prolongation of the wrist, but very nearly continuous with the long curve of the palm, which is set with very many slender spines and spinules (smooth or almost smooth), and defined by some short palmar spines, near to which is a long row beginning with stout spines near the margin, and continued for some distance across the inner surface with longer and shorter stiff setæ; the long curved finger exactly matches the length of the palm, it has a small dorsal cilium near the base, its inner edge is smooth, except for three or four teeth or notchings near the base.

Second Gnathopods.—The side-plates broader above than below, the front margin convex, the hinder sinuous, the lower bounded by a small tooth at either end. The branchial vesicles narrow, much smaller than the first joint of the limb. The marsupial plates as narrow as the branchial vesicles, nearly as long as the first joint, fringed with setæ. The first joint reaching much below the side-plate, not so long as the hand, the front margin concave, the armature much as in the first gnathopods, with which in other respects the second closely agree, but the third joint is apically pointed, the hand is very much larger, and the seven teeth of the inner margin of the finger reach more nearly to the tip; the group of spines and setæ on the inner surface near the commencement of the palm is scarcely so large as in the other gnathopods, but there are some additional groups of spines near the outer margin.

First Peræopods.—The side-plates like the preceding pair. The limb slender; the first joint reaching below the side-plate, carrying long setæ on both margins; the third joint longer than the fifth, the fourth shorter, all three with setæ or slender spines on the hind margin; the finger narrow, a little curved, more than half the length of the fifth joint.

Second Peræopods.—Side-plates nearly as broad as the first pair, rather deeper than the third, excavate behind, the hind margin below the excavation straight, cut into four teeth. The limb like that of the first peræopods.

Third Peræopods.—First joint expanded, front margin convex, with spines at nine points, hind margin less convex, cut into nine notches; second joint short; third joint much longer and broader than the fourth or fifth, with spines at five points of the straight front margin and three of the convex hind margin; fourth joint slightly longer than the fifth, each straight, with an apical group of spines behind, and four groups on the front margin; finger small, half the length of the fifth joint.

Fourth Peræopods.—Side-plates shallow. Branchial vesicles narrow and short. First joint of the limb longer than in the preceding pair, with spines at nine points of

the front margin and some feathered cilia near the top, the hind margin nearly straight, serrate with ten teeth; the other joints resembling those of the third peræopods but longer.

Fifth Peræopods.—Side-plates very small. The first joint longer and broader than in the preceding pair, the hind margin very convex, notched into thirteen teeth; the third joint stronger than in the preceding pair, not so long as the fifth, armed with spines at five points in front and four behind; the fourth joint nearly as long as the third; the whole limb considerably longer than any of the preceding.

Pleopods.—Coupling spines small, slender, and much curved, with a row of five little lateral teeth just below the apex; below them is a slender plumose spine; the cleft spines appear to be four in number; the joints of the rami ten on the inner, eleven on the outer, branch. Only one pair of pleopods was examined.

Uropods.—Peduncles of the first pair but little longer than the rami, the inner apex sharp, the outer armed with a long spine, the outer ramus a little longer than the inner, the outer with two marginal spines, the inner with one, both with curved pointed apices; peduncles of the second pair reaching as far back as those of the first pair, equal in length to the rami; the rami equal, similar in armature to the first pair; peduncle of the third pair rather shorter than the rami, which reach beyond the other pairs with almost their whole length; the inner ramus a little shorter than the outer, broader, with two spines on the inner edge.

The Telson reaching beyond the peduncles of the third uropods, not quite twice as long as broad, cleft rather beyond the centre, slightly dehiscent between the apices, each of which is double, the outer point produced a little beyond the inner, with a long spine inserted between the two points.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the apex of the third uropods, a little over two-fifths of an inch.

Locality.—Station 149, Accessible Bay, Kerguelen, January 9, 1874; depth, 20 fathoms; bottom, volcanic mud. One specimen, female.

Station 151, off Heard Island, February 7, 1874; depth, 75 fathoms; bottom, volcanic mud. One specimen, from which the upper lip and maxillæ were figured.

Remarks.—The specific name refers to the obviously very close relationship between this southern species and the northern *Liljeborgia pallida*, Spence Bate. The present species is distinguished by its superior size, the greater number of spine-teeth on the outer plates of the maxillipeds, the less dentate inner margin of the finger of the first gnathopods, the relative proportions in the joints of the peræopods, and those in the three pairs of uropods; the telson here is cleft but little beyond the centre, while, according to Boeck, in *Liljeborgia pallida* it is cleft to the base.

Liljeborgia haswelli, n. n. (Pl. XCII.).

1880. *Eusirus dubius*, Haswell, Proc. Linn. Soc. N.S.W., vol. iv. p. 331, pl. xx. fig. 3.
 1882. " " Haswell, Catalogue of the Australian Stalk and Sessile-eyed Crustacea, p. 247.
 1885. " " Haswell, Proc. Linn. Soc. N.S.W., vol. x. pt. i., extract, p. 6, pl. xiv. fig. 1.

Rostrum narrow, sharply pointed, not half the length of the first joint of the upper antennæ, lateral lobes of the head rather broadly rounded, outdrawn between the upper and lower antennæ; the last two segments of the pereon and first five of the pleon dorsally produced backwards into a tooth; in the first and second segments of the pleon a large central tooth is accompanied by two others on each side, the nearer smaller than the more distant, on the third segment a very small tooth has on either side a large projecting lobe of the hind margin; the postero-lateral angles of the second and third segments have sharp points, very slightly produced; the sixth segment carries a pair of dorsal spines, beyond which its dorsal margin becomes duplex, diverging on each side of the telson.

The Eyes are oval, situated on the lateral lobes; when the ocelli are withdrawn there are markings left on the integument as if of incipient facetting.

Upper Antennæ.—First joint narrowing distally, much longer than the two following joints united; the second joint short, with the upper margin longer than the lower, carrying two groups of setæ, the distal margin oblique; the third joint broader than long; the flagellum of thirty-four joints, the first a little longer than the third joint of the peduncle, most of the joints having distally a group of setæ and a cylinder; the secondary flagellum of eighteen joints equalling in length the same number of the primary.

Lower Antennæ longer than the upper, the first joint a little inflated, the second very distinct, with a short and broad blunt gland-cone; the third joint but little longer than the second; the fourth joint long, with many groups of spines on the margins; the fifth still longer, with slenderer spines; the flagellum of twenty-four joints, of which the first is the longest, the whole flagellum much shorter than the peduncle.

Upper Lip.—The distal plate transversely oval, with no trace of insinuation of the distal margin.

Mandibles similar in structure to those of *Liljeborgia consanguinea*, but here the trunk is broader, while the palp is more slender, shorter than the trunk of the mandible, the third joint with three or four long setæ on the inner margin and three at the apex; the secondary plate of the left mandible is also considerably smaller than the principal plate.

Lower Lip.—The lobes dehiscent, ciliated round the narrow tops; the mandibular processes short, divergent, apically rounded.

First Maxillæ.—Inner plate small, with a long seta at the apex; outer plate short
 (ZOOL. CHALL. EXP.—PART LXVII.—1887.)

and broad, with ten spines on the truncate apical border, none of them stout, many of them long, the innermost nearly straight, very minutely dentieulate near the apex, the next very short, four long ones in the middle curved at the apex, and having four denticles below it, the rest shorter, with fewer denticles ; the first joint of the palp very short, the trunk of the maxillæ rising to a point which overlaps it on the outer side, the second joint reaching far beyond the outer plate, with slender spines round the apical and much of the outer and inner margins, together with rather long spine-teeth on the apical margin.

Second Maxilla.—Inner plates broadly oval, shorter and slightly broader than the outer, the rounded apical margin crowded with spines, which also descend halfway down the inner margin, at the lowest point being accompanied by long setæ or setiform spines ; the outer plate has spines at intervals along the inner border, closely set round the apical, and of much diminished size along the distal half of the outer margin.

Maxillipeds.—The inner plates small, reaching a little beyond the base of the first joint of the palp, with several spines passing from the distal part of the inner margin across the outer apex, the truncale apical border having three rather long spine-teeth ; the outer plates very narrow, reaching a little beyond the first joint of the palp, with ten spine-teeth along the serrate inner margin, including the longer two at the apex, which is scarcely distinct from the line of the inner margin ; the first joint of the palp short, with a pointed apex on the outer side, at and within which are several slender spines ; the second joint long, narrowed at both ends, fringed on the inner margin with spines, and having a few on the surface and on the distal part of the outer margin ; the third joint shorter than the second, but much longer than the first, almost evenly broad except at the narrow bent base, with groups of spines on the lower part of the outer margin, along almost all of the inner margin, round the apical, and on both surfaces in closer rows at some distance within the inner margin ; the finger narrow, much shorter than the third joint, rather longer than the first, with a small dorsal cilium near the base, a small cilium at the base of the minute nail, the inner edge finely pectinate.

First Gnathopods.—Side-plates narrow at the base, wide below, the front margin running obliquely forwards, rounded below and scarcely indented, the hinder margin indented but not serrate where it meets the lower margin. The first joint about as long as the hand, a little dilated at the centre, fringed with spines or setæ on both margins, the second joint as long as the third ; the third with three or four groups of spines on the hind margin, which is apically acute ; the wrist with a very short hind margin, distally eup-like, behind produced and fringed with many rows of pectinate spines ; the hand large, not twice as long as broad, broadest beyond the commencement of the palm, which is very convex, set round with numerous slender spines or spinules of various lengths, and defined by palmar spines, some of which, including one long one, are inserted on the inner surface with a group of setæ close by ; the fringing spines of the palm are

pectinate, with two hairs near the middle on one side conspicuous ; the long front margin is not very convex, and like the short hind margin not armed unless by a few adjacent setæ ; the long finger curves closely over the whole palm margin ; dorsal cilium close to the base, very small.

Second Gnathopods.—Side-plates much narrower below than above, the front margin very convex, the lower scarcely distinguishable from it ; the hind margin forming a little tooth where it joins the lower. The branchial vesicles as long as the first joint and rather broader. The marsupial plates longer, much narrower, fringed with setæ. The limb like that of the first gnathopods, but the first joint longer, with the front margin slightly concave, the second joint broader, the third with a more elongate apex, the wrist broader, the hand and finger considerably larger ; the finger has seven teeth or notchings of the inner margin beginning from the hinge, the dorsal cilium is very small ; submarginal to the outer rim is a row of setules over the notched part of the inner margin.

First Peræopods.—Side-plates like the preceding pair. Branchial vesicles nearly as long as the first joint and more than twice as broad. Marsupial plates as long as the first joint, but narrower ; the first joint reaching much beyond the side-plate ; fringed with setæ ; the third joint longer than the fourth, shorter than the fifth but much broader, the hind margin nearly straight, carrying a few spinules ; the fourth joint with slight spines at six points of the hind margin ; the fifth joint with a row of eleven spines along the hind margin, and a long one at the apex of the front ; the finger not half the length of the fifth joint, not much curved.

Second Peræopods.—Side-plates broad, though not quite so broad as the lower part of the first side-plates, the excavation behind narrow, the margin below it parallel with the front, having a small notch at the centre and one where it meets the lower margin. Branchial vesicles longer than the first joint, broader than the preceding pair. Marsupial plates and the limb as in the preceding pair.

Third Peræopods.—First joint expanded, the front margin convex, with spines at nine points, the hind margin nearly straight, with eleven notches of different depths, the lower margin almost straight ; the second joint with the convex hind margin apically acute ; the third joint longer than the fourth or fifth, with spines at five points in front and at four behind ; the fourth joint shorter than the fifth, with spines at four points in front and two behind ; the fifth with spines at eight points on one margin, and setæ and perhaps spines at eleven points on the other ; the finger slender, not one-third the length of the fifth joint.

Fourth Peræopods.—Broken below the third joint ; the first three joints very like those of the third pair, but larger.

Fifth Peræopods.—Like the third pair, but very much larger, the first joint at the top broader than in the fourth pair, as that is broader than in the third pair ; the hind

margin deeply cut; the fifth joint with two rows of spines, but so far as observed without setæ.

Uropods.—Peduncles of the first pair scarcely longer than the rami, apically acute within, and on the outer side having a broad apical spine, the rami subequal, the inner perhaps a little the longer, with fewer and stronger marginal spines; the peduncles of the second pair not reaching back quite so far as those of the first, scarcely so long as the inner ramus; the outer ramus shorter than the inner, with the marginal spines less strong, its upper surface more deeply channelled; peduncles of the third pair not so long as the rami, reaching beyond the other two pairs with almost their whole length; the rami broad, lanceolate, reaching back beyond the other pairs, spined on both margins, which are partially pectinate, especially the inner edge of the outer ramus, which is rather shorter and narrower than the inner.

Telson long and narrow, reaching a little beyond the peduncles of the third uropods, cleft nearly to the base, the apices double, the outer point of each produced much beyond the inner, the spine inserted between them reaching beyond the outer point.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the apex of the third uropods, three-fifths of an inch.

Locality.—At Station 162, off East Monceur Island, April 2, 1874; lat. $39^{\circ} 10' 30''$ S., long. $146^{\circ} 37' 0''$ E.; depth, 38 fathoms; bottom, sand and shells. One specimen, female.

Remark.—The specific name is given in compliment to Mr. Haswell, who has described and figured this species from Tasmania and Port Jackson, calling it *Eusirus dubius*, but as there is in fact no doubt whatever that it belongs to the genus *Liljeborgia*, the specific name *dubius* must be sacrificed in spite of its priority.

Liljeborgia æquabilis, n. sp. (not figured).

The specimen on which this species is founded was taken together with *Liljeborgia haswelli*, and bore so great a general resemblance to it that it was dissected as a variety, before any figure of the animal had been drawn. It appeared to be without dorsal teeth, but some small ones may have escaped observation; the third, fourth, and fifth segments of the pleon were compressed, but scarcely earinate; the postero-lateral angles of the first three segments of the pleon were produced in small sharp points; the third segment was lobed at the upper part of the hind margin.

Eyes large, with very numerous small ocelli, very dark in the specimen preserved in spirits.

Upper Antennæ with a broad tapering flagellum of twenty-three joints, the secondary flagellum of thirteen, together equal in length to eleven or twelve of the primary.

Lower Antennæ with a short, broad, tapering flagellum of eighteen or nineteen joints.

Mandibles.—The secondary plate on the left mandible has four strong teeth, on the right mandible it is very feeble and minutely denticulate; the spine-row consists of nine spines, their apices diverging a little fanwise; these are followed by a group of four seta-like spines, the nearer two short, the others long; the palp is broader than in *Liljeborgia haswelli*, the first joint the broadest, the second longer than the first, with two spines on the inner margin and four about the squarish apex, the third joint narrower than the second, shorter than the first, with three spines on the outer, one on the inner, margin, and three on the conical apex.

First Maxillæ.—The very short first joint of the palp is almost overlapped by an apically rounded process of the trunk of the maxilla.

Second Maxillæ.—The spines on the outer plate do not pass so far down the inner margin as in the compared species.

Maxillipeds.—The spine-teeth of the inner plate are fewer and larger; the finger is proportionately longer, compared with the first joint of the palp.

First Gnathopods.—These and the following pair are a little less massive than in the other species.

Second Gnathopods.—The branchial vesicles shorter than the first joint.

Second Peræopods.—The hind margin of the side-plates below the excavation without a notch, except an almost imperceptible one where it curves round to meet the lower margin. The third, fourth, and fifth peræopods differ from those of *Liljeborgia haswelli* in regard to the first joint, which has the hind margin convex, in the fifth pair very convex, and in all so minutely serrate as to appear almost smooth, in contrast to the deep notching of the other species; the fingers are very short, and a little curved; the fourth and fifth joints are fringed with long setæ or seta-like spines, but on this stress cannot be laid as a mark of distinction, since in the other species there are traces indicating the possibility that these ornaments were once present.

Pleopods.—Coupling spines small, apparently with two pairs of retroverted hooks; cleft spines four in number in one instance, five in another; the joints of the rami sixteen in number.

Uropods.—Peduncles of the first pair longer than the rami; the rami nearly equal, the inner a little the longer; peduncles of the second pair about as long as the inner ramus, which is broader and rather longer than the outer; the peduncles of the third pair shorter than the rami; the rami broad, lanceolate, spined on both margins and partially peetinate, but very finely; the outer ramus shorter and narrower than the inner.

Telson long and narrow, cleft almost to the base, the apices double, with two small points, the inner reaching scarcely beyond the outer, a small spine and a spinule occupying the interstice.

In the details of the mouth-organs and the limbs, apart from those which have been just specified, the specimen agreed so nearly with *Liljeborgia haswelli*, obtained in the same dredging, that recapitulation seemed unnecessary.

Locality.—Station 162, off East Moncoeur Island, April 2, 1874; lat. $39^{\circ} 10' 30''$ S., long. $146^{\circ} 37' 0''$ E.; depth, 38 fathoms; bottom, sand and shells.

Remark.—The specific name refers to the comparative paucity of notches and teeth in the body and limbs of this animal.

Family PARDALISCIDÆ, G. O. Sars, 1882.

In 1870 Boeck instituted the Pardaliscinæ as the eighth subfamily of the Gammaridæ, and in his subsequent work transferred the group to the Leucothoidæ as the fifth subfamily, but without altering the definition, and in each case assigning the same three genera, *Pardalisca*, *Halice*, *Nicippe*. Sars in 1882 changed the subfamily into the family Pardaliseidæ. Boeck gave the following definition:—

“ *Upper Lip* broad, insinuate below [distally].

“ *Mandibles* without molar tubercle, not alike, apically dentate; one with, the other without, an accessory plate; the palp three-jointed; its second joint elongate.

“ *First Maxillæ* with the palp tolerably broad, apically furnished with many teeth; the inner plate nodiform.

“ *Second Maxillæ* with narrow plates.

“ *Maxillipeds* with the inner plates little or obsolete, the outer plates either broad but rather short, or narrow; the palp elongate, narrow; the last joint unguiform.

“ The body thick, inflated, with small side-plates.

“ *Upper Antennæ* slender, with an accessory flagellum; the peduncle very short; the anterior joints of the flagellum in the male coaleseed and together forming a large joint, furnished on the inner side with bundles of setæ.

“ *First and Second Gnathopods* of the same shape.

“ *First and Second Peræopods* strong, the third joint short.

“ *Fourth Peræopods* longer than *Third*, *Fifth* than *Fourth*; in these three pairs the first joint not strongly dilated; the finger long.

“ *Uropods* biramous; the rami almost equal in length; those of the third pair laminar.

“ *Telson* elongate, cleft.”

Buchholz in 1874 expressed the opinion that in *Pardalisca* both mandibles possess a secondary plate, but he was probably misled by observing a broad spine on the right mandible worn down by use to a stumpy condition, suggestive of its being a plate instead of a spine. Bruzelius in describing the right mandible of *Pardalisca cuspidata*, Krøyer,

says that it "has not any inner plate, but only a very little apically bifid tooth, situated on the inner side." J. S. Schneider in 1884, describing the same species, says of the right mandible that "the spine-row consists only of two curved spines serrate on one edge." Boeck mentions neither the two spines nor their equivalent, the bifid tooth. Of his own species, *Pardalisca abyssi*, he says that the mouth-organs are the same as in *Pardalisca cuspidata*. Schneider observes that in Boeck's *De Skand. og Arkt. Amph.*, pl. xii., the figure (5g) which is numbered as representing the second maxillæ of *Pardalisca cuspidata* in fact belongs to *Syrrhoë crenulata*. He also remarks that in *Pardalisca cuspidata* the telson is not, as stated by Krøyer and Boeck, cleft to the base, but only for three-quarters of its length.

Genus *Pardalisca*, Krøyer, 1842.

For the original definition of the genus, see Note on Krøyer, 1842 (p. 199). Boeck defines it as follows:—

"*Mandibles*.—The right mandible apically armed with four strong teeth; the left mandible furnished with weak teeth.

"*Maxillipeds* with the outer plate broad but short, not very prominent; the inner plate wanting.

" The *Upper Antennæ* longer than the lower; the peduncle very short.

" *Lower Antennæ* with the peduncle not very elongate.

" *First and Second Gnathopods* with the wrist more or less dilated; the hand narrow and not subheliform; the finger (*unguis*) broad.

" *First and Second Peræopods* with the third joint dilated, but tolerably short; the fourth joint ovate, the finger laminar.

The *Third, Fourth, and Fifth Peræopods* not very elongate."

The statement, that the upper antennæ are longer than the lower, cannot be worth retaining, since Boeck himself says of *Pardalisca abyssi* that the upper antennæ are slightly *shorter* than the lower.

It will also be more accurate to speak of the inner plates of the maxillipeds as rudimentary or wanting, rather than as wanting without exception or qualification.

Pardalisca abyssi, Boeck (Pl. XCIII.).

1870. *Pardalisca abyssi*, Boeck, Crust. amph. bor. et aret., p. 72.
 1874. " *cuspilata*, Buehholz, Die zweite deutsche Nordpolarfahrt, p. 306, Taf. 1, fig. 3,
 Taf. 2, fig. 1.
 1876. " *abyssi*, Boeck, De Skand. og Arkt. Amph., p. 486.

Rostrum short, not very sharp at the apex, lateral lobes of the head not prominent, extending to the lower corners, which are rounded; postero-lateral angles of the first two pleon-segments acute, not produced, of the third a little rounded; the hind margin of the third and fourth segments with a pair of dorsal teeth, wider apart on the third than on the fourth segment.

Eyes not observed.

Upper Antennæ.—The first joint thick, as long as the two following together, the third not longer than broad, not half the length of the second; the flagellum much longer than the peduncle, of many short joints (more than forty); the secondary flagellum slender, of six joints, together equal in length to the first seven or eight of the primary.

Lower Antennæ.—The peduncle much longer than that of the upper pair; first joint dilated, gland-cone of the second long, decurrent; third joint short, scarcely longer than the second; fourth elongate, narrowing a little distally, fringed above with setules; fifth joint more slender, a little shorter, similarly fringed; the flagellum of more than thirty-three joints.

Upper Lip distally smooth, the broad shallow emargination making it not very unequally bilobed.

Mandibles.—Cutting edge of the left mandible of great breadth, with a little curved denticle at the top, whence the front margin runs out forwards and downwards, its straightness only interrupted by a little irregular blunt denticulation, then again retiring it forms three large teeth, the first the most prominent, the lowest by far the largest, broken in our specimen, but seen within in readiness for the next change of skin; the secondary plate is also broad, roughly triangular, its distal border pectinately denticulate, and in general outline looking like a hasty copy of the principal plate, but without the large lowest tooth; two curved spines, serrate on the concave edge, take their rise at the base of the secondary plate; the cutting edge of the right mandible is divided into four very pronounced teeth, of which the uppermost and shortest is incompletely subdivided, the lowest but one is the broadest; near the lower edge of the mandible there are two curved spines, one much broader than the other, with a double pectination on its concave side; the second which is much slighter seems to rise from the base of the first; the first

joint of the palp is more than twice as long as broad, the second joint is long, much curved, the outer margin concave, the convex inner margin fringed with slender pectinate spines, of which one near the centre is very long; the third joint is shorter than the second, both margins a little convex, the inner and the narrow truncale apex set with rows of finely pectinate spines.

Lower Lip.—The principal lobes distally narrow and strongly ciliated both there and on the inner margins, widely dehiscent; the inner lobes tumid, broad at the top, and much ciliated; the mandibular processes long, the outer margin making an elbow, the apical flat, sloping outwards.

First Maxillæ.—The inner plate small, with a single plumose seta at the apex; the outer plate widening distally, the distal margin oblique, carrying seven spines, the first long, seta-like, plumose or fury, the four following shorter, slender, with curved tips, the next very much stouter, the last again both longer and stouter, quite out of proportion to the rest; submarginal to the last but one is an eighth very slender curved spine, smooth-edged like the other six; the first joint of the palp longer than broad, the second curving round the outer plate, widening almost fan-like to a great breadth distally, the distal margin being set round with twenty small spine-teeth, accompanied by some setules which are continued down the inner border.

Second Maxillæ.—The inner plate rather longer and considerably broader than the outer, with the apex and most of the inner margin fringed by four and twenty very long plumose setæ, the outermost at the apex being shorter than those which immediately follow, but otherwise the size diminishing with great regularity from the apex downwards; the strap-shaped outer plate carries three similar setæ on the truncate apex.

Maxillipeds.—The inner plates rudimentary, rather longer than broad, the narrow truncale apex tipped with two long setæ; the joint which bears them is very short compared with the elongate second joint; this is fringed on both margins with numerous spinules or setules, and on the outer surface near the slightly concave inner margin armed with numerous very long setæ; the plates are about one-third of the total inner length of the joint, very little longer than broad, not reaching beyond the first joint of the palp, the slightly convex distal margin fringed with long spines, the series of spinules being resumed on the outer margin; the first joint of the palp is short, the second much longer, fringed on the inner side with very many long setæ and spines, and short setæ on the outer side; the third joint not longer than the first, fringed like the second; the finger not so long as the third joint, with spinules along the inner margin; the full breadth of the palp is not seen in the figure.

First Gnathopods.—Side-plates almost square, a little longer than broad, a little broader above than below, the lower margin fringed with spine-like plumose setæ. The first joint reaching far beyond the side-plate, widest at the distal end, the front apex of which is rounded, both margins fringed with various spines; the second joint with spines

along the hind margin; the third joint not elongate, distally rather eup-like, the upper part of the hind margin unarmed, the lower part fringed with long pectinate spines; the wrist not quite so long as the first joint, much longer and thicker than the hand, the front margin smooth, rather irregularly convex, the hind margin nearly straight, fringed with numerous spines, many of them very long; the hand more than half the length of the wrist, the front margin convex, smooth, the hinder slightly concave, densely fringed with spines which are finely pectinate on two edges; the finger much curved, a little shorter than the hand, of which it continues the front curvature, close to the smooth inner edge carrying a row of some sixteen submarginal spines, and a couple of cilia, one at, the other near, the base of the nail. The finger is not adapted for impinging against any part of the hand, but evidently hand and finger co-operate to enable the nail to reach the wrist.

Second Gnathopods.—The side-plates closely resembling the preceding pair. The branchial vesicles longer than the first joint, somewhat lageniform. The marsupial plates longer than the branchial vesicles, not narrow, fringed on both margins with long setæ. The limb closely resembling that of the first gnathopods; the second joint with a large group of spines on the hinder apex; the wrist much longer than in the preceding pair, widest just below the third joint, then narrowing towards the hand, the upper part of its hind margin more densely fringed than the lower.

First Peræopods.—Side-plates, branchial vesicles, and marsupial plates as in the preceding pair. The first joint reaching far below the side-plate, widening distally, the front margin serrate below and apically rounded, both margins fringed with very many spines; the second joint short, with long spines on the hind margin and its apex; the third joint triangular, twice as long as broad, the apex of the front margin having a group of spines, the hind margin serrate, fringed with long pectinate spines; the fourth joint longer than the third or fifth, a very narrow oval, attached to the front of the oblique distal margin of the third joint, its front margin smooth, the hinder fringed with long and short pectinate spines, the short continuing quite to the apex; the fifth joint long, almost linear, with spines at six points of the slightly convex front margin, the hind margin fringed with many pectinate spines; the finger short, less than half the length of the fifth joint, with a very small dorsal cilium near the base, the inner margin almost straight, with a very fine decurrent tooth on the inner margin at the base of the nail.

Second Peræopods.—Seareely differing from the preceding pair, even in the size of the side-plates.

Third Peræopods.—Side-plates broader than the preceding pair, almost as deep in front, much shallower behind, with a sinuous lower margin, but seareely to be called bilobed. The branchial vesicles and marsupial plates rather shorter than in the two preceding pairs. The first joint of the limb nearly three times as long as broad, with

some small spines spaced along the slightly convex front margin, and spinules on the convex lower part of the hind margin, the rounded end of which partially overlaps the following joint; the second joint short, having like the preceding joint a group of small spines on the front apex; the third joint long and narrow, shorter than the first, longer than the fourth or fifth, fringed with spines along the front border, and having submarginal groups of small spines near both borders; the fourth and fifth joints, which are equal to one another in length, have likewise these submarginal groups, but with stronger spines, and have their front margin fringed with long, slender, beautifully plumose spines, while the fourth has also on this margin five or six groups of long and strong spines; the finger is short and straight, not one-third the length of the fifth joint, its nail also is very short, curved; the apical spines of the fifth joint, round the base of the finger, have short accessory threads, and the margin below the thread finely pectinate, many of the other stouter spines being probably furnished in the same manner.

Fourth Peræopods.—The side-plates much broader than deep, rounded behind, not much deeper in front than behind; the front and lower margins nearly straight, fringed with spines. The branchial vesicles broader above than below, so attached to the narrow neck as to hang parallel to the first joint of the limb; near the neck there is a small accessory lobe. The limb resembles that of the third peræopods, but with all the joints longer, except the second; the first has four or five groups of slender spines at the top and six of shorter and stouter spines below; it is rather wider in most parts than the first joint of the third peræopods; the third, fourth, and fifth joints are about equal in length, with stout spines on both margins, but none of the long plumose ones seen in the preceding pair; the finger is larger in proportion to the increased size of the other joints.

Fifth Peræopods.—Side-plates like the preceding pair, on a smaller scale. Branchial vesicles broadest distally, not so long as the first joint of the limb, with an accessory lobe nearly half the size of the principal, and another much smaller. The limb similar to that of the preceding pair, except that the first joint is more expanded, its upper margin to the rear of the attachment slopes downwards, till at the greatest breadth of the joint it forms an obtuse angle with the hind margin, which takes a straight course to the narrowly rounded apical margin; the fourth and fifth joints are a little longer than in the preceding pair.

Pleopods not examined in the adult. In the young taken from the pouch, the coupling spines were very long and thin, with a lateral row of five sharp retroverted teeth, the inner ramus had but three joints, the first very long, with a single eleventh spine near the top; the outer ramus had four joints.

Uropods.—The peduncles of the first pair longer than the rami, with numerous spines along the margins, and some strong ones at the apex; the outer ramus rather shorter than the inner, and with fewer marginal spines, each with a group at the apex; the

peduncles of the second pair shorter than the inner ramus, the outer ramus shorter than the inner, these rami being respectively rather longer than those of the first pair, similar in armature, the peduncles reaching back as far as those of the first, but not as those of the third pair; the peduncles of the third pair short, with a spine near the middle of the inner margin; the rami long and broad, the outer shorter than the inner, the outer margins almost straight, the inner and apical margins curved, thickly set with long plumose setæ.

Telson reaching beyond the peduncles of the third uropods, as long as the outer ramus of that pair, cleft for three-quarters of its length, the sides of the cleft diverging halfway down towards the apex, while the outer margins converge, a pair of double apiees being formed, with a long spine in each cavity; near the lateral margin on either side the telson has four large spines, the two sides not being entirely symmetrieal in the arrangement of them.

Length.—The specimen, in the position figured, measured one inch in a straight line from the rostrum to the apex of the second uropods.

Locality.—Station 49, south of Halifax, Nova Scotia, May 20, 1873; lat. $43^{\circ} 3'$ N., long. $63^{\circ} 39'$ W.; depth, 85 fathoms; bottom, gravel, stones; bottom temperature, 35° . One specimen, female.

Remarks.—It will be observed that this species is distinguished from *Pardalisca cuspidata*, Kröyer, by several particulars; the mandibular palps are longer, the spines on the outer plate of the first maxillæ have no lateral tooth, the outer plate of the second maxillæ is rather shorter instead of rather longer than the inner plate, the palps of the maxillipeds, and in especial the second joints, are longer, and the fingers of the two pairs of gnathopods are of very different structure.

Pardalisea marionis, n. sp. (Pl. XCIV.).

Rostrum small, the sides of the head scarcely lobed. The pleon missing.

Eyes not observed.

Upper Antennæ.—The first joint longer than the two following united; the third more than half the length of the second; of the flagellum eighteen joints remaining, together longer than the peduncle, the first joint as long as the third joint of the peduncle; the secondary flagellum of five joints, the first as long as the first of the primary.

Lower Antennæ similar to those of *Pardalisca abyssi*, but not apparently having the gland-cone elongate; the flagellum of twenty-nine joints, together not very much longer than the peduncle.

Upper Lip rather deeply emarginate, one side of the emargination being a straight

line which forms an angle with the convex lateral margin, while on the other side the lobe is rounded.

Mandibles in general like those of *Pardalisca abyssi*, but on the right mandible the upper semi-divided tooth is apically rounded, the other three being acute; there are two adjacent denticulate spines, one rather broader, the other rather longer, than its companion, both much longer in the new growth than the pair in actual use; the first joint of the palp is not twice as long as broad; the second joint is short, though longer than either the first or third, having on the convex inner margin and adjacent surface four short and four long pectinate spines; the oval third joint with a flattened apex, is armed with some eighteen or twenty pectinate spines.

Lower Lip as in *Pardalisca abyssi*, but seemingly less strongly ciliated.

First Maxillæ.—Inner plate not clearly observed; the outer plate with a widened distal margin carrying nine spines, the innermost long, plumose, setiform, the others with a single lateral tooth at or below the middle of the inner margin, the two outermost being the thinnest and shortest; on the surface near the outer corner there is a tenth submarginal spine, small, shaped like the majority; the first joint of the palp is but little longer than broad, the second from a narrow base expands rapidly, and the broad rounded distal portion is crenate, with fifteen little spine-teeth and slender spines in the interstices.

Second Maxillæ.—The inner plate broader but not quite so long as the outer, with seven long plumose setæ on the distal part of the inner margin and the oblique apex; the outer plate with three on its truncate apex.

Maxillipeds.—The inner plates scarcely distinct from the short joint which carries them, the distal margin forming an almost continuous slope, the part belonging to the plate, however, being flat and carrying two setæ, one moderately long, the inner very short; the second joint long, with a fringing on both margins of setules intermixed with spines, the plate much more than a third of the total length, reaching a good way beyond the first joint of the palp, its distal margin sloping outwards, having three setules on the outermost part, and a dozen spines of no great stoutness on the remainder; the first joint of the palp short, the second not very much longer, with some setules on the outer margin, three setæ on the inner, and two or three long ones at the apex; the third joint about as long as the first, narrowly oval, with spines along the outer margin and at the apex of the inner; the finger short and broad, with four curved spinules along the side, and a sharp narrow nail.

First Gnathopods.—Side-plates nearly square, but deeper than broad, not wider above than below, lower margin only slightly fringed. The first joint reaching much below the side-plate, of great breadth, about twice as long as broad, the front margin nearly straight, fringed with spines, of which there are several also along the surface, the very convex hind margin seeming to be free from them except at the apex; the second joint

short, with a spine at the apex of the hind margin; the third joint not long, distally cup-like, with a few spines along the hind margin; the wrist long oval, equal in length to the first joint, with a spinule or two on the convex front margin, and a fringe, but not a dense one, of pectinate spines on the moderately convex hind margin; the hand not nearly half the length or breadth of the wrist, twice as long as broad, with five plumose spines on the hind margin; the finger broad, exclusive of the nail not much longer than broad, with the nail nearly as long as the hand of which it seems to usurp the place, the hinder and distal margins set round with fourteen strong but very unequal spines, nine on the hind margin reaching the nail, and five on the apex at the other side of it; there are two cilia at the base of the nail.

Second Gnathopods.—Side-plates nearly like the preceding pair, but wider above than below, the setæ of the inner surface not reaching the lower margin. The branchial vesicles about as long as the first joint, rather narrow, widening a little below, with a slight curve at the centre, uniform with the three following pairs. The limb very like that of the first gnathopods, but with longer joints and the wrist slightly narrower; the first joint has the hind margin evenly convex; there are many pectinate spines on the lower half of the hind margin of the third joint; the wrist is densely fringed with pectinate spines of various sizes, but some of great length, along the hind margin, the density of the fringe becoming less near the apex; the hand, which is about a third the length of the wrist, is fringed on the hind margin with shorter spines; the finger is as in the first gnathopods.

First Peraopods.—Side-plates like the preceding pair. First joint of the limb widening distally, with spines along the almost straight front margin, and at the lower part of the rather convex hind margin; the short second joint with a distal group of spines; the third joint triangular, and (measured from the top of the hind margin to the apex of the front) nearly as long as the fourth joint, with four groups of spines on the hind margin, and one on the decurrent apex of the front; the fourth joint a narrow oval, attached near the hind margin of the preceding joint, its own hind margin fringed with pectinate spines; the fifth joint three-quarters the length of the fourth, much narrower, with six groups of spines along the hind margin, one at the apex of the front, and a spinule higher up; the finger rather broad, more than half the length of the fifth joint, with pectinate edges and a very small curved nail.

Second Peraopods.—Side-plates like those of the preceding pair. The limb missing.

Third Peraopods.—Side-plates much deeper in front than behind, but in front not so deep as the preceding plates. The limb missing.

Fourth Peraopods.—Side-plates a little deeper in front than behind, fringed below with spines. The first joint broad, not twice as long as broad, not so long as the third joint, with spinules along the convex front margin, the hind margin at first a little sinuous, then almost straight, the rounded apex partially overlapping the short second joint,

which has some small spines at the apex in front; the third and fourth joints long, equal in length; the fifth joint broken, probably equalling either of the two preceding in length; all three with marginal spines.

The *Fifth Peræopods* and all the *Pleon* missing.

Length.—The half specimen, in the position figured, measured, from the rostrum to the end of the peræon, three-twentieths of an inch.

Locality.—Station 145, off Marion Island, December 27, 1873; depth, 100 fathoms; bottom, volcanic sand.

Remarks.—The specific name is derived from the locality whence the specimen was obtained. This species from the south is remarkably like the northern species *Pardalisca cuspidata*; the mandibular palp is rather shorter, the spines on the outer plate of the first maxilla more numerous, the setæ on the inner plate of the second maxillæ less numerous, the maxillipeds broader, the first joint of the first gnathopods broader, and the finger in both the first and second gnathopods broader. Boeck speaks of the third joint in the first and second peræopods of *Pardalisca cuspidata* as very short, which would by no means agree with the present species, but in a specimen from Kvænangen, kindly sent me by Konservator J. Sparre Schneider, I find that the joint in question agrees well with that above described for the present species.

Genus *Synopioides*, n. gen.

Mandibles each with a secondary plate; the palp greatly elongate, the third joint linear.

Maxillipeds with long four-jointed palp.

The Gnathopods not subchelate, the hands tapering; in the first pair the hand longer than the wrist.

The Third (Fourth?) and Fifth Peræopods very elongate.

The Uropods with the rami of the first and third pairs equal or nearly so; in the second pair the outer ramus much shorter than the inner.

The Telson reaching beyond the peduncles of the third uropods, deeply cleft.

Fifth and sixth pairs of side-plates broader than the preceding pairs; none of the side-plates deep.

By the head and antennæ this genus recalls *Synopia*, Dana, whence the generic name, but in the hinder peræopods, in the third uropods and telson, it is suggestive of *Nicippe*, Bruzelius, and it seems to find a suitable place near, if not in, the family Pardaliscidæ. The inclusion of the genus in that family cannot, however, be accomplished without altering the character assigned to the mandibles, according to which one of them is devoid of a secondary plate.

Synopioides macronyx, n. sp. (Pl. XCIV A.).

Outline of head and back similar to that of *Synopia scheeleana* except at the fourth segment of the pleon, which appeared to have a laminar triangular process produced backwards on either side of the dorsal line, but these processes were not satisfactorily made out; the postero-lateral angles of the first three pleon-segments were more or less acute, those of the third segment most so.

Eyes not perceived.

Upper Antennæ.—The peduncle very short, the first joint scarcely projecting beyond the head, broad, about as long as the other two united, the upper margin longer than the lower; the second joint abruptly narrower than the first, a little longer than the still narrower third joint; the flagellum about five times as long as the peduncle, at first very thick, after the first six or seven joints tapering very rapidly to the thirteenth, and then becoming very slender for the remaining joints, which are about twenty in number; the first joint is as long as the following five or six united, and together with the next eight or nine carries a large brush of broad and long cylinders, as well as slender spines; some of the remaining joints have small setules; the secondary flagellum has three joints, together about as long as the first eight of the primary, the first joint considerably longer than the other two united, and much broader, the second longer and broader than the third; the third linear, tipped with two setæ.

Lower Antennæ longer than the upper; the first joint dilated, second very short, gland-cone small, a little prominent; the third joint about as long as the two preceding united, broad, with one margin convex, carrying some small spines; the fourth joint long and slender, widest near the base, armed at intervals with spines, some setiform, others stout, these latter being bristly for part of their length, a peculiarity shared by the stout spines in other parts of this animal; the fifth joint elongate, but shorter and thinner than the fourth, with spinules at intervals; the flagellum longer than the peduncle, consisting of about thirty unequal slender joints, with setules at the apices of most of them.

Upper Lip.—The distal margin of the principal plate not very broad, flattened, smooth; the outer plate not reaching nearly so far forward, with the distal margin almost the full breadth of the plate, emarginate but not deeply, smooth.

Mandibles.—The cutting edge of the left mandible (the right on the Plate) is broad and squared, with a sharp, projecting tooth at the upper end, accompanied by a smaller one above it, not projecting, and a rounded one alongside of it; at the lower end there is a smaller projecting tooth, with a still smaller below it, less projecting; the intermediate margin straight, cut into many minute teeth; the secondary plate is not much less broad, the upper corner rounded, minutely denticulate, the denticulation being continued for some distance along the front margin, and then followed by a row of six stronger teeth, and a seventh much larger and more prominent than the rest; the cutting edge of the

right mandible appeared to be simply convex, with one tooth or division at the lower end; its secondary plate is very small, widest distally, the distal margin being cut into several little teeth, and having a deep notch near the lower end, from which the denticles form a return row; there appeared to be two strong but not elongate spines on the spine-row, planted amidst a brush of cilia; the palp is remarkably long; the first joint short; the second very long, curved near the base, narrowing distally, fringed with long setiform spines, slightly plumose; the third joint long and narrow, more than half the length of the second joint, tipped with four or five long setiform spines.

The Lower Lip rather deep, the texture of extreme tenuity, distally finely furred; the mandibular processes narrow, divergent.

First Maxillæ.—The inner plate not ascertained; the outer plate having on the distal margin eight long spines, on which the lateral denticles did not appear to be either strong or numerous; the first joint of the palp is short, the second joint widening distally and curving over the outer plate, having on the distal margin seven spine-teeth, followed by six slender spines descending the serrate inner margin.

Second Maxillæ.—The inner plate broad at the base, tapering to a narrow truncate apex, on which there are three plumose setæ, the outermost very strongly feathered; the inner margin is fringed with about fourteen strong plumose setæ; the outer plate is very little longer than the inner, narrower except at the apex, which, as in the inner plate, has three long plumose setæ, the middle one perched on a little eminence beyond the other two, the outermost the strongest and most strongly feathered.

Maxillipeds.—Narrow (not in good order for examination). The inner plates appear to be very small, carrying some setæ on the inner margin and apex; the outer plates very long, but not reaching nearly to the apex of the palp's second joint, with some slender spines at distant intervals along the inner margin, and some strong curved spine-teeth on the apical margin; the palp very elongate, apparently both the first and second joints very long, the second rather the longer, both with many long setæ; the third joint not specially long, widening distally, carrying numerous setæ on both margins and the surface; the finger shorter than the third joint, scabrous, little curved, most so at the nail.

First Gnathopods.—The side-plates a little broader than deep, the front margin tending to concave, the lower margin straight, with a setule near the front corner. The first joint long, widening distally, attached near the lower hind corner of the side-plate, channelled in front, the front margins being concave, the hind margin convex; the second joint short, rounded in front, with some setiform spines near the apex of the hind margin; the third joint triangular, the hind margin considerably longer than the front, produced into a point lying close to the wrist, having a few setiform spines not far above the apex; the wrist channelled behind, slender, longer than the third joint, fringed on both the hind margins with long, slender spines or setæ; the hand longer than the wrist,

channelled behind, curved, widening slightly from the base, then narrowing to the apex, the front margin convex, with some slight spines at intervals, the hind margins carrying spines of very various lengths; the finger narrow and elongate, about half the length of the hand, with a dorsal cilium at about two-thirds of the length from the base, the inner margin nearly straight, with some short setules at intervals, and a series of four or five near the base of the nail, which is preceded by a strong nail-like tooth, between which and the actual curved nail there is a cilium.

Second Gnathopods.—The side-plates broader than deep, the front margin nearly straight, the lower very convex. The branchial vesicles narrow, lageniform, rather longer than the first joint, which they exceed in width. The marsupial plates longer than the branchial vesicles, fringed with very long setæ, which are distant except at the apex. The first joint channelled in front and a little convex, with spinules along the margins; the second joint short, with a group of several long and short setiform spines at the apex behind; the third joint produced to a long acute apex, the hind margin fringed with setiform spines, those near the apex of very great length; the wrist much longer than the third joint, and longer than the hand, with a few spines on the long front margin and at its apex; the hind margin where free from the third joint is slightly convex, and densely fringed with numerous groups of setiform spines of various lengths, some very long indeed; the hand widening a little from the base, then narrowing to the apex, the front margin very convex, with few spines, the hind margin gently concave, densely fringed with spines, more closely set than those on the wrist, but not so long, and having a few spines longer and stiffer than the rest, finely pectinate, with the ends flexible; the finger more than half the length of the hand, nearly as in the first gnathopods, but the tooth on the inner margin slighter.

First Peræopods.—The side-plates similar to the preceding pair, but rather deeper; the branchial vesicles also rather larger, and the marsupial plates longer. The first joint almost entirely free from the side-plate, with a few slender spines on the front and at the apex of the hind margin; the second joint short, with a group of setiform spines on the apex behind; the third joint widening distally, shorter than the fourth, with setiform slightly feathered spines at six or seven points of the hind margin, and apex in front; the fourth joint elongate oval, the hind margin fringed with many long slender spines; the fifth joint subequal in length to the fourth, or a little longer, but narrower, the hind margin serrate, with seven groups of spines; the finger long and slender, more than half the length of the fifth joint, straight till near the tip, the edges with a finely pectinate appearance.

Second Peræopods scarcely distinguishable from the first.

Third Peræopods.—The side-plates considerably larger than the preceding pairs, broader than deep, deeper in front than behind, the front margin oblique, the lower margin nearly straight, with a very slight convexity. The limb very long, its first joint

not greatly expanded, twice as long as broad, the front margin slightly convex, with nine or ten short spines on the lower two-thirds; of the hinder margins, one straight, the other convex, both smooth; the second joint very short; the third not broad, but longer than the first joint, the front margin straight, with five long spines at intervals, and some spinules; spines also at five points of the scarcely convex hind margin; the fourth joint rather shorter than the third, the front margin strongly serrate, the hinder slightly, each with spines at four points; the fifth joint very slender, longer than the third, serrate on both margins, with spines at nine points on each, the points not opposite one another; the finger long and thread-like, if complete in our specimen, measuring about one-third of the fifth joint.

Fourth Peraopods missing. The side-plates rather smaller than the preceding pair, but similar, much broader than deep, exceeding in breadth any of the first four pairs of side-plates.

Fifth Peraopods.—The side-plates apparently broad and shallow. The limb of great length, the first joint between oval and pear-shaped, being much dilated above so that the length does not greatly exceed the greatest breadth, the hind margin smooth, the front with two or three small spines on the lower part, and a larger one on the apex; the second joint very short, overlapped behind by the first, with a spine or two on the apex in front; the third joint considerably longer than the first, the hind margin with four strong spines on the convex upper part, the lower part almost straight, smooth, but with two spines at the apex; the front margin with eight or nine groups of small spines, the apex having also a long one; the fourth joint rather shorter than the third, straight, with serrate margins, the hinder having a single spine, and four strong groups, the front having five strong groups and two small ones; most of these spines, including even the small ones, appear to be finely pectinate in at least two lines; the fifth joint is broken, the remaining portion has both edges serrate and armed with spines.

Pleopods.—The peduncles stout, broader above than below; the coupling spines rather large and broad, the apical part fringed with a row of little retroverted teeth or spines, of which the lowest are the largest, but all are small; the eleft spines are large, two in number, the longer arm with many little tubercles on the inner side; the rami are equal, with about twenty joints in each.

Uropods.—The peduncles of the first pair are subequal in length to the rami, with numerous long spines on the two upper margins and on the apical margin; the rami equal in length, also with two rows of many marginal spines and some on the narrow but not pointed apices, the margins pectinate and the spines sabrous; the peduncles of the second pair about equal in length to the outer ramus, having spines on the two inner or upper margins; the outer ramus much shorter than the inner, the inner even longer than those of the first pair, both strongly spined on two margins and with pectinate edges; the peduncles of the third pair much shorter than the rami, with a spine at the inner apex;

the rami long, reaching beyond those of the other pairs, broadly lanceolate, the outer edges nearly straight, except at the distal end, the inner edges deeply serrate as well as peetinate, narrowing rapidly at the distal end to the acute apex, which on the outer ramus forms a small nail, and by so much extends beyond the inner ramus. Each ramus shows the remains of a fringe of setæ on the inner edge, the setæ being densely plumose and some of them of great length; the outer ramus has one or two spines in notches on its outer margin above the apex.

The Telson reaches considerably beyond the peduncles of the third uropods; the length about once and a half the breadth, left almost to the base, each division sharply incised at the apex, the outer point being produced beyond the inner, both acute, the interval between the outer apical points being rather less than half the breadth near the base.

Length.—The length of the specimen was unfortunately not taken before dissection; it was, I believe, without the antennæ, about two-fifths of an inch.

Locality.—Station 295, off the west coast of South America, November, 5, 1875; lat. $38^{\circ} 7'$ S., long. $94^{\circ} 4'$ W.; depth, 1500 fathoms; bottom, Globigerina ooze; bottom temperature, $35^{\circ}\cdot 3$. One specimen, female. In the tow-net attached to the trawl.

Remarks.—The specimen had been mounted in glycerine during the voyage, and was labelled "Tow-net at the trawl, 6 Nov. 1875, 1500 fathoms." There can be no doubt this refers to Station 295.

The specific name, from the Greek *μακρός*, long, and *ὤνυξ*, nail, alludes to the fact that the fingers (*ungues* of Latin descriptions) are long in both the gnathopods and (so far as observed) in all the peræopods in this species.

Family GAMMARIDÆ, Leach, 1814.

In 1870 Boeck adopted the title "Gammarinæ. Dana, 1849," for the fifteenth subfamily of the family Gammaridæ. In it he included the genera, *Gammarus*, *Pallasia*, *Mæra*, *Melita*, *Elasmopus*, *Cheirocratus*, *Gammaracanthus*, *Niphargus*, *Amathilla*, *Melphidippa*. In 1872–1876 he made the Gammarinæ the eighth subfamily of the Gammaridæ, with the same definition and including the same genera as before. In 1882 Sars changed the subfamily into a family, with the title Gammaridæ, presumably accepting Boeck's definition, as he includes in it the same list of genera without addition or diminution, and with only the nominal exchange of *Eriopis*, *Bruzellius*, for *Niphargus*, *Sehiødte*. For this group Boeck gives the following definition:—

"Mandibles both alike, robust, apically dentate; the inner plate also dentate; the molar tubercle very prominent; the palp elongate, three-jointed."

“Lower Lip with very broad plates; the inner plates large.

“First Maxillæ armed with strong spines, some furcate some serrate; the palp large, two-jointed; the palp of the left maxilla apically armed with spines, that of the right with teeth; the inner plate more or less strong.

“Maxillipeds with the outer plate larger or smaller, but never very large, armed on the margin with teeth (rarely spines) and apically with curved setæ; the inner plate elongate, furnished with three teeth and many setæ; the palp elongate; the last joint towards the apex very narrow, unguiform.

“The body more or less compressed.

“The four anterior [pairs of] side-plates generally of moderate size, rarely small.

“Antennæ elongate; the *Upper* with a multi-articulate flagellum and an accessory flagellum; the *Lower* only with a short flagellum.

“First and Second Gnathopods with the hand subcheliform.

“The Fourth Peræopods a little longer (paulatim crescentes) than the Third, the Fifth than the Fourth.

“Uropods biramous; very rarely the last pair uniramous (simplices).

“Telson laminar, cleft or not cleft.”

In regard to the mandibles it should be noticed that as a rule the inner plate of the right mandible differs from that of the left; it may be questioned whether Boeck's distinction between the armature of the palp on the left and that on the right in the first pair of maxillæ is of general application; in regard to the comparative length of the hinder peræopods there is an exception to Boeck's rule, by his own account, in *Gammaracanthus loricatus*, Sabine, of which he says that the fifth peræopods are shorter than the preceding; lastly, with respect to the uropods, it will be found that he does not describe any of his genera as having the third pair uniramous, although in *Melita* the inner branch is very small (*minimo*), and little (*parvulo*) in *Niphargus*.

For the earliest definition of the “Gammarinæ” as a family, see Note on Latreille, 1802 (p. 72).

For the earliest definition of the family “Gammaridæ,” see Note on Leach, 1814 (p. 86); Leach places in it the genera *Melita*, *Mæra*, *Gammarus*, *Ampithöe*, *Pherusa*, the first three of which are still retained in the family.

 1813. " Leach, *Crustaceology*, *Edinburgh Encyclopædia*, vol. vii. p. 402.
 1814. " Leach, *Crustaceology*, *Appendix, Edinburgh Encyclopædia*, vol. vii. p. 432.

For the original definition of the genus *Gammarus*, see Note on Fabricius, 1775 (p. 40). From the time of Leach the genus has been so universally accepted (for more or less numerous species) by writers on the Amphipoda, that it is scarcely necessary here to continue the synonymy, a clue to which will be found in the index. The following definition is given by Boeck in 1876 :—

" *Mandibles* with the third joint of the palp elongate, narrow.

" *First Maxillæ* with the inner plate broad, long, furnished on the inner margin with very many plumose setæ.

" The body not carinate. The three hinder segments of the pleon furnished in the middle with fascicles of spines. The anterior side-plates of moderate size.

" *Upper Antennæ* longer than the *Lower*; the peduncle moderately elongate.

" *Lower Antennæ* with a short flagellum.

" *First and Second Gnathopods* with the hand small; the *Second* larger than the *First*.

" The *Third Uropods* with long rami, furnished on the margin with spines and plumose setæ, extending beyond the rami of the two preceding pairs; the inner ramus more or less shorter than the outer.

" *Telson* long, cleft to the base."

For Dybowsky's definition of the genus, see Note on Dybowsky, 1874 (p. 427). Definitions of later date than Boeck's will be found in Carus, *Prodromus Faunæ Mediterraneæ*, p. 411 (1885), and in Gerstaecker, Bronn's *Klassen und Ordnungen*, Bd. v. Abth. ii. p. 511 (1886).

Gammarus locusta (Linn.).

1767. *Cancer locusta*, Linn., Syst. Nat., Ed. xii. p. 1055.

 1887. " Chevreux, Catalogue des crust. Amph. Bretagne, p. 19.

For the original definition of the genus *Mæra*, see Note on Leach, 1813 (p. 84), for that of *Ceradocus*, see Note on Costa, 1857 (p. 298), for that of *Leptocephoe*, see Note on Stimpson, 1854 (p. 277), and for that of *Megamoera*, see Note on Spence Bate, 1862 (p. 335). Boeck's definition of *Mæra* is as follows :—

"Mandibles with the third joint of the palp narrow, not very elongate.

"First Maxillæ with the inner plate narrow and apically furnished with few plumose setæ.

"Body elongate, narrow.

"Side-plates little; the fourth pair scarcely larger than the fifth.

"Upper Antennæ much longer than the lower, the peduncle elongate.

"The legs slender, elongate; the Second Gnathopods with the hand much larger than in the first pair; the Third, Fourth, and Fifth Peraopods with the first joint more or less dilated.

"The Third Uropods extended beyond the First and Second pairs; the rami elongate, narrow, very setose on the margin; the inner ramus only a little shorter than the outer.

"The Telson not very elongate, deeply cleft."

In *Mæra longimanus*, Leach, the third joint of the mandibular palp is longer than the second, and in *Mæra rubromaculata* (Stimpson) the inner plate of the First Maxillæ has the plumose setæ numerous instead of few, and not confined to the apex. The epithet "few" should, I think, be omitted from the generic character of the First Maxillæ.

 pl. xv. figs. 5-12.

Rostrum minute, lateral lobes of the head not very prominent, nasiform, the lateral margin below the lobe sigmoid; the first five segments of the pleon prettily serrate across the back, with setules in the serrations, in one of the specimens with fifteen teeth on the first segment, seventeen on the second, fifteen on the third, nine on the fourth, seven on the fifth, the central tooth being the most prominent, especially in the third and fourth segments; the postero-lateral angles of the first three segments sharply pointed, with a little serration of the lower margin in the first and second segments, and sometimes in the third, which also has the lower part of the hind margin serrate; the sixth pleon-segment with a dorsal tooth over the base of the telson, and a tooth further on and lower down on each side of the telson, which may be regarded either as dorsal or lateral, the segment also sharply pointed below. The ornamentation in this species seems liable to considerable variation.

Eyes oval, situated close to the margin of the lateral lobes.

Upper Antennæ with the peduncles a little, and the flagella much, longer than those of the lower antennæ; the first joint long, carrying some cilia and setæ, and armed along the serrate under side with four or five stout spines; the second joint more slender than the first but of equal length, or sometimes a little longer, with many groups of setæ, and on the under side several spines; the third joint scarcely more than a fifth of the length of the second, carrying some groups of setæ; the flagellum having in three different specimens respectively twelve, twenty-eight, and thirty-three joints, but the specimen with twenty-eight joints had on one antenna only sixteen, that with twelve had on one antenna only ten; in every case the first joint of the flagellum was much the largest, subequal to the third joint of the peduncle, while the last joint was in each case minute; the secondary flagellum varied similarly, having but four joints in the small specimen to accompany the primary of twelve, eight in the large specimen for the primary of sixteen, twelve for the primary of twenty-eight, in the third specimen, also large, ten for the primary of twenty-three, but on the other antenna eleven for a primary of twenty; the joints had apical groups of setules in both primary and secondary flagella, in the former also one or two short cylinders.

Lower Antennæ.—The lobe of the first joint not much expanded, the second joint short except for the very long decurrent gland-cone, which nearly reaches the distal end of the long third joint; the third joint carries some groups of setules; the fourth joint thinner than the third, but between two and three times as long; the fifth joint both shorter and thinner than the fourth, both carrying many groups of setæ; the flagellum

of sixteen joints in the specimen which had twenty-eight joints in the upper flagellum, of eighteen in that with thirty-three.

Upper Lip.—The distal portion almost semieircular, the central part of the margin furred.

Mandibles.—The cutting plate divided into five teeth; the secondary plate of the left mandible very similar to the principal, with its edge divided into four teeth; the secondary plate of the right mandible bifid, with four or more noticeable teeth or denticles above the two slender apical teeth, the group forming rather a bunch than a row as on the other mandible; spine-row of nine or more closely-set curved denticulate spines; molar tubercle massive, with an irregularly oval denticulate crown and a plumose seta; there is a process between the molar tubercle and the palp; palp set well forward, the first joint subequal in length to the third, the second long, concave on the outer margin, the inner margin and surface set with slightly feathered spines, some of them very long; the short third joint having a group of small spines about the middle, and a group of still longer ones at the apex, almost all of these spines being much longer than the joint.

Lower Lip.—The front lobes having a little projecting point where the distal and inner margins meet, strongly ciliated on both those margins, dehiscent, the space partially filled by the thick oval inner lobes; the mandibular processes divergent, the ends a little ciliated.

First Maxillæ.—The inner plate with its whole inner margin from the apex downwards closely fringed with some four and twenty plumose setæ; the outer plate having on the truncate margin nine spines, three of which are furcate, with a denticle within the fork, two or three have a single tooth below the apical, and the rest are pectinate; the first joint of the palp more than half the length of the second; the second not dilated, having several slender spines on its truncate margin, and several submarginal spines.

Second Maxillæ.—The inner plate not narrower but a very little shorter than the outer, with a long row of plumose setæ, beginning low down on the inner margin, and passing towards the outer apex, in a large specimen numbering twenty-nine; the apex is crowded with long spines, of which there is a row down two-thirds of the inner margin; the spines on the apex of the outer plate are as usual longer than those of the inner, the apical margin slopes outward, being there occupied, not, as often, with short spines, but with long ones that are plumose, and almost by their tenuity and flexibility deserving to be called setæ.

Maxillipeds.—The inner plates broad, reaching much beyond the first joint of the palp, with a row of plumose setæ beginning on the upper part of the inner margin and passing along the surface to the middle of the apical; the apical margin truncate, with a strong tooth at the inner corner, below which is a curved pectinate spine-tooth, two

large spine-teeth are on the border and a long row of stiff feathered setæ; the inner plates not quite reaching the end of the second joint of the palp, armed along the inner margin with large finely pectinate spine-teeth, the series continuing with increasing size and curvature round the distal margin, the spines there being plumose below, and the last one or two of the row becoming more or less setiform; there are besides on the surface adjoining the inner margin many slenderer, but not pointed spines; the palp has a first joint shorter than the third, the second long, the third short, oval; the finger subequal in length to the third joint; the nail much more than one-third the total length, with some setules on the inner margin near it; the dorsal cilium near the base of the finger is shorter than the nail.

First Gnathopods.—The side-plates shallow, with an appearance, not confined to this pair, as if the true first joint were enclosed between two side-plates, the inner being much the smaller, the lower margin outdrawn in front to a sharp point, slightly crenate, and fringed with setules. The first joint extending for almost its whole length beyond the side-plate, the front margin nearly straight, with setules, the hinder with long setæ above, and below these three groups of spines, of which some are finely pectinate; the second joint short, much narrower than the first, with an apical group of spines behind; the third joint oblong, produced to a sharp apex, the hinder margin fringed with many groups of spines; the wrist nearly as long as the first joint, longer than the hand (the difference seemingly greater in the large than the small specimens), crowded with pectinate spines on the hind margin and most of the inner surface, some showing along the front margin and at its apex; the hand at the commencement of the palm broader than the wrist; with many groups of spines along the hind margin, the longest row being at the commencement of the palm on the outer side; there are several groups also on the inner surface a little way from the hinder margin, and several close to the longer front margin; the oblique slightly convex palm is finely denticulate and fringed with submarginal spine-teeth and setules; the finger fits closely over it.

Second Gnathopods.—Side-plates broader above than below, broader than deep, with some small spines on the lower margin. Branchial vesicles tending to oval, broad distally. Marsupial plates narrow. The first joint rather broad, all but the narrow neck clear of the side-plate, the hinder margin fringed with long setæ or setiform spines; the second and third joints much as in the first gnathopods, but the third joint with only one group of spines on the hind margin in addition to the apical group; the wrist short, triangular, distally cup-like, its hind margin fringed with many pectinate spines; the hand massive, much longer than the first joint, widest distally, much wider than the wrist, with small groups of spines near the front margin and along and near the hind margin, which is apically produced into a tooth with a strong palmar spine on each side of it; the palm is convex, very oblique, and the sculpture of it varies not only in different specimens but on the two sides of the same animal (at least this was the case in three of the specimens

examined, one of them a female, and the same thing is noticed by Mr. Chilton in his account of *Mæra spinosa*, Haswell); the simpler form of palm regularly denticulate, and fringed with spine-teeth and setules, the other palm in the female specimen having a straight portion near the hinge, then a gap, and the remainder sinuous; the other specimen had two gaps in the palm margin, not very wide apart; the armature is the same in all forms; the finger is strong, gently curved or more strongly hooked, but always closing down into the cavity between the apical tooth of the hind margin and the palm border.

First Peræopods.—Side-plates and branchial vesicles similar to those of the preceding segment. The first joint extending far beyond the side-plate, with long setæ on the front margin above and spinules below, many long setæ on the upper half of the hind margin and spines on the lower half; the second joint with an apical spine behind; the third joint longer than the fourth or fifth, scarcely decurrent, with spines at four points on each margin; the fourth joint longer than the fifth, with groups of spines at six points of the serrate hind margin, and spinules at three points in front; the fifth joint with five groups of spines on the serrate hind margin, spinules at two points in front, and an apical group of spines; the finger short and stout, about half the length of the fifth joint, with a dorsal cilium near the base, and one or two setules at the angle of the inner margin in front of the nail, and a cilium near the outer margin.

Second Peræopods.—Side-plates a little broader at the base than the preceding pair, but otherwise similar. The first, third, and fourth joints of the limb shorter than in the first peræopods, to which these are in other respects similar.

Third Peræopods.—Side-plates with the front lobes as deep as the preceding side-plates, spinules on the lower margin, the hind part shallow and scarcely lobed. The branchial vesicles oval. The first joint long, about twice as long as broad, the margins nearly parallel throughout, the front with spines, the hinder serrate but not deeply; the second joint with an apical group of spines in front, the third, fourth, and fifth joints subequal in length, the third with apical groups of spines before and behind, setules on the front margin, spines at three points of the hinder, the fourth with five groups of spines in front and four behind; the fifth widens a little distally, and carries four groups of spines in front, and three behind; the finger is larger than in the preceding pair.

Fourth Peræopods.—Side-plates similar to the preceding pair but rather smaller, and with the front lobe much narrowed. The limb very similar to that of the third peræopods but much larger, and the armature much stronger, many of the spines, especially those at the apex of the fourth and along the hind margin of the fifth joint, being of very striking length; the fifth joint is rather longer than the third or fourth, but this appears to be sometimes the case also in the third peræopods.

Fifth Peræopods similar to the fourth pair, but with the first joint and the third smaller.

Pleopods.—Coupling spines very short, with two strong, lateral, retroverted teeth below the apical tooth, and several marginal denticles; there are some slender spines close beside the coupling spines, and some stronger spines at the apex of the peduncle; the cleft spines have short arms which are not very unequal; in specimen A the series consisted of six in the first pair, five in the second, and four in the third pair, but in specimen B the number was eight in the third pair, and therefore probably more in the preceding pairs; in specimen B I counted twenty-nine joints on the inner ramus, thirty on the outer ramus, of the third pair.

Uropods.—Peduncles of the first pair longer than the rami, carrying, besides the marginal and strong apical spines, a very conspicuous spine high up on the outer or under margin, which is interrupted to receive it; the outer ramus rather shorter than the inner, both carrying marginal spines, those of the inner curiously unequal in size, its margin finely pectinate, the blunt apices of both rami having groups of spines; peduncles of the second pair apically pointed, equal to the outer, shorter than the inner ramus, which has the same irregularity of spines as in the first pair, and its edge pectinate; both rami are blunt-ended, apically spined, reaching back little or not at all beyond the peduncles of the third pair; these are shorter than the rami, having two principal groups of spines, one on the somewhat produced outer apex and one on the inner edge, with others round the sculptured distal border; the rami subequal, broad and long, strongly serrate, and spined on both margins, besides having spines and spinules on the narrow but not pointed apex.

Telson short, shorter than the peduncles of the third uropods, broader than long, deeply cleft so as in a lateral view to appear double, the laminæ widely dehiscent, especially below, where the acute apices are almost as widely apart as the extreme breadth of the telson; between these and the angled but not outdrawn apices of the inner margins some long spines are inserted, two or three in each lamina.

Length.—The female specimen B (Pl. XCVI.), in the position figured, exclusive of the antennæ and the back-turned rami of the third uropods, measured seven-tenths of an inch.

Locality.—Station 142, off Cape Agulhas, December 18, 1873; lat. $35^{\circ} 4'$ S., long. $18^{\circ} 37'$ E.; depth, 150 fathoms; bottom, green sand; bottom temperature, 47° . One specimen (E, Pl. XCV.).

Station 163D, off Sydney, June 12, 1874; lat. $33^{\circ} 57' 30''$ S., long. $151^{\circ} 39' 15''$ E.; depth, 120 fathoms; bottom, green sand. Several specimens.

Off Port Jackson; depth, 30 to 35 fathoms. One specimen.

Remarks.—It will be noticed that two of the Stations, the one at the Cape, the other at the east of Australia, though not at very remote latitudes, are separated by more than 130° of longitude. *Megamæra serrata*, Spence Bate, was found at "Flinders's and

Hummoek Islands, Bass's Straits, in sea-weed on a sandy beach." Dana's *Gammarus asper*, from the Sulu Archipelago, bears a suspicious resemblance to the present very variable species, but his enlarged drawing of the second gnathopod shows a wrist much too elongated to permit the identification. *Mæra spinosa*, Haswell, is from Tasmania, *Gammarus rubro-maculatus*, Stimpson, was found "on muddy bottoms in the circum-littoral zone, Port Jackson, Australia," and has been found in the same locality by Mr. Haswell.

The inner plates of the first and second maxillæ differ in armature from those of *Mæra grossimanus*, Montagu, but they differ also from those of *Megamæra longimanus* (Leach) Bate, in which, moreover, the third joint of the mandibular palp is longer than the second, while here it is shorter, so that I have not ventured to rely on these characters of the mouth-organs for re-establishing *Megamæra* against the general view that it is synonymous with *Mæra*.

Mæra bruzelii, n. sp. (Pl. XCVII.).

Head long in proportion to its depth, rostrum rudimentary, lateral lobes of the head rounded, the lower angle immediately below and a little to the rear of the lobes; first two segments of the pleon with postero-lateral angles produced in small points, but with the convexity of the hind margin extending beyond these points; the postero-lateral angles of the third segment sharply outlined, and the lower part of the hind margin sharply serrate; the sixth segment emarginate behind, forming a pair of dorsal teeth separated by nearly the width of the telson.

Eyes oval, situated near the margin of the lateral lobes of the head.

Upper Antennæ.—First joint long, rather narrowed distally, grooved on the under side, carrying a few setæ and at the apex below a spine; second joint longer and much thinner than the first, carrying a few slender setæ or setules; third joint about one quarter the length of the second; flagellum broken, thirty-five joints remaining in one antenna, thirty-six in the other, of which the first is the longest; secondary flagellum slender, of nine joints, together as long as the first eleven joints of the primary.

Lower Antennæ broken, evidently much smaller than the upper. First joint not inflated, gland-cone decurrent, not nearly reaching the end of the third joint, which is twice as long as broad, with a small spine in the middle of the upper margin and a group of setæ on the lower apex; the fourth joint slender, rather longer than the first of the upper antennæ, with spines at two points of the upper margin near the base, and groups of setæ on the lower margin; the rest missing.

Upper Lip broadly rounded, the greatest width not far from the front.

Mandibles.—Cutting plate with one tooth at the upper and two at the lower end of a broad margin; secondary plate of the left mandible with the broad edge divided into four

or five teeth, the lowest the most prominent; on the right mandible this plate has a bifid termination, with two or three accessory teeth higher up; spine-row of seven or eight denticulate spines; molar tubercle with prominent dentate crown; the process between the molar tubercle and the palp is broad-headed; the palp set a little in advance of the molar tubercle, contrasting by its slenderness with the breadth and bulk of the trunk of the mandible, the first joint unusually long, more than twice as long as its greatest breadth, the second joint longer than the first, bent, with seven or eight setæ, or thin setiform spines, along and near the convex inner margin; the third joint straight, subequal in length to the second, with three or four long thin setæ on each margin and a group of six at the apex.

Lower Lip broad, not very deep; the principal lobes widely dehiscent, much of the gap being occupied by the large inner lobes; the mandibular processes well developed, with rounded ends.

First Maxillæ.—Inner plate small, oval, apparently with one apical seta; outer plate with spines variously denticulate on the rather narrow truncate distal margin; these spines were worn and damaged, but the new ones (obscurely seen) in preparation within the plate appeared to be ten in number; the palp reaching beyond the outer plate, its first joint more than half the length of the second, with two setules at the upper part of the outer margin, the second joint broad, with two setules on the convex outer margin, ten or eleven long feathered spines round the distal margin, and some submarginal setiform spines.

Second Maxillæ.—The inner plate narrower and a little shorter than the outer, with spines round the distal border, and some plumose setæ at the upper part of the inner margin, also one or two setules lower down; the outer plate apically fringed with spines, the apex sloping towards the convex outer margin, which is fringed with setules.

Maxillipeds compact. Inner plates reaching far beyond the first joint of the palp, with plumose setæ on the upper part of the inner margin, which is apically produced into a tooth, the truncate distal margin being fringed with spine-teeth and curved spines; the outer plates reaching the distal end of the second joint of the palp, the inner margin fringed with long serrate teeth, of which there are eight round the apical border, longer and curved, none of them setiform; on the outer surface near the inner margin are groups of long spines, not dissimilar in character to the marginal teeth; first joint of the palp very short, a little longer than broad; second joint very long, between two and three times as long as the first, with numerous groups of spines along the inner margin; the third joint longer than the first, broadest at the centre, with spines on the inner margin and about the apex; the finger nearly as long as the third joint, with a spine-like nail, four or five setules along the slightly serrate inner margin, the dorsal cilium long, at some distance from the base.

First Gnathopods.—Side-plates greatly produced below and in front, so that the

depth of the plate is not equal to its breadth below; the lower margin serrate. The first joint reaching below the side-plate, with setæ on the hind margin, in groups on the inner surfacee, and at the lower part of the sinuous front margin; the second joint with an apical group of slender spines behind, and a spine higher up on the hind margin; the third joint apieally pointed in front, slightly serrate, with two groups of spines behind, at the lower hind corner a row of ten small spines, followed by several long ones extending to the front apex; wrist longer than the hand, nearly as long as the first joint, both front and serrate hind margins and the distal half of the inner surface lined with groups of feathered spines; the hand oval, at the centre a little wider than the wrist, the front margin, the hind margin and palm, and the surfacee near the two latter, carrying many groups of more or less feathered spines; the palm minutely dentate, almost continuous with the serrate hind margin, distinguished from it by the denticulation, by palmar spines, and by the extent of the finger, which fits closely over it; the palm is also fringed with many submarginal spines and setules.

Second Gnathopods.—Side-plates not deeper than those of the preeeding segment, not much deeper than broad, lower margin serrate, hinder sinuous, with some spines below. Branchial vesicles a broad oval, as long as the side-plate, but not quite so broad. First joint reaehing much beyond the side-plate, rather longer than the branchial vesicle, with long setæ on both margins; third joint not much longer than the second, both front and hind margins apieally produced to a point; the wrist triangular, eup-like, length and breadth subequal, the convex serrate hind margin apieally pointed, with numerous groups of long and short serrate spines along it, the straight front margin almost unarmed; the hand oval, wider than the wrist and considerably more than twice its length, with eight groups of spines on the hind margin, and several small groups near and at the apex of the long front margin; the palm is oblique, fringed with numerous short spines and setules, and the somewhat massive finger closes over it, laying its tip on the inner surfacee between two palmar spines, one of which is on the surface, the other on the margin, but the surfacee spine is accompanied by a curved group of setules placed in a small depression of the inner surfacee.

First Peræopods.—Side-plates scarcely differing from the preeeding pair, the branchial vesicles rather longer. First joint of the limb more slender than in the preceding pair, with several spines along the hind margin, besides setæ of various lengths on both margins; the third joint much longer than the fourth or fifth, with a few spines and spinules on the margins; fourth and fifth joints subequal, with spines on the hind margin and spinules on the front, with an apical group of setæ; the finger small, not half the length of the fifth joint, the inner margin raised above the minute nail and there carrying two short setules.

Second Peræopods.—The side-plates a little deeper, and branchial vesicles a little longer, than in the preeeding pair, otherwise similar; the limb similar.

Third Peræopods.—The front lobe of the side-plates produced below the hinder part, of which the lower margin is almost straight. The branchial vesicles like the preceding. The first joint long, with the hind margin strongly serrate, nearly straight, the front a little convex, with spines, the apical one long; the second joint short, almost completely overlapped by the rounded lower hind margin of the first joint; the third joint longer and much broader than the fourth or fifth, most expanded just below the narrow base, with spinules on the slightly convex front margin, five spines on the hind margin, below the fifth forming a short triangular decurrent apex; the fourth joint with the upper part broader than the lower, spines at five points of the front margin, one group about the middle of the hind margin and another at its apex including a long spine; the fifth joint slender, as long as the fourth, a little widened distally, with a single spine and four groups of spines on the front margin, and a group of long ones at the apex behind; the finger as in the preceding pair; the dorsal cilium near the base.

Fourth Peræopods missing.

Fifth Peræopods.—Side-plates with the front margin ciliated, deeper behind than in front. The first joint broader but not longer than that of the third peræopods, broader above than below; the third joint a little longer than in the third pair, of more even breadth, with spines at four points on each margin, the triangular apex behind having two little cilia; the fourth joint subequal in length to the third, but shorter than the fifth, with three groups of spines, besides spinules, on the front margin, and two groups behind; the fifth joint with spines at six points in front, and some spinules behind; the finger similar in shape to that of the third peræopods, but larger.

Pleopods.—Coupling spines very slender except at the base, with one large lateral tooth, and seven denticles including the apex; there is a simple spine beside the two with hooks; the cleft spines from three to four, placed far down the joint; the joints of the rami eighteen in number, the peduncles long, apparently grooved, with an apical process on the outer side, folded to assist in coupling the two rami; on the third pair one of the edges of the peduncles proved to be serrate below and spined.

Uropods.—Peduncles of the first pair longer than the rami, with spines on the margins, and a larger one on the produced outer apex, the outer ramus rather shorter and less broad than the inner, both with few marginal spines, and each with a group inserted in the apical cavity; peduncles of the second pair about as long as the outer ramus, this being a little shorter than the broad inner one, which has several marginal spines; each ramus with an apical group; the edge of the inner ramus in this and the preceding pair is finely pectinate, possibly also that of the outer ramus; peduncles of the third pair much shorter than the rami, which are moderately broad, lanceolate, subequal in length, with serrate margins carrying spines, and tipped with spines, the length of these rami equalling that of the inner ramus of the first pair, and reaching back a little beyond it.

Telson longer than broad, rather longer than the peduncles of the third uropods, cleft almost or quite to the base, apically a little dehiscent, about a quarter of its length from the apex, each division forming a little tooth on the inner margin with a spine in the cavity between the tooth and the continuation of the margin; the apical part of each division has four serrate points, not symmetrically arranged, being in one lamina all on the outer margin, in the other distributed, two on the outer, one on the inner, in each case the apex being the fourth.

Length.—The specimen, in the position figured, measured, without the antennæ, half an inch.

Locality.—Station 142, off Cape Agulhas, December 18, 1873; lat. $35^{\circ} 4'$ S., long. $18^{\circ} 37'$ E.; depth, 150 fathoms; bottom, green sand; bottom temperature, 47° . One specimen.

Remark.—The specific name is given out of respect to the eminent carcinologist, Bruzelius.

Genus *Elasmopus*, Costa, 1853.

- 1887. *Elasmopus*, Chevreux, Catal. Crust. Amph. Bretagne, p. 20.

Mandibles with the third joint of the palp larger than the second.

First Maxillæ with seven spines on the apical border of the outer plate.

Second Maxillæ having the inner plate ovate, with setæ at the apex.

Upper Antennæ longer than the lower, with elongate peduncles.

Second Gnathopods larger than the first.

Third, Fourth, and Fifth Peraopods broad.

Third Uropods with broad, subequal, not very elongate, rami.

Telson deeply cleft.

For Costa's original definition, see Note on Costa, 1857 (p. 298). The present definition is altered from Boeck, who speaks of the third joint of the mandibular palp as being much greater than the second, curved, very setose; the third uropods he defines as having rami equal in length, short and broad, and the telson as very large, very deeply cleft; but in Costa's type species the telson is not very large, nor is it in Mr. Haswell's species, *Megamæra subcarinata*; therefore the epithet seemed unsuitable. Boeck is no doubt right in supposing that *Megamæra brevicaudata*, Sp. Bate, should be included in this genus, and in that species also the telson is small. The number of spines on the inner

plate of the *First Maxilla* may not be constant either in the genus *Mæra* or in the genus *Elasmopus*, but, so far as I have been able to examine, in species of *Mæra* there are not fewer than nine of these spines, while in species of *Elasmopus* there are not more than seven. It is possible that *Moera incerta*, Chilton, 1882-3, may belong to the latter rather than to the former genus. *Moera crassipes*, Haswell, 1880, also in all probability belongs to this genus.

 1885. " " Chilton, Ann. and Mag. Nat. Hist., ser. 5, vol. xvi. p. 368.

Rostrum rudimentary, lateral lobes of the head rounded, with a very small lobe immediately below the large one, from which the margin slopes backwards, gently concave, to the rounded lower corner; first three segments of the pleon with the postero-lateral angles acute; submarginal spines at six points along the lower border of the third segment; the fourth segment behind the dorsal depression becoming dorsally binate, the carinae produced a little apically in sharp teeth, bending slightly towards one another.

Eyes large, reniform, situated near or on the lateral lobes of the head, dark coloured in spirits; ocelli small, numerous.

Upper Antennæ longer than the lower; first joint long, equal in length to the second but twice as broad, with three spines along the lower margin; second joint with many groups of setæ about it; third joint three times as long as broad, not half the length of the second, similarly furnished; flagellum broken, fifty-two joints remaining, the first longer than broad, the next thirty or so broader than long, all widening a little distally, and there carrying groups of setæ with an occasional cylinder; secondary flagellum of six joints tipped with setæ; the last joint rudimentary, the six together longer than the first six of the primary flagellum, or than the third joint of the peduncle.

Lower Antennæ.—Peduncles and flagella respectively shorter and thinner than those of the upper pair; the first three joints short, the first not expanded, the gland-cone well developed, decurrent, the distal margin of the two coaleseid joints bearing three small spines above, below these being produced into a process longer than the gland-cone, and as long as the third joint; the third joint with a subdistal spine and setæ; the fourth joint much longer than the first three united, longer than the fifth, carrying numerous

groups of setæ on the margins and surface, and on one side near the base a group of spines; the fifth joint elongate, without the spines, but otherwise furnished like the preceding; the flagellum scarcely as long as the peduncle, of about seventeen joints, with apical groups of setæ, the first joint the longest, with marginal as well as apical setæ.

Upper Lip broad and deep, the distal margin rounded, closely ciliated, with the slightest central emargination, as narrow as it is shallow.

Mandibles.—Cutting plate with a smooth or faintly denticulate edge between a tooth at the top and two or three at the lower end; the secondary plate of the left mandible distally widened, divided into five teeth; on the right mandible the secondary plate is weaker, distally bifid, with a small process on the front margin near the base; the front tooth the stronger, with six or seven denticles along the edge, the hinder tooth with one minute denticle; the spine-row of three denticulate spines longer in our specimen on the right than on the left mandible; the molar tubercle very robust, with strongly dentate crown and plumose seta; a small process projects close to the base of the palp; palp slender and feeble, the first joint nearly three times as long as broad, the second longer than the first, with three setiform spines at the distal end, and one a little lower down; third joint nearly as long as the first and second together, with two setiform spines, longer than the joint itself, at the apex, a shorter one beside them, and three on the margin just below.

Lower Lip.—Principal lobes rather dehiscent, the inner and distal margins thickly furred, and, in addition to the cilia, having on each lobe a pair of very short, blunt-headed spines, one on each side of the inner distal corner; the inner lobes rather thick, oval, distally narrowed; the mandibular processes very long, subacute, very divergent.

First Maxilla.—Inner plate with three, not very long, plumose setæ on the apex; outer plate with only seven spines on the truncale, slightly oblique, and rather narrow distal margin, the two outermost spines the strongest, with a single tooth just below the apex, the two next with two teeth so placed, the next with three short denticles, the next with three long ones, and the innermost with five or six that are minute; the dentation not exactly alike in both maxillæ; the first joint of the palp not more than half the length of the second, carrying a small spine at the outer apex; the second joint with a double row of rather long slender spines, sixteen in number, round the apex and oblique distal portion of the inner margin.

Second Maxilla.—Plates elongate, the inner narrower and a little shorter than the outer, fringed round the sloping apex with many long pectinate spines, the row continued by plumose setæ on the distal part of the inner margin; the outer plate having its apex fringed with longer spines, this apical border sloping outwards, while that of the inner plate slopes inwards; the outer plate has some small setæ near the base of its outer margin.

Maxillipeds.—The inner plates not reaching so far as the distal end of the first joint

of the palp, carrying a row of ten plumose setæ, which from the upper part of the inner margin pass towards the outer apex; round the apical margin there is a row of eight plumose spines, followed by some elongate spine-teeth, with two short spine-teeth at the inner corner, these details being made out with some difficulty owing to the crowding of the garniture; the outer plates not nearly reaching the apex of the second joint of the palp, with ten graduated spine-teeth along the inner margin, followed without interruption by five on the apical border, the last of which is very long, and succeeded in turn by seven long setæ; the second joint of the palp is about twice the length of the first, fringed along the inner margin with many setæ or setiform spines; the third joint rather longer than the first, with many groups of spines or setæ about the distal half, apically produced on the outer side in a small ciliated process; the finger about as long as the third joint, with a slender nail, five or six setules along the distal half of the inner margin, and a small dorsal cilium not far from the base.

First Gnathopods.—Side-plates longer than broad, outdrawn below in front, the lower margin not serrate, but bearing some setæ and setules. The first joint reaching much beyond the side-plate, with many long setæ on the hinder margin, chiefly at the upper part, and a row on the surface directed forwards; the second joint with two groups of setæ on the hind margin; the third rhomboidal, with the lower border pointed behind, rounded in front, fringed with setæ, of which there are also four groups along the hind margin; the wrist a little shorter than the hand, with a long group of setæ at the apex of the front margin, many groups along the free part of the hind margin, and five groups on the inner surface; the hand oblong, a little widened distally, with a group of setæ at the apex of the rather convex front margin, and another below the apex, eight groups along the shorter serrate hind margin, nine passing obliquely across the inner surface, and a sinuous line of forty-three, thirty-six of which are short and of even length; the palm, which is pectinate, slightly oblique and convex, is fringed with setules, and has besides four groups of setæ on the outer surface, a continuation of the series on the hinder margin; the point of the finger closes down against a row of four or five small palmar spines on the inner surface; the dorsal cilium is small, near the hinge.

Second Gnathopods.—Side-plates not outdrawn, but the front margin descending below the hinder. Branchial vesicles with a narrow attachment, widening greatly, equal in length to the first joint of the limb. The first joint not nearly as long as the massive hand, distally lobed in front both on the outer and the inner side, some long setæ on the upper part of the inner margin; the second joint distally lobed like the first, in each case the outer lobe being larger than the inner; the third joint oblong, but with the hinder apex rather strongly produced, four groups of setæ on the hind margin; the wrist very short and broad, eup-like, with many setæ and spines on the small hind margin; the hand swollen out to a greater width than the wrist, slightly

contracting again distally, its length once and a half the greatest breadth, the front margin rather sinuous, almost unarmed, the shorter hind margin fringed with a continuous brush of very long setæ, which also cover a large part of the inner surface, and are continued along the palm; the palm begins with a small tooth-process, runs almost in a continuation of the hind margin obliquely to a larger tooth-process, which is followed by a small cavity and then by a bulky process armed with short spines and groups of setæ; over this the finger closes with a finely crenulate inner margin, making a bend over the cavity, touching the central tooth-process by the angular projection of its own inner margin, and with its point reaching the palm near the smaller tooth, its own curved outer margin being bent almost at a right angle.

First Peræopods.—Side-plates oblong, rather longer than the preceding pair, lower margin convex. Branchial vesicles with a narrow neck, distally of great breadth, longer than the first joint. First joint reaching much beyond the side-plate, curved a little backwards, with many setæ and setules on both margins; second joint short, with an apical group of setæ behind; third joint much thicker than fourth, longer than either fourth or fifth, with spines at four points in front, groups of setæ at five points of the nearly straight, slightly serrate, hind margin; fourth joint shorter than fifth, with spines at seven points of the hind margin, two apical setules on the front margin, and one minute one high up on the same; the fifth joint slightly curved, with nine groups of spines on the serrate hind margin, an apical group of setules on the front, and a small setule below its centre; the finger short, broad, more than half the length of the fifth joint, the inner margin forming an angle at the base of the short curved nail, with three setules shorter than the nail implanted at that point; the dorsal cilium very small, near the base of the finger.

Second Peræopods.—Side-plates broad, narrowly excavate. The limb as in the preceding pair.

Third Peræopods.—Side-plates not very deep. Limb as in the following pair, but on a smaller scale.

Fourth Peræopods.—First joint rounded oblong rather than oval, with a group of setæ at the top of the front margin, and spines at eleven points along it, the hind margin more convex, serrate, the serration continued on the rounded lower margin; the short second joint a little overlapped behind, carrying an apical group of spines in front; the third joint broad and strong, expanding distally, and distally a little decurrent before and behind, with spines at five points of the serrate hind margin, and a group fringing the truncale apex, mixed groups of spines and setæ at five points of the serrate front margin; the fourth joint widened distally, with mixed groups of spines and setæ at four points of the serrate front margin, a similar group on the apex of the hinder, and some setules and spinules higher up; the fifth joint equal in length to the third, not so broad as the fourth, but still stoutly built, with seven groups on the serrate front margin, five (chiefly

of setæ) on the hinder; the finger short, similar to that of the first peræopods, but broader and more curved.

Fifth Peræopods.—The first joint differing from that of the preceding pair in being much larger, the hinder expansion being extended considerably above and below the front part of the joint; the second joint entirely overlapped behind by the first; the rest of the limb similar in structure to that of the fourth peræopods, but still more massive, the third and fourth joints much, and the fifth a little, longer; the margins strongly serrate; the third joint with spines at four points of the hind margin, and a large group of spines and setæ at its apex; on the front margin a small spine at one point, followed by four large mixed groups; the fourth joint, almost as long as the fifth, is surrounded by great groups of spines and long stiffly outstanding setæ; the fifth joint has many more groups of a similar kind; this joint, as shown in the figure *prp.5*, has a capacity for twisting into a direction the opposite of its normal position, without becoming detached.

Pleopods.—Coupling spines small; a long spine inserted on the peduncle above them, and many plumose setæ on the sides of the peduncle; cleft spines four to six in number, with short, nearly equal arms, set some way from the base of the long first joint; joints of the inner ramus seventeen, the last very short.

Uropods.—Peduncles of the first pair a little longer than the rami; the outer ramus rather shorter than the inner, both with blunt ends and groups of strong apical spines, the inner branch with five along one of its edges, the outer with three on one edge, four on the other; the peduncles of the second pair broad, scarcely so long as the broad inner ramus; the outer ramus a little shorter than the inner, both with blunt ends and groups of strong apical spines, also closely spined along the margins; peduncles of the third pair shorter than the very broad rami, of which the outer is a little longer than the inner, which has three groups or rows of spines on the inner, and one on the outer, margin, while the outer ramus has four rows on each margin, those on the outer margin the stronger, each ramus having also a large row of spines along the broad, truncate, slightly emarginate, apex.

Telson not so long as the peduncles of the third uropods, concave below, not quite so long as broad, cleft nearly to the base, widely dehiscent, the convex outer margins being apically produced in long points considerably beyond the acute apices on each side of the cleft, the interval between each pair of apices being occupied by two long unequal spines.

Length.—The specimen figured measured, in a straight line from the front of the head to the end of the sixth peræon-segment, three-tenths of an inch, and as much more from the end of the sixth segment of the peræon to the extremity of the uropods.

Locality.—Station 161, off Melbourne, April 1, 1874; depth, 33 fathoms; bottom, sand. Two specimens.

A specimen of this species was labelled as having been taken "June 3, 1874, off Port Jackson, 30 to 35 fathoms."

Station 168, off New Zealand, July 8, 1874; lat. $40^{\circ} 28' S.$, long. $177^{\circ} 43' E.$; depth, 1100 fathoms; bottom, blue mud; bottom temperature, $37^{\circ} 2$. One specimen.

Mr. Haswell, in establishing the species, records it from "Port Jackson (very common at low water among Algae, etc.), Botany Bay; Port Stephens."

Remarks.—By the kindness of Mr. G. M. Thomson I have been enabled to dissect a specimen from Lyttelton, New Zealand, of his *Moera petriei*. In that specimen the inner plate of the first maxillæ has only two apical setæ, the first pair of side-plates are less downturned at the lower front angle, the sculpture of the palm of the second gnathopods differs greatly from that in the Challenger species above described, the hand is without the great brush of long hairs or setæ, the finger ends obtusely like that of *Melita proxima (obtusata)*, Sp. Bate, the rami of the third uropods are less broad, each lamina of the telson has four apical spines, and in the fourth and fifth peræopods the hind margin of the first joint is less convex. On the other hand the description and figures given by Mr. Thomson of *Moera petriei*, from Port Pegasus, agree so closely with the Challenger specimen above described that I feel bound to withdraw the specific name *persetosus* engraved on the Plate, and also to accept the conclusion at which Mr. Chilton has arrived, that *Megamoera subcarinata*, Haswell, and *Moera petriei*, Thomson, are one and the same species, although presenting some variety of form even in the same sex. Mr. Chilton in the New Zealand Journal of Science says, "I have both male and female specimens from Sydney, the females resembling those from Lyttelton Harbour, and described in the Transactions of the New Zealand Institute, vol. xv. p. 82. Curiously enough the males agree with those described by Mr. Thomson from Stewart Island, and differ from my Lyttelton specimens in having 'the whole lower surface [of the propodos of the posterior gnathopoda] very densely fringed with two rows of long simple hairs.' These hairs, which are of the same size throughout their whole length, and thus differ from the ordinary setæ found in this genus, are entirely absent in the Lyttelton specimens. An interesting question thus arises, but for the present must remain unanswered:—What is the function of these hairs, and why should specimens from Sydney and Stewart Island have them, while those from Lyttelton have not?" Mr. Chilton tells me that he subsequently found that "the form of the propodos is slightly different in the specimens from the two localities. In the Annals and Magazine, when considering the question whether the species presents an example of "dimorphic" males, Mr. Chilton says, "I would like to point out that I have not as yet had a sufficient number of specimens of *Moera subcarinata* to make me feel quite sure that the two forms are not simply animals of different ages." He refers also to the possibility of alternating forms, as discovered by Faxon in *Cambarus*. As to the long setæ of the second gnathopods, my

observation does not entirely confirm Mr. Chilton's, for in the Challenger specimens they appear to run out as usual to a fine apex, unless where broken or surmounted by some parasitic growth, although it is quite true that for almost the whole length the thickness is uniform.

Elasmopus delaplata, n. sp. (Pl. XCIX.).

Rostrum rudimentary, lateral lobes of the head with flattened curve, and a small lobe just below and a little to the rear; first and second segments of the pleon with the postero-lateral angles not very sharp, the third segment with these angles rather out-drawn, the lower part of the hind margin rather strongly serrate, and one serration on the lower margin just behind the angle; submarginal spines on all the three segments.

Eyes rather small, oval, placed near the margin of the lateral lobes, white in the specimen preserved in spirits, the oeelli small.

Upper Antennæ with the peduncles and flagella respectively much longer than those of the lower pair; first joint elongate, narrowing a little distally, longer and thicker than the second joint, carrying a few elia; second joint widening a little distally, carrying several groups of setæ on either side; third joint shorter than the second, but also elongate, widening distally, and carrying many groups of setæ; the flagellum longer than the peduncle, of thirty-five joints, the last minute, tipped with setæ, the others carrying two apical groups of setæ and a cylinder; the secondary flagellum slender, consisting of three long and one short joint, the tip of which reaches the end of the fourth joint of the primary flagellum.

Lower Antennæ.—First three joints very short, lobe of the first not protruding, gland-cone decurrent, reaching the end of the third joint, fourth joint much longer than the first three united, nearly as long as the second of the upper antennæ, carrying several groups of setæ; fifth joint a little shorter, much more slender, carrying many groups of setæ; flagellum of sixteen joints, the first as long as the two following together, the others increasing in length from the second to the thirteenth, all carrying apical groups of setæ, and, all but the last three, central groups also.

Upper Lip tending to circular, with the distal margin a little flattened, ciliation slight.

Mandibles.—Cutting plate with an almost smooth edge, bounded by a not very prominent tooth at the top, and two large ones below; secondary plate of the left mandible, broad at the base and the distal margin, the latter cut into five strong teeth, of which the lowest is the largest; in the Plate these teeth are seen in profile; on the right mandible the secondary plate is bifid, the forward tooth the longer, both more or less denticulate; the spine-row on the left mandible of four, on the right of three, dentieulate curved spines; the molar tubercle massive, dilated at the crown, which is surrounded by denticles, covered on one side by a honeycomb pattern, and carries

some short setæ besides the usual long one; the process over the molar tubercle is long and conspicuous; the first joint of the palp, immediately above this, is short, widening distally; the second joint is moderately long and straight, and, besides setæ along the inner margin, has a succession of groups upon the inner surface, that near the apex containing a row of some ten very long setæ; the third joint is longer than the two preceding united, has four or five groups of setæ on the outer surface near the convex outer margin; the inner margin is sinuous, forming with the outer a sharp apex; not far from the base it presents a groove or fold, about the middle of which begins a marginal row of short pectinate spines, more than seventy in number, succeeded by six long ones which carry the series to the apex.

Lower Lip.—Mandibular processes large, rounded at the ends.

First Maxillæ.—Inner plate oval, small and narrow, with a plumose seta on the apex, and below it three or four setules; outer plate with seven spines on the oblique trunecate apex, the three innermost spines having from five to seven long denticles towards the upper part, the others five or fewer; the second joint of the palp rather wide, reaching beyond the outer plate, having round its convex dentate margin ten thin spines, the apical pectinate on both edges, and eight submarginal spines.

Second Maxillæ.—The inner plate rather shorter and narrower than the outer, the rounded distal margin fringed with spines, the series not reaching the outer margin, and bounded by plumose setæ just at the top of the straight inner margin; the spines round the apical margin of the outer plate descend the convex outer margin a little way.

Maxillipeds.—The prismatic inner plates reach as far as or a little beyond the first joint of the palp; the plumose setæ commencing on the inner margin number about ten, the pectinate spines which fringe the apical border number about thirteen; there is also a long submarginal spine-tooth near the inner apex; the outer plates reach beyond the middle of the second joint of the palp, and are fringed along the inner margin, round the apical, and a short way down the outer margin with about thirty-two spines, of which the outer five are setiform, the apical ten elongate, curved, the remainder moderately long, straight, spine-teeth; the first joint of the palp is very short, the second considerably more than twice as long, fringed on the inner border with many slender spines; the third joint much longer than the first, with groups of spines on the inner margin, the adjoining inner surfaces, and the distal part of the outer margin; the outer distal end is prolonged over the base of the finger in a short, ciliated, round-ended process; the finger is long, with a sharp nail having two or three setules at its base; the dorsal cilium small, near the base of the finger.

First Gnathopods.—Side-plates much outdrawn in front, lower margin carrying some setules. First joint reaching beyond the side-plate, rather broad, widest distally, carrying long setæ on both margins at the upper part, an apical group of pectinate spines on the convexly bent hind margin; a larger group on the hind apex of the short second

joint; the third joint not much longer than broad, with spines on the lower border, which is produced in a short apex behind; the wrist as long as the hand, an apieal group on the long front margin, almost all the inner surface covered with rows of long spines, the inner margin with very many groups of long, slightly plumose spines on the outer side, and on the inner side a dense brush of shorter strongly pectinate spines; the hand tending to oblong, widening slightly distally with groups of setiform spines along the serrate hind margin, rows on the inner surface near the centre, and near the front margin a continuous row of small spines, the row curving over to the front margin, in approaching which the spines become very long; four other rows succeed this, the last being apieal; the spines appear to be finely pectinate; the convex palm-margin is closely set with short spines, each having an accessory thread near the tip; the nail of the stout curved finger reaches a little beyond the somewhat longer spines which define the palmar margin; the dorsal cilium is small.

Second Gnathopods.—Side-plates narrower than the preceding pair, narrower below than above. First joint similar to that of the first gnathopods but larger; third joint with a few spines on the lower part of the hind margin, which is produced into a conspicuous apex; the wrist short, broader than long, cup-like, with many pectinate spines on the short hind margin and a row along the distal border of the inner surface; the hand large, broader than the wrist, longer than the first joint, with many groups of slender feathered spines along the hind margin, a complete brush of them on part of the inner surface, and some small groups also on that surface near the front margin; the palm-margin has an irregular toothed eminence close to the hinge of the finger, over which the crooked finger bends, leaving a gap between its inner margin and the palm, and within this rises a smaller projection of the palm; the finger closes down against the inner surface between two small processes set upon that surface.

First Peraopods.—Side-plates like those of the preceding segment. The limb slender, first joint reaching beyond the side-plate, longer than the first joint of the second gnathopods, similarly bent and armed; second joint not very short; third joint longer than the fourth or fifth, a little decurrent in front, with slight spines at five points of the front margin, and at six of the hinder; fourth joint a little shorter than the fifth, with slender spines at five points of the hind margin; the fifth joint with spines at six points of the hind margin, and some setæ at two or three points in front; the finger broad, about half the length of the fifth joint, distally broader than the base of the nail, with two setules at the raised point of the inner margin which also has a small cilium before reaching the setules; the dorsal cilium near the base of the finger small.

Second Peraopods.—Side-plates not very broad, the margin of the narrow but deep excavation sinuous, convex at first and then concave. The limb closely resembles that of the preceding pair, but is a little shorter.

Third Peraopods.—Front lobe of the side-plates rounded below, the hind lobe more

deeply produced and pointed. Branchial vesicles oval, descending a little beyond the hind lobe of the side-plate. First joint long and rather narrow, slightly wider above than below; the front margin nearly straight, with some small spines and setæ, the hind margin serrate, continued in a crenate lobe below, partially overlapping the short second joint; the third joint longer than the fourth, equal to the fifth, apically produced, more behind than in front, slender spines at four points on each margin; the fourth joint also distally widened, a little produced behind, and there tipped with spines, of which there are three groups on the front margin; the fifth joint has spines at six points in front, and at four or five behind, of these the apical group being large and strong; the finger as in the preceding pereiopods.

Fourth Pereiopods.—The side-plates with a minute front lobe, the hinder as in the preceding segment. The limb broader and stronger than the preceding pair, the first and second joints larger but otherwise similar, the third joint more pronounced at the hinder apex, longer than the fifth joint; the fourth joint not at all produced behind, decidedly shorter than the fifth.

Fifth Pereiopods.—The side-plates deeper than broad, crenate below. The first joint considerably larger than in the preceding pair, the hind margin more convex, all the joints after the second longer, especially the fourth joint; the fifth joint scarcely so broad, rather more decidedly drawn down at the apex of the hind margin than in the two preceding pairs.

Pleopods.—Peduncles long in comparison with the rami; coupling spines slender, with an apical and a lateral retroverted tooth, and a row of several denticles beginning at the apex and descending one side; eight spines set far down the joint, six in number on the first two pairs, five on the third, seemingly with nearly equal branches, though as the tips of these branches easily get broken, it is not safe to speak positively on this point; joints of the rami from sixteen to eighteen.

Uropods.—Peduncles of the first pair longer than the rami, with two strong apical spines besides the smaller marginal ones, the rami a little curved, the outer rather shorter than the inner, both with a few marginal spines and a group within the cavity formed by the producing of the outer margin to a point beyond the inner; peduncles of the second pair subequal in length to the rami, which are broader than those of the first pair, but respectively not so long, spined in a similar manner, the outer a little shorter than the inner; peduncles of the third pair shorter than the rami; the rami broad, lanceolate, but with slightly emarginate apices, the outer longer than the inner, equal in length to the outer of the first or the inner of the second pair, with spines at five points on each margin, of which the outer is serrate; each ramus has spines at the apex, the outer has also a group on the outer margin near the apex, otherwise its margins are smooth; the first pair reaches back nearly as far as the third, the second falling short of both.

Telson reaching beyond the peduncles of the third pair, eight nearly to the base, its

two halves apically a little delinsecent, together forming a broad oval, truncate at the base; on the outer sides, a little above each apex, the convex margin is interrupted and the angle carries a spine and a cilium. The difference between the telson of *Elasmopus subcarinata* and that of *Elasmopus delaplata* corresponds pretty exactly with the difference between the telson of *Mæra rubromaculata* and that of *Mæra bruzelii*.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the extremity of the third uropods, three-fifths of an inch.

Locality.—Station 320, off Monte Video, February 14, 1876; lat. $37^{\circ} 17'$ S., long. $53^{\circ} 52'$ W.; depth, 600 fathoms; bottom, green sand; bottom temperature, $37^{\circ}.2$. One specimen.

Remark.—The specific name refers to the place of capture off the mouth of the Rio de la Plata.

Genus *Parelasmopus*, n. gen.

Near *Elasmopus*, Costa.

The mandibular palp with the second joint much shorter than either the first or third.

Upper Antennæ with small accessory flagellum.

The *Uropods* of moderate breadth.

The sixth segment of the *Pleon* very small.

It is perhaps doubtful whether this genus should be separated from *Elasmopus*, which in general it so closely resembles, but the proportions of the mandibular palp appear to be unique.

Parelasmopus suluensis (Dana) (Pl. C.).

1852. *Gammarus Suluensis*, Dana, Proc. Amer. Acad. Sci. and Arts, vol. ii. p. 210.

1852. " *suluensis*, Dana, U.S. Explor. Exped., vol. xiii. pt. ii. p. 947, pl. lxv. fig. 3.

1862. *Megamoera Suluensis*, Spence Bate, Brit. Mus. Catal. Amph. Crust., p. 230, pl. xl. fig. 6.

No rostrum; lateral lobes of the head rounded, lower angles produced in a sharp point which does not project beyond the lateral lobes; seventh segment of the peræon and first two of the pleon distally produced into a small sharp tooth on either side of the median line, the third segment by dorsal emargination of the hind margin forming on each side an angle of the hind margin rather than a tooth, the fourth segment with a long sinuous dorsal line, which at the centre forms two branches, each ending in a sharp upcurved tooth; the first and second segments of the pleon have the postero-lateral angles produced in short sharp points, while the third segment has these angles sharply

produced upwards, with the adjoining part of the lower margin cut into four or five serrations; the sixth segment very small.

Eyes large, oval, placed close to the lateral lobes of the head, the ocelli small, about sixty-six in number, the crystalline cones not longer than broad.

Upper Antennæ much longer than the lower, first joint long and slender, but thicker and a little shorter than the second joint, with three spines along the lower margin; second joint carrying a few groups of slender setæ; third joint less than one-third the length of the second, only a little longer, or not longer, than the first joint of the flagellum; the broken flagellum contained seventeen joints, of which the first was the longest; the secondary flagellum of two slender joints, together a little longer than the first of the primary.

Lower Antennæ slender, the peduncles and flagella respectively shorter and thinner than those of the upper antennæ; first joint little expanded, gland-cone decurrent, produced quite to the distal end of the third joint; fourth joint longer and thicker than the fifth, shorter than the first of the upper antennæ; fifth joint long and slender, furnished like the fourth with some groups of slender setæ; flagellum much shorter than the peduncle, of ten joints, furnished with setæ, the first joint the longest, the last minute.

Upper Lip deeper than broad, with the distal margin rounded, but not broadly, closely ciliated.

Mandibles.—Cutting plate divided into eight or nine teeth; the secondary plate on the left mandible distally broad, divided into six teeth; on the right mandible the secondary plate is slighter, distally bifid, the front tooth the longer, having three teeth along the front side and a little outward-pointing process above them; spine-row on the left mandible consisting of four, on the right of three, curved denticulate spines; molar tubercle with a strongly denticulate crown and a plumose seta; the process near the base of the palp prominent; palp very slender, not so long as the body of the mandible, set just over the molar tubercle, the first joint as long as the third, and double or more than double the length of the second; the second very short, narrower than the first, a little broader than the third; the third narrow, slightly tapering, tipped with two long setæ, or setiform spines.

Lower Lip.—The principal lobes deep, a little narrowed distally, very slightly dehiscent, with many cilia, including a pair on each lobe that are spiniform; the inner lobes deep and narrow, much ciliated on the distal and inner margins; mandibular processes long, narrow, rather divergent.

First Maxillæ.—Inner plate small, ovate, tipped with two plumose setæ; outer plate with seven spines on the truncale oblique distal margin, the denticles minute on the slender innermost spine, prominent on the next three but only two or three in number, while on each of the three outermost spines there is not more than a single

denticle; the first joint of the palp more than half the length of the second, the second broad, with convex outer margin, reaching beyond the outer plate, carrying round the distal margin seven long finely pectinate spines, with four or five submarginal spines.

Second Maxillæ.—The inner plate a little shorter and narrower than the outer, the oblique apical portion fringed with pectinate spines, followed by plumose setæ on the distal part of the inner margin; many long pectinate spines fringe the apical border of the outer plate.

Maxillipeds.—The inner plates nearly reaching the apex of the short first joint of the palp, the truncale distal border sloping inwards, fringed with long spines, some of which are strongly denticulate, the inner part of the apex perhaps having spine-teeth; the outer plates not reaching the distal end of the second joint of the palp, with graduated spine-teeth beginning low down on the inner margin, the lower small, all of them closely set, to the number of twelve on the inner margin, followed by five, long and curved, on the distal border, with a sixth not dentiform; there are also numerous groups of not-tapering spines on the surface near the inner margin; the second joint of the palp is stout, nearly twice as long as the first, fringed with slender spines on the inner margin; the third joint as long as the first, its inner margin finely pectinate, some slender spines around the distal portion, the apex produced on the outer surface into a small oval or conical lobe, finely ciliated, and shown on the Plate as appearing through the transparent finger; the finger with its inner margin finely pectinate, many adpressed cilia on the surface, cilia or setules at the base of the very elongate nail, and a dorsal cilium at a little distance from the base of the finger.

First Gnathopods.—Side-plates not much deeper than broad, a little outdrawn below in front, the hinder part of the lower margin serrate, a few spines and setæ and setules fringing the lower margin; the first joint reaching below the side-plate, not as long as the wrist and hand united, with a few long setæ on the front and hind margins; the second joint short, with two slender spines at the hinder apex; the third joint not much longer, rhomboidal, with spines at two points of the hind margin, a row of ten along the distal margin, with a row of six little spinules above them; the wrist nearly as long as the hand, and distally a little wider, with numerous groups of long pectinate spines on the hind margin and inner surface, and two apical spines on the outer margin; the hand oblong, twice as long as broad, with many groups of long spines on the hind margin and inner surface, and an oblique row along the central part of the inner surface of twenty short spines, continued distally by longer spines; the somewhat oblique palm is well defined, with two or three palmar spines inserted on the surface on each side, among which the finger closes down; the palmar rim is cut into minute erect teeth, and has a fringe of submarginal setæ and setules; the finger has some setules along the inner margin, two longer ones at the base of the long nail; the dorsal cilium is small, at a little distance from the hinge.

Second Gnathopods.—Side-plates a little longer than the preceding pair, whieh they resemble, except that they are not outdrawn in front. Branehial vesicles as long as the first joint, nearly twiee as long as broad. First and seeond joints of the limb as in the preeeding pair, but larger ; third joint drawn out to a pointed apex behind as well as in front, with spines at two points of the hind margin ; the wrist only equal in length to the preeeding joint, broader than long, eup-shaped, with five groups of spines on the short hind margin, and a couple of short spines at the apex of the front margin ; the hand of great size, longer than the first and second joints united, much broader than the wrist, nearly twiee as long as broad, with a few spines along the long front margin, seven or eight groups of setæ along the shorter hind margin ; the palm oblique, of very irregular outline ; from the two edges between whieh the hinge of the finger is inserted arises a large prominenee with seven spines, three pairs and an odd one, above its sinuous margin, this prominenee being followed by four emarginations, bounded each by a spine, the outermost a very small one, on either side of which there project from the inner surfacee two proeesses evidently intended to reeeive the point of the strong curved finger, as in *Cheirocratus sundevallii*; the dorsal eilium is very small, at some little distanee from the base of the finger, the inner margin of whieh shows some small hairs.

First Peræopods.—Side-plates similar to those of the preeeding segment; branehial vesicles more inflated at the eentre. First joint of the limb longer than in the preeeding pair, with the front margin rather more sinuous, some very long setæ at the upper part of the hind margin ; third joint longer than either the fourth or the fifth, not deeurrent, with spines at three points of the front margin, setiform spines or spinules at four points of the hind margin ; the fourth joint equal in length to the fifth, with spines at four points of the hind margin, spinules at two points of the first ; the fifth joint with spines at six points of the hind margin, spinules or small setæ at two points of the front ; the finger short and broad, not much more than half the length of the fifth joint, the inner margin forming an angle in front of the little eurved nail, two elia being inserted at this point ; the dorsal eilium small, close to the hinge ; there is another cilium on the dorsal line near the base of the nail.

Second Peræopods.—The side-plates deeply but not widely excavate. The branehial vesicles at the eentre as broad as two-thirds of their length. The limb nearly as in the preeeding pair.

Third Peræopods.—Side-plates not very broad. Branehial vesicles widest distally. First joint of the limb much longer than broad, broader above than below, with spines at eight points of the front margin, the hind margin nearly straight, serrate, forming an angle with the serrate hind part of the lower margin ; the seeond joint with a group of spines at the apex of the front margin ; third joint with spines at four points of the straight front, and four of the eonvex hind, margin ; the rest of the limb missing.

Fourth Peræopods.—Side-plates narrow. Branchial vesicles smaller than the first joint, in position pointed backwards. First joint similar to that in the preceding pair, but larger, rather more widened at the top, with spines at nine points of the front margin; the two following joints also like those of the preceding pair, but larger, with stronger spines, and the third joint proportionately a little more decurrent both in front and behind.

Fifth Peræopods.—Side-plates small. The first joint larger than in the preceding pair, broader at the centre; the two following joints similar to those of the preceding pair, not larger.

Pleopods.—Coupling spines broad at the base, with from two to three pairs of retroverted teeth below the apex; in the third pair there is a strong spine at the inner apex of the peduncle close to the coupling spines, and many times as long, and another spine about half its length at the outer apex; cleft spines four in number in the first two pairs, three in the third pair, the arms nearly equal in length; the joints were nine to the inner, ten to the outer, ramus of the third pair.

Uropods.—Peduncles of the first pair a little longer than the rami, with several spines along the margins, and some large and strong ones about the apex, the outer ramus a little shorter than the inner, each with a few spines on the margin, and a strong apical group; the peduncles of the second pair a little shorter than the rami; the rami respectively shorter than those of the first pair, but, as well as the peduncles, very similarly armed; the inner margin of the inner ramus more closely spined; third uropods missing.

Telson small, scarcely longer than broad, cleft nearly to the base. The dehiscence boat-shaped, bounded by a sharp apex on either side, while the slightly converging outer lateral margins form two other apices still more produced, each pair of apices having the interval between the two points occupied by two long unequal spines, which extend back much beyond the apices themselves.

Length.—The specimen, in the position figured, measured, from the front of the head to the back of the third pleon-segment, a quarter of an inch.

Locality.—Station 186, between Cape York and the Arrou Islands, September 8, 1874; lat. $10^{\circ} 30' S.$, long. $142^{\circ} 18' E.$; depth, 8 fathoms; bottom, coral mud. One specimen.

Remarks.—Dana's *Gammarus suluensis* was taken in the "Sooloo Sea; from a small island off the harbour of Soung; among seaweed floating off the shore." He states that "the stylets [uropods] are all long, and extend equally far backwards."

Family AMPELISCIIDÆ.

In 1856 Spence Bate made the Tetromatides the third subfamily of the Gammaridæ, with the single genus *Tetromatus*; in 1857, finding that *Tetromatus* was identical with *Ampelisca*, he altered the name of the subfamily to Ampeliscades. A paper by Costa, of which a preliminary notice had appeared in 1853, was given to the world in full in 1857; in this paper the Ampeliseini were the first subfamily of the Gammaridei, and to it Costa assigned the genera *Ampelisca* and *Araneops*, which are in fact one and the same, but he also noticed that *Haploops*, Liljeborg, ought to be placed in the same group. In 1861¹ Bate and Westwood call the subfamily Ampeliscides, including in it the genera *Ampelisca* and *Haploops*. In 1865 Lilljeborg made the Ampeliseina the ninth subfamily of the Gammaridæ, with the same two genera. Boeck in 1870 placed the Ampeliseinae as the sixteenth subfamily of the Gammaridæ, adding *Byblis* as a third genus. With the same genera and with the definition unaltered, in his subsequent work Boeck changed the subfamily into a family, with the name Ampeliseaidæ, which he placed fifth in his arrangement of the Amphipoda Gammarina. In 1882 Sars writes the name Ampeliscidæ instead of Ampeliscaidæ. In 1886 Gerstaecker adopts the title “*Ampelisca*, Sp. Bate” for the fourth subfamily of the Gammaridæ. The following is the copious definition which Boeck gives of the family:—

“ *Upper Lip* broad, apically little arcuate.

“ *Mandibles* like one another, apically broad, dentate; the accessory plate also much dentate; the molar tubercle very prominent; spines of the spine-row numerous, long, strong, and apically more or less furcate and sometimes (partim) serrate; the palp more or less elongate, three-jointed.

“ *Lower Lip* very broad; the inner plate broad.

“ *First Maxillæ* with the inner plate long, but not broad, apically furnished with a few plumose setæ; the palp two-jointed, apically armed with a few strong teeth and spines.

“ *Second Maxillæ* with the outer plate longer and sometimes (partim) broader than the inner.

“ *Maxillipeds* robust; the inner plate elongate; the outer large, armed on the inner margin with broad teeth, apically with curved spines.

“ The body elongate, deep, compressed; the side-plates tolerably large or of moderate size, with setæ on the lower margin; the head apically produced; the eyes two (?) or four, simple.

“ The two hinder [fifth and sixth] segments of the pleon coalesce.

“ *Upper Antennæ* with a long flagellum, without accessory flagellum, attached to the apex of the head.

¹ In explanation of the fact that Bate and Westwood in 1861 give references to the Brit. Mus. Cat. Amph. Crust. of 1862, it will be remembered that the two works were being produced simultaneously and practically by the same author.

"Lower Antennæ also with very long flagellum, attached under the head.
 "First and Second Gnathopods slender, with small, subcheliform hands.
 "First and Second Peræopods narrow; the third joint broad.
 "Third and Fourth Peræopods retroverted; the fingers small.
 "Fifth Peræopods much shorter than the Third or Fourth; the first joint much dilated below and behind.

"Uropods biramous; the rami of the third pair laminar and setose.

"Telson more or less deeply cleft."

In regard to this definition it may be remarked that the likeness between the two mandibles does not extend to the secondary plate, since that on the right mandible is as usual of weaker construction than that on the left; of the third and fourth peræopods it is rather the two terminal joints (and perhaps the third) that are retroverted than the whole of the limb; notice might also well be taken, among the family characteristics, of the gland-cells in the first and second peræopods.

For the original definition of the genus, see Note on Krøyer, 1842 (p. 199); for the definition of *Araneops*, see Note on Costa, 1857 (p. 296); for that of *Pseudopthalmus*, see Note on Stimpson, 1854 (p. 279); and for that of *Tetromatus*, see Note on Spence Bate, 1857 (p. 293). Boeck in 1876 gives the following definition to *Ampelisca* :—

“ *Mandibles* with the second joint of the palp broad; the third joint much narrower, but almost of the same length as the second.

“ *Maxillipeds* with the third joint of the palp apically much dilated.

“ *Eyes* four, placed on the anterior margin of the head.

“ *Lower Antennæ* with the first and second joints of the peduncle not externally visible.

“ *Fifth Peraopods* with the first joint triangular, elongate behind and below; the fifth joint elongate, oval, longer than the fourth; the finger lanceolate.

“ *Third Uropods* extended beyond the extremity of the *First* and *Second* pairs, the rami elongate, laminar, furnished with long plumose setæ.

“ *Telson* elongate, more than twice as long as broad, cleft to the base.”

The Challenger species do not show the palp of the mandibles in all cases with its second joint broad, or with its third joint¹ almost of the same length as the second, and in one species, *Ampelisca abyssicola*, the fifth joint of the fifth pereopods is shorter, instead of longer, than the fourth.

Spence Bate, in his definition of *Ampelisca* in 1878, includes the character “eyes imperfect,” but though the eyes in the Ampelisidae are very differently constituted from those of other Amphipoda, it is doubtful whether they should be considered imperfect: behind each of the four bright lenses in the head of an *Ampelisca* there is a circle of very numerous optical elements (indicated in fig. *a.i.* Pl. CIII.), which are by no means suggestive of imperfect vision.

Ampelisca acinaces, n. sp. (Pls. CI., CII.).

The animal acutely compressed all along the dorsal line, the head elongate, in front narrow and rather sinuously truncale; the postero-lateral angles of the first two pleon-segments rounded, the third segment having the lower margin nearly straight and making almost a right angle with the hind margin; the fourth segment of the pleon having a

¹ Boeck himself finds this third joint only half as long as the second in *Ampelisca eschrichtii*.

transverse dorsal depression, whieh facilitates its teleseoping with the segment before it ; the partially coalesceent fifth and sixth segments have a similar depression between them.

Eyes round, simple, the upper pair near the rounded upper corner of the head, the lower pair close to the lower corners.

Upper Antennæ.—First joint short ; second more slender, but much longer, with about a dozen long slender spines on the lower margin ; the third joint nearly as long as the first, not distinguishable from the joints of the flagellum, of which there are ten, together longer than the peduncle, having setiform spines on the lower margin.

Lower Antennæ much longer than the upper, about equal to the length of the animal. The first two joints short and comparatively broad, the third a little longer than the second, direeted upwards close to the lower margin of the head, beyond which it scarcely reaches ; the fourth joint more slender, longer than the whole peduncle of the upper antennæ, with slender spines at a few points of the under margin ; the fifth joint thinner and shorter, similarly armed ; the flagellum longer than the peduncle, of thirty-four slender joints, armed with slender spines, many of them long.

The *Upper Lip* appears to have distally a faint unsymmetrical emargination, with very slight ciliation.

Mandibles.—The cutting plate bent at almost a right angle to the upper edge of the trunk, divided into five teeth, of which the uppermost extends beyond the rest ; on the left mandible there appear to be two extra denticles on this largest tooth ; the secondary plate is narrow, apically divided into three, or perhaps five, teeth ; it is of slighter strueture on the right than on the left mandible, in each being more or less parallel to the prineipal plate ; the spine-row is of thirteen or fourteen closely set, backward-curving spines, which are denticulate and nearly evenly broad till they suddenly narrow to the apex ; the molar tubercle is prominent, its oval crown set with strong denticles, and having a long low ridge with an angled margin just above its distal border ; a broad process rises beside the base of the palp ; the palp is longer than the trunk, set over the molar tubercle, its first joint more than twice as long as broad, its margins carrying two or three small spines ; the second joint twice as long as the first, with slender spines at five or six points on each of two edges ; the third joint is longer than the first, but shorter than the second, very thin, the hind margin convex, the narrow apex carrying two or three spines, and the straight front margin having three pairs.

Lower Lip.—The prineipal lobes deeply but not widely divided and strongly ciliated on the inner margins, the ciliation passing round only the inner portion of the rather flatly convex distal margins ; the inner lobes reaching nearly as far forward as the prineipal ; the mandibular processes very short, with the narrow rounded apiees slightly converging.

First Maxillæ.—Inner plate small, with a short seta or spine on the narrow apex, and a long plumose seta some way below the apex on the inner margin, which below this is

densely ciliated; the outer plate has the inner margin produced into an apieal tooth; the truncate slightly convex distal margin carrying eleven spines, of which some, chiefly the outer ones, have lateral denticles, while the inner ones have the two edges serrate; the outer apex of the joint which carries this plate has some small spines; the first joint of the palp is quite short, the second reaches much beyond the outer plate, widening distally, the distal margin cut into five teeth, beside which are planted five spine-teeth, the outermost the longest, and six submarginal elongate spines.

Second Maxillæ.—The inner plate narrow, shorter and narrower than the outer, the lower half of its inner margin densely ciliated, the upper half and apex fringed with strongly plumose setæ or spines; the semieircular apex of the outer plate is fringed with spines, four or five on its outer margin being plumose and more setiform; low down on the outer margin there are one or two small spines.

Maxillipeds.—The basal joint is fringed with setæ, many of them very long and densely plumose. The inner plates are narrow, reaching beyond the first joint of the palp, the distal margin serrate, sloping outwards, carrying three spine-teeth near the inner apex, which are almost concealed from the inner view by a row of five or six long plumose setæ crossing the surface; the outer plates large, reaching almost to the apex of the second joint of the palp, the lower part of the inner margin smooth, with two or three small spines upon or near it, the upper part strongly crenate and carrying six strong spine-teeth, somewhat spoon-shaped in outline; round the apical margin there are five longer spines, the outermost being the narrowest; the first joint of the palp is short, the second long, the inner margin fringed with long spines; the third joint longer than the first, narrowest at the base, the inner margin and apex fringed with spines, of which there are groups also on the surfaces; the spines on the inner margin appear to be plumosely pectinate in the lower half; the finger is small, little curved, with a rather long nail, near which on the inner margin the finger has some four decurrent spinules or setules; the dorsal eilium is small, near the hinge.

First Gnathopods.—Side-plates much wider below than above, the rounded lower corner in front being produced over the basal joints of the lower antennæ, the lower margin fringed with numerous long plumose setæ and some shorter smooth setæ inserted more deeply; the smooth hind margin forms apically a small tooth which does not reach beyond the lower margin. The first joint not reaching below the side-plate, a little widened distally, with short setæ on the front margin, long ones on the surfaces, long and short on the hind margin; the second joint short, with a group of apical spines behind; the third joint oblong, with the front apex pointed, the hinder rounded and fringed with long spines; the wrist longer and wider than the hand, widest after it becomes free from the third joint, the front margin carrying six or seven groups of spines, almost all the free hind margin crowded with slender pectinate spines of very various lengths, the apex having some very short by the side of some that are very long; the hand a narrow oval,

with half a dozen groups of setæ or spines on the front margin, many spines on the apex, and eleven groups of spines on the hind margin, in character resembling the series on the wrist; the finger slender, curved, a little more than half the length of the hand, with six or seven decurrent spinules along the inner margin, the nail short; the dorsal cilium spine-like, placed near the hinge.

Second Gnathopods.—Side-plates long, widening a little below, carrying on the surface some vertical streaks, the lower margin fringed and the hind margin apically toothed as in the preceding pair. The branchial vesicles not very broad, but as long as the side-plates. The marsupial plates shorter and much narrower than the branchial vesicles, fringed with very long setæ. The first joint reaching perhaps a little below the side-plate, curved, expanding distally, the front margin sinuous, with some long setæ both above and below and short spines in the middle; the hinder margin carrying numerous long setæ, the lower ones plumose; the second joint with a seta in the middle of the hind margin and a group at the apex; the third joint nearly oblong, narrowing apically, with a few spines along the hind margin and an apical group; the wrist very long and narrow, much longer than the hand, armed as in the first gnathopods, but with the groups in front more numerous, behind less closely set, and the spines longer; the hand longer and narrower than in the first gnathopods, the margins similarly armed, the inner surface closely set with rows of spines; the finger longer than in the preceding pair, but otherwise like it.

First Peræopods.—Side-plates nearly as in the preceding pair, but with less difference in width above and below. First joint not reaching the end of the side-plate, a little curved and slightly expanded distally, the upper part of the hind margin bare, the lower carrying long setæ; the second joint short; the third long and broad, with very long plumose setæ on the lower half of the front and more than the half of the hind margin; the fourth joint scarcely longer than broad, much narrower than the third joint, with many long setæ on the hind margin, and two small spines at the apex of the front; the fifth joint somewhat oval, much longer than the fourth, with the long plumose setæ on both margins except at the proximal part, eight on the hind margin, and twice that number on the front; the finger slender, curved, with smooth edges, much exceeding in length the fourth and fifth joints united.

Second Peræopods.—Side-plates broad, with many of the vertical striations which seem to occur generally on the side-plates in this genus, the front margin slightly convex, the lower margin nearly straight, fringed, but not closely, with setæ and spinules, the excavation behind not deeper than broad, the hind margin below the prominent rounded angle sloping forwards with a slight concavity, and merging without any intervening tooth in the lower margin. The branchial vesicles as in the two preceding pairs. The marsupial plates narrow, as long as the branchial vesicles. The limb differs in some respects from that of the preceding pair; the second joint has the hind margin

fringed with plumose setæ; the third joint is longer, and strongly fringed with long densely plumose setæ along the whole of both margins, it is slightly less broad at the distal end than higher up; the hand is rather longer, and the finger not being longer is therefore less in excess of the length of the two preceding joints united.

Third Peræopods.—The side-plates broad but shallow, the hind lobe less deep than the front, and having the hind margin of the first joint attached to it. The branchial vesicles not very large, bent forwards across the first joint, with the upper edge concave. The marsupial plates narrow and short, with seven long setæ about the distal end. The first joint of very irregular shape, the greatest breadth about equal to the length, the front margin describing a great curve, which ends near the apex of the second joint; it has several spines at intervals, and long plumose setæ inserted either on the margin or at some distance within it; the hind margin is short and smooth, almost straight, scarcely reaching the top of the second joint; the second joint is short, partly covered in front by the lower lobe of the first joint; it has an apical spine and spinule; the third joint has the appearance of being reversed, the hind margin being straight, with two small apical spines, the front margin very convex, with some spines of different lengths, the apex a little decurrent but not pointed; the fourth joint is longer, with parallel sides, the front fringed with spines, the hinder straight and smooth, but its slightly decurrent apex carrying a notable group of spines of very various lengths, some of which have for part of their length three lines of denticles; besides eight stout spines, there are three slender ones, the terminal part of the longest delicately pectinate; the fifth joint is rather longer than the fourth but more slender, straight, the longer front margin with its apex produced below the insertion of the finger, and armed with a dozen long spines, most of them partially pectinate; there is also a long spine at the apex, beside two or three spinules; the hinder margin, which is straighter than the front, has seven spines, of successively greater length; the finger is very short, abruptly upturned, with a small dorsal cilium close to the hinge, and on the middle of the back a group of many little denticles.

Fourth Peræopods.—The side-plates very shallow, not lobed, but deeper in front than behind, where they form a rounded point. The branchial vesicles small, placed as in the preceding segment. The first joint of the limb large, projecting in front above, with feathered setæ round the prominent corner, the long margin below this almost straight, having small spines at intervals, its lower lobe overlapping the second joint to its apex; the hind margin curved above and below, but for the chief part nearly straight and smooth, the lower margin behind standing clear from the next joint; the next two joints as in the preceding pair; the fourth joint rather wider distally, the hinder apex similarly armed, the front margin with stronger spines; the fifth joint is set on, as in the preceding pair, near the front apex of the fourth joint; it has seven spines, rather stout but not elongate, along the front margin, and some on the apex; there are three on the hind margin; the finger is as in the preceding peræopods.

Fifth Peræopods.—Side-plates shallow and not very broad, with two setæ and a small spine on the convex lower margin; at the narrow line of attachment, both in this and other species of the genus, these side-plates seem to be almost coalesced with the segment. The first joint with the front margin nearly straight, carrying nine spinules and an apical spine; the lower margin, after passing across the top of the second joint, abruptly descends along the back of it, but before reaching the end curves up again, and with a slightly convex course, closely fringed with long plumose setæ, makes an obtuse angle with the slightly convex, backward-tending, smooth hind margin, the greatest breadth of the joint being at the angle; on a large part of the inner surface of this great wing there are long setæ; the second joint with the sides almost parallel, the front margin a little decurrent, with an apical spine, and two spinules; within the apex there are three spinules on the lower margin; the third joint is shorter than the second, especially behind, where it has two or three long setæ and two or three spines; in front its apex is decidedly decurrent, set about with three or four slight spines; the fourth joint is longer than the third, shorter than the second, widening distally, the apex behind slightly decurrent, carrying a spine; the apex in front more decurrent, with several spinules on the lower margin within the apex; the fifth joint is nearly as long as the three preceding joints united, broader above than below, the front and hind margins slightly convex, smooth, the lower margin obliquely truncate, the surface having some short submarginal spines and some spinules difficult to discern, and there are some at the apex; the finger is much narrower, but with something of the same laminar appearance, and about three-quarters of its length, lanceolate in shape, with very little firmness of texture; there is a small seta near the hind margin below the middle.

Pleopods.—The coupling spines broad at the base, having a lateral tooth much stronger than the apical on one side, and on the other a succession of small teeth; the peduncles have also groups of long plumose setæ; the inner ramus of the first pair has on its long first joint a plumose seta followed by six cleft spines, with the outer arm clearly serrate on the inner edge; this joint has also four plumose setæ below the cleft spines; there are twenty-eight joints on the outer ramus of this pair, and twenty-two on the inner.

Uropods.—The peduncles of the first pair are shorter than the rami, with small spines along the upper margins, the rami are slender, reaching little beyond the peduncles of the second pair, the outer rather the shorter, each curving to the acute apex, the inner carrying a few spinules on the margins high up, and some minute surface spines; the peduncles of the second pair nearly as long as the rami, with spines along the upper margin; the inner ramus rather longer than the outer, with thirteen spines along the serrate upper margin, which is apically curved and acute; the outer ramus has sixteen spines on the serrate upper margin of the outer surface, and side by side with these on the inner surface another row of eleven or twelve, more decurrent, the last five long, and with the apical

portion denticulate; the peduncles of the third pair much shorter than the rami, apically acute below, with a spine and some spinules on the upper margin; the rami lanceolate, subequal, reaching much beyond the preceding pair, carrying marginal spines of various kinds, some being slender and setiform.

Telson subequal in length to the peduncles of the third uropods, cleft for three-quarters of its length, the cleft nowhere dehiscent; the outer margins converging little for the first two-thirds of the telson's length, then rapidly; a feathered cilium and lower down an apically plumose spine or seta are inserted on the margin just before the apex is reached; the surface on either side has five spines or setules.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the apex of the third uropods, seventeen-twentieths of an inch.

Locality.—Station 163B, Port Jackson, June 3, 1874; depth, 35 fathoms; bottom, hard ground; bottom temperature, $63^{\circ}0$. One specimen, female.

Remark.—The specific name, derived from the Latin word *acinaces*, a Persian sabre, refers to the sharp curved dorsal outline of the animal.

Ampelisca chiltoni, n. sp. (Pl. CIII.).

The acuteness of the dorsal compression seems to be limited to the head, which is truncate in front; the posterior lateral angles of the third pleon-segment produced in a small acute point; the fourth segment having a small transverse dorsal depression, beyond which the dorsal line is rather sinuous, ending in an angular apex; the dorsal division between the fifth and sixth segments is very slightly marked; the dorsal line of the sixth segment divides at about the centre, forming two small wings, the median line convex, the wings straight at the top, ending angularly on each side of the telson, the postero-lateral angles sharply produced at the base of the uropods, and furnished with spines, the lower margins carrying plumose setæ.

Eyes and Antennæ nearly as in *Ampelisca acinaces*. In one specimen examined there were twenty-eight joints on the flagellum of the lower antennæ; the first two joints of the peduncle appeared rather more dilated than in the compared species, the flagellum also being shorter.

Upper Lip.—The distal margin of the inner plate flatly convex, ciliated, with a faint emargination not central; the outer plate broader, with an almost semicircular outline, and a faint distal central emargination.

Mandibles similar to those of *Ampelisca acinaces*; but the spine-row consists of ten spines; the molar tubercle has a tooth on the forward side; the margin of the crown is set with strong denticles in the left mandible on the inner side only, the opposite side

being divided into three strong simple teeth ; on the third joint of the palp there are four pairs of spines to the front margin and a pair on the apex.

Lower Lip.—The principal lobes broad, the distal margins broadly convex ; the inner lobes rather tumid, distally well ciliated ; the mandibular processes small and little prominent.

First Maxillæ.—Inner plate apically narrowed, and carrying on the apex two small plumose spines or short setæ, the outer a little longer than the inner ; the eleven spines on the outer plate are not very dissimilar to those of *Ampelisca acinaces* ; the inner ones have lateral denticles instead of serrate edges, but possibly in the other species the denticles have been worn or accidentally broken off ; the second and third of the innermost have, however, in this species their concave inner edges smooth ; the palp has the distal edge of the second joint cut into sharper teeth and bordered with sharper and longer spine-teeth than in the other species ; there are eleven submarginal spines.

Second Maxillæ.—Rather below the middle of the inner margin of the inner plate begins a row of about thirteen long plumose setæ, which cross the surface a little below the apex ; another row begins nearer to the apex, which itself is narrowed, sloping outwards, fringed with many long spines ; the inner plate is longer than the outer, wider towards the apex, which has an outward sloping curve, and is fringed with very many long spines.

Maxillipeds resembling those of *Ampelisca acinaces*, but with the distal margin of the inner plates more squarely truncate ; the outer plates with nine spoon-shaped spine-teeth on the inner border, and six spines on the broad indented distal margin, the two outermost being plumose, setiform ; the second joint of the palp is long, crowded with spines on the inner margin and apex, and also has a single spine on the outer margin below the centre ; the third joint is widest not far from the base, and then narrows to the broad flat apex, round which and the inner margin there are many spines ; the finger is inserted far below the apex ; it is very narrow, and has a long thin nail which constitutes nearly half its total length ; on the inner margin near the base of the nail it has about four decurrent spinules ; the dorsal cilium is small, near the hinge.

First Gnathopods like those of *Ampelisca acinaces*, differing as follows :—The side-plates are much less widened below, the hind margin is straight with no concavity, though it may be noticed that it has the little terminal tooth ; the setæ that project below the lower margin are here less regularly set on the surface ; the second joint has spines at two points of the hind margin above the apex ; the third joint has very numerous spines along the hind margin, and a row which crosses the surface above the apex ; there is a long row of long spines on the inner surface of the wrist ; the hand is a little more dilated near the base, and the spines on the inner surface seem to be more numerous than in the other species.

Second Gnathopods.—Side-plates a little dilated below, the hind margin nearly

straight, with a small apical tooth. The branchial vesicles broad, not quite so long as the side-plates. The marsupial plates narrow, longer than the branchial vesicles. The first joint not reaching the end of the side-plate, the setæ on its hind margin of great length; the second joint having setæ or spines at three points of the hind margin; the rest of the limb nearly as in *Ampelisca acinaces*, but narrower, with more spines on the hind margin of the third joint; the hand less than half the length of the wrist, set over the inner surfacee with many rows of short spines; six of the spinules which fringe the inner margin of the narrow finger are spinous on two edges, the seventh, which lies beside the nail and is of equal length with it, appears to be smooth.

First Peraopods.—The side-plates of nearly equal width throughout, the hind margin without an apical tooth. The branchial vesieles broad, longer than the side-plates. The marsupial plates narrow; longer than the branchial vesicles. The limb differing little from that of *Ampelisca acinaces*; the hind margin of the first joint more convex; the third joint apieally narrower; the fourth joint with many long setæ on the hind margin, and at the apex of the front one long and one short seta; the fifth joint fringed with setæ and slender spines along more than half the convex front margin, but with only two straight slender spines standing out from the hind margin; the finger a little longer than the two preeeding joints united.

Second Peraopods.—Side-plates with the front margin very slightly eonvex, the exeavation behind of little depth, the hind margin below the acute upturned angle being nearly as long as the front margin. The first joint of the limb about reaching the end of the side-plate, fringed with numerous setæ, those in the middle of the hind margin being longer than those lower down; the seeond joint having the hind margin fringed with plumose setæ; the third joint longer than in the preceding pair, densely fringed on both margins; the short fourth joint fringed on the hind margin except near the base, and with an apieal group in front; the fifth joint having spines or setæ along the lower half in front, and on the hind margin three slender spines, each with an attendant spinule; the finger longer than the two preeeding joints united, a short dorsal eilium close to the hinge; as in the preeeding species, there is on the front margin of the third joint a series of long setæ strongly but loosely feathered, and another series densely feathered.

Third Peraopods.—Side-plates broad but not deep, the front lobe wider and rather deeper than the hinder one. The branchial vesicles small, bent forwards across the first joint, but not reaching the front of it. The marsupial plates short and narrow, with nine setæ. The first joint large, its greatest breadth exeeeding the length, the front margin describing an immense curve, fringed, except at the lower part, with some setæ and small spines, the hind margin double, nearly straight, as if soldered above to the side-plate, neither this nor the front margin at all overlapping the short second joint, which has a couple of spinules on the front apex; the third joint once and a half the length of

the second, with a spinule on the straight hind margin and another at its apex, the convex front margin having several slender setiform spines, and a strong apical spine; the fourth joint longer than the fifth, broad and straight, fringed in front with slender spines, and having at the apex a long strong one; within the smooth hind margin there are three groups of short spines, and a complex apical group with three slender spines, four short stout ones, and one or two that are long and stout; the fifth joint with eighteen slender spines or setæ along the serrate front margin, some long spines on its produced apex, the hind margin straight and smooth; the finger very short, abruptly upturned, with a dorsal cilium and a dorsal denticle.

Fourth Peræopods.—The side-plates deeper in front than behind, with some feathered setæ on the lower part of the front margin and the hinder part of the lower margin. The branchial vesicles as in the preceding segment, but rather smaller. The first joint larger than in the preceding pair, its greatest breadth equal to the length, in front projecting in a great rounded angle, the sides of which are straight, the lower side longer than the upper; about the angle there are some feathered setæ, and spinules on other parts of the margin; the apex forms a narrow, scarcely decurrent, little lobe; the hind margin is much and evenly curved, armed with a few spinules; the second and third joints are much as in the preceding pair; the fourth joint is strongly spined along the front margin, having five long spines, and a dozen others smaller, of different lengths; within the hind margin are several short spines on the surface, the apical group being in general as in the third peræopods, the two long spines being denticulate in the lower portion; the fifth joint is longer than in the preceding pair, but still not quite so long as the fourth; its serrate front margin and apex carry eighteen long spines; the hind margin has one submarginal spine; the tiny finger has three dorsal denticles, its distal half abruptly narrower than the proximal, and carrying two little curved dorsal setules, possibly marking the base of a nail.

Fifth Peræopods.—The side-plates shallow, the lower margin preceded by plumose setæ, and fringed with slender spines. The first joint with the front margin nearly straight, armed with eleven spinules; the lower margin crossing the top of the second joint, behind descending much below it; the hind margin smooth, sloping backwards with a gentle convexity to join the upward curve of the lower margin, the whole free part of which is densely fringed with plumose setæ; the greatest breadth of the joint is at the meeting of the hinder and lower margins; there are many long setæ on the inner surface; the second joint is short, with two or three small apical spines in front; the third joint is longer than the second, the decurrent apex in front having four small spines; the hinder apex acute, much more decurrent; the hind margin fringed with about a dozen long plumose setæ, of which one on the apex is of great length; the fourth joint longer than the third, with some short spines on the hinder apex, the front margin very convex, with five groups of short spines on the surface near it, a spine and spinules

on a quasi-apex, beyond which the true apex is decurrent, and has on its lower or inner margin four short but strong spines; the fifth joint scarcely longer than the fourth, narrower at the base than elsewhere, laminar, with the front and hind margins smooth, slightly convex, the distal margin obliquely truncate, having four small sharp spines with accessory threads at the front, and two or three at the back; the finger lanceolate, as long as the fifth joint, with a short setule at the back where the narrow sharp nail commences.

Pleopods.—The coupling spines sinuous, with a large lateral retroverted tooth on one side, and on the other a row of six or seven small teeth succeeding the apical tooth; there are also many plumose setæ on the peduncles; the cleft spines numbered six in the ramus examined, the longer arm being obviously serrate on the inner side; the outer ramus had twenty joints.

Uropods.—The peduncles of the first pair a little shorter than the longer ramus, with many spines along the upper margins, and a submarginal series near the lower border; on the inner distal margin there is a small tooth and a long spine; the rami are slender, somewhat curved, apically acute, the lower longer than the upper, but much less conspicuously spined; the peduncles of the second pair quite as long as the rami, reaching much beyond those of the preceding pair; of the upper edges the inner has many spines, the outer few but longer ones; the rami are broad, reaching little beyond the preceding pair, the upper rather longer than the lower, both with curved acute tips, the upper edges fringed with many spines, the lower ramus having a second series ending near the apex with a spine of great length, distally denticulate; the peduncles of the third pair much shorter than the rami, apically produced below, the upper margin carrying a small group of spines; the rami lanceolate, subequal, reaching much beyond the other pairs, the upper one with its upper margin smooth, except for a small feathered spine near the top, the lower margin serrate, armed with spines and feathered setæ, the lower ramus rather the longer, serrate on both margins, setiferous.

Telson longer than the peduncles of the third uropods, nearly twice as long as its greatest breadth, cleft for more than three-quarters of its length, not dehiscent, the sides at first almost parallel, then converging gently to the distal end; the apices slightly emarginate, each having a spine and a cilium, the inner corner slightly more produced than the outer; several small spines are dotted about the surface of the telson.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the apex of the third uropods, three-fifths of an inch.

Locality.—Station 167, off New Zealand, June 24, 1874; lat. $39^{\circ} 32'$ S., long. $171^{\circ} 48'$ E.; depth, 150 fathoms; bottom, blue mud. Four specimens.

Remark.—The specific name is given in compliment to my obliging friend, Mr. Charles Chilton, of New Zealand, who is doing so much good work upon the Sessile-eyed Crustacea.

Ampelisca abyssicola, n. sp. (Pl. CIV.).

The back of the peraeon and first three pleon-segments rounded, the head dorsally compressed, in front a little emarginate at the top, so that the lower part forms a slightly prominent lobe of irregular outline on either side, sloping backwards below; the postero-lateral angles of the first two pleon-segments rounded, of the third not rounded, but not produced or upturned; the fourth segment earinate, the earina interrupted by a transverse dorsal depression, and having a small tooth almost at the distal end; the fifth and sixth segments coalesced, the dorsal point of division depressed, very faintly marked, the segments slightly earinate, the after part of the sixth segment forming a free angle on each side of the central dorsal line, which has a pair of setules; the postero-lateral angles are sharply produced.

No Eyes of the character usual in the genus *Ampelisca* could be discovered.

Upper Antennæ not nearly reaching the end of the peduncle of the lower; the first joint moderately thick, with setules along the central part of both margins, and some slender spines near the narrowed apex; the second joint longer and thinner than the first, not so long as the head, with thin spines chiefly along the lower margin; the third joint rather more than a quarter the length of the second, quite distinct from the flagellum, with spines at two or three points of the lower margin; the flagellum shorter than the peduncle, with ten joints in one antenna, eleven in the other, the joints slender, all but the last widening a little distally and armed with spines longer than themselves, the terminal joint with three not longer than itself.

Lower Antennæ.—The first two joints very short, the second with a small lobe on the side not pointing forwards, its distal margin produced into two points, one of which is very acute; the third joint as long as the two preceding united, with one margin straight, the other convex; the fourth joint long and narrow, with a few spinules on the lower margin and the surface; the fifth joint rather longer, with a slight curve, similarly armed; the flagellum slender, with fifteen joints remaining, which are tipped with spines, those on the second, fourth, sixth, ninth, twelfth, and fifteenth being long ones.

Upper Lip.—The inner plate projecting, rather strongly elevated near the rounded corners of the distal margin, which centrally is almost straight; the outer plate is much wider, transversely oval, with the distal margin flattened, straight, and smooth.

Mandibles.—All the cutting plates strong except the secondary plate on the right mandible, of which the teeth are sharp and almost spine-like; the outer plates have four or five strong teeth apiece; in the spine-row there are on the left mandible eight strongly denticulate backward-curved spines; on the right mandible there are nine, rather longer and less curved; the molar tubercle is strong, with an irregularly shaped crown set with little teeth; the palp is strong, with a rather short first joint set as usual low down on the outer side of a high, broad, somewhat folded process which looks like a

joint, and which has a small secondary process projecting from its inner surface; the second joint is long and broad, at the base projecting over the first joint in front, its hind margin slightly concave, carrying spines at seven points, the front margin fringed with stiffer spines, which towards the slightly narrowed truncale apex are of great length; the third joint moderately broad, though a good deal narrower than the other two, longer than the first, considerably shorter than the second, with two groups or rows of spines near the top of the hind margin, three or four groups along the front, and some strong spines on the slightly rounded apex, one of the spines being conspicuous among the rest for its size.

Lower Lip much the same as in *Ampelisca chiltoni*.

First Maxillæ.—The inner plate rather long, with a plumose seta on the inner margin below the apex, and a shorter spine or seta on the apex as in *Ampelisca acinaces*; of the eleven spines on the outer plate the innermost, which is as usual straight, has three tiny denticles some way below the apex on the inner margin, the next has two denticles on the outer margin, the rest, except the outermost, being more or less denticleate, but none strongly, so that the spines appear smooth except under a high power; the second joint of the palp is strong, nearly parallel-sided, its distal teeth acute, and the five spine-teeth slender; there are seven or eight submarginal spines.

Second Maxillæ differing little from those of *Ampelisca chiltoni*.

Maxillipeds in general like those of *Ampelisca chiltoni*, but resembling *Ampelisca acinaces* in having the distal margin of the inner plates sloping outwards; the plumose setæ descending to nearly the middle of the inner margin; the large outer plates have from eleven to twelve or thirteen spine-teeth along the inner margin, and eleven spines on the broadly convex distal margin, the outer six of the latter being rather setiform; the third joint of the palp is shorter than in *Ampelisca chiltoni*, with numerous and strong spines on the surface as well as the inner margin and apex and upper part of the outer margin; the finger is longer than the third joint, and has six long decurrent spinules on the inner margin as it approaches the nail, which constitutes about half the length of the finger.

First Gnathopods.—Side-plates directed forwards so as to cover the basal joints of the lower antennæ, rather wider below than above, the lower margin very convex though irregularly, with the usual setæ, the lower row inserted with some regularity; the hind margin is slightly convex, and below curves round to a small apical tooth. The first joint not reaching the end of the side-plate, proximally narrow, but for the most part very wide, with the usual armature; the second joint broader than long, with one or two small spines low down on the hind margin and an apical group of plumose setæ; the third joint broad, widening distally, its hind margin fringed with plumose setæ and spines; on the inner surface transverse rows of long spines are inserted at various heights above the apex; the wrist is of great breadth, where free from the third joint its

breadth being about half its total length, the hind margin crowded as usual with spines, many of them conspicuously peetinate at the centre, the inner surface having a series of spines down the centre and another close to the front margin; the hand, which is as long as the free hind margin of the wrist, has its greatest breadth near the base; both margins are armed with many spines; a dozen spines are arranged along the eentre of the inner surfacee; the finger is narrow, much curved, much more than half the length of the hand, and inserted close to its hind margin; the inner margin of the finger fringed with eight or nine microscopically feathered spinules; the nail long but not nearly half the total length of the finger; the dorsal cilium at a little distancee from the hinge.

Second Gnathopods.—Side-plates direeted forwards, not wider below than above, the hind margin almost straight, curving a little to the small apical tooth. The branchial vesicles broad, not so long as the side-plates. The marsupial plates narrow, longer than the branchial vesicles. The first joint curving forwards, expanding distally, both margins fringed almost throughout with long setæ; the second joint with two or three spinules on the hind margin; the third joint with two convex margins converging to the pointed apex, the spines on the inner surfacee near the front margin being more numerous than those on the hinder margin; the front margin of the wrist nearly straight, and the free portion of the hind margin only slightly convex, fringed as usual with many spines; on the inner surface are several small groups of spines near the front margin, and larger groups along it nearer the centre, set obliquely; the hand is much more than half the length of the wrist, but not so long as its free hind margin; its greatest width is not far from the base, where the spines of the hind margin begin and may be considered as defining a palm; besides the usual spines of the margins and apex, the inner surface is thickly set with rows of peetinate spines, except near the base and along the hinder part, which has only a few scattered spines; the finger is narrow, much curved, closely resembling that in *Ampelisca chiltoni*, not reaching the end of the palm-margin.

First Peræopods.—Side-plates directed forwards, of even breadth throughout, the hind margin ending in a small apieal tooth. The banchial vesicles and marsupial plates like the preeeding pair. The first joint long and rather narrow, curved forwards, reaehing a little beyond the side-plates, with some very long setæ on the middle of the convex hind margin; the second joint short, with one or two apical spinules; the third long and almost parallel-sided, with marginal spinules and long feathered setæ at seven or eight points on each margin, the upper part of the front margin quite smooth; the fourth joint short, the hind margin fringed as usual, the front having three apical setæ, of which one is much longer than the following joint; the fifth joint apically narrower, twice as long as the fourth, with feathered setæ at six points of the convex front margin, a spine and a seta at three points of the sinuous hind margin; the finger slender, curved, a little longer than the two preeeding joints united.

Second Peræopods.—The side-plates directed forwards like the three preceding pairs, the front margin nearly straight; the long lower margin very slightly fringed, sloping rather sharply upwards, and almost continuous with the short piece of the hind margin which slopes sharply forward below the prominent angle of the excavation, which is deeper than broad. The branchial vesicles and marsupial plates much as in the preceding segments. The first joint reaching a little below the side-plates, the hind margin fringed, except at the upper part, with many plumose setæ, the front margin free above for a short space, then armed with spines, and below with plumose setæ; the second joint bearing four long plumose setæ on the hind margin; the third joint longer than in the first peræopods, densely fringed on both margins; the fourth joint as in the preceding pair; the fifth joint more than twice as long as the fourth, the three setæ of the hinder margin being on its upper half; the finger very little longer than the two preceding joints united.

Third Peræopods.—The side-plates broad, not very deep, the front lobe deeper than the hinder, both unfringed. The branchial vesicles not large, directed more downwards than forwards. The marsupial plates short and narrow, with seven long setæ. The first joint large, its front margin forming a great bend, what may be called the angle of the curve being nearer the distal end than the base; along some of the lower part plumose setæ project from the inner surface, along the upper part there are spinules; the double hind margin is in each case nearly straight above and bent below; the short second joint, which is partially overlapped in front by the first joint, has one or two apical spinules; the third joint has three very slender spines on the convex front margin, a strong bent spine at its apex, and a spinule at the apex behind; the fourth joint is straight, much longer than the fifth, or than the two preceding joints united; it has along the front margin and apex thirteen long slender spines, distally pectinate, one at the apex being thicker than the rest; near the smooth hind margin are some minute surface spines, its slightly produced apex carrying the usual mixed group of spines, one nearly as long as the following joint, distally denticulate, three others shorter in various degrees, of the same character, three very short but stout, three long and very slender; the fifth joint is narrow, and has on the serrate front border sixteen long and slender spines, two rather stronger on the produced apex, and on the hind margin two spinules; the minute upturned finger has two or three dorsal denticles.

Fourth Peræopods.—Side-plates small, with a couple of setæ on the hinder part of the lower margin. The branchial vesicles small, bent down and a little forwards. The first joint of the limb shaped as in *Ampelisca chiltoni*; on the most prominent part of the front margin there are seven plumose setæ close together; on the surface behind there are many slender setæ remote from the margin; the second joint has an apical spine and two spinules in front; the third has three slender spines along the scarcely convex front margin, and at its apex a stronger spine and two spinules, also a small spine at the apex

of the hind margin; the straight fourth joint is longer than the fifth, and has in front five large spines of graduated size, besides thirteen other spines and spinules; there are a few small spines on the surface near the smooth hind margin, the apex of which has the usual group; the fifth joint has ten strong spines on the serrate front margin, one on the produced apex, accompanied by a spinule and two long slender spines; the tiny upturned finger has a dorsal cilium close to the base, and two or three dorsal denticles a little way from it, the narrow part of the finger being longer than the thicker proximal part.

Fifth Peræopods.—Side-plates very small, narrowed behind, the lower margin carrying setæ on the front and spines on the after part. The first joint very similar to that in *Ampelisca chiltoni*, but the lower margin even more drawn down behind, and the hind margin forming an even more continuous curve with the lower; the second joint with two or three small spines on the front apex, the hind margin rather longer than the front one; the third joint scarcely longer than the second, the hind margin carrying five long feathered setæ, each apex a little decurrent and armed with some small spines; the fourth joint longer than the preceding two united, or than the fifth, its hind margin slightly concave, with an apical group of spines and a seta, the front margin convex, with short surface spines dotted about near it, a spine and two setules at the quasi apex, and some small spines on the serrate lower margin within the decurrent incurved true apex; the fifth joint almost oval, with two spines at the apex behind, and seven or eight round the apex in front, both margins smooth, but the surface near the hind margin marked as if for the insertion of some eight spines or setæ; the lanceolate finger has six or seven similar marks, its hind margin more convex than the front, and a suddenly narrowed tip, less than a fourth of its total length, at the base of which two setules are inserted; the finger is a little shorter than the hand.

Pleopods.—The peduncles have many plumose setæ; the coupling spines were not examined; on the first joint of the inner ramus of one pair, probably the third, there were four eleventh spines, with one plumose seta above and four below this series; the joints of the inner ramus numbered nineteen, of the outer twenty-three.

Uropods.—The peduncles of the first pair rather longer than the rami, with spines as in *Ampelisca chiltoni*; the rami with the apices curved, acute, the marginal spines not numerous, the lower ramus the longer; the peduncles of the second pair a little longer than the rami, the upper ramus very little longer than the lower, the marginal spines less numerous than in the species just mentioned, the long one near the end of the lower ramus strongly dentieulate; the peduncles of the third pair as in the preceding species; the rami lanceolate, the upper noticeably longer than the lower, both of them serrate on both margins and furnished with spines and plumose setæ.

The Telson equal in length to the peduncles of the third uropods, not twice as long as broad, the sides nearly parallel for the first half, then gently curving to the broad apices, which are sharp at the inner corner, at the outer carrying a spine with accessory thread

and a setule; the eleft is nearly four-fifths of the total length of the telson, the surfacee has on each side a couple of slender spines near the top, and low down two stouter ones.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the apex of the third uropods, thirteen-twentieths of an inch.

Locality.—Station 24, off Culebra Island, St. Thomas, March 25, 1873; lat. $18^{\circ} 38' 30''$ N., long. $65^{\circ} 5' 30''$ W.; depth, 390 fathoms; bottom, Pteropod ooze. One specimen, female.

Remarks.—The speefie name refers to the considerable depth from whieh the species was obtained.

The present speeies bears a great external resemblance to *Ampelisca odontoplax*, G. O. Sars, taken in the Norwegian North Atlantie Expedition, “off the coast of Helgeland (Station 147) at a depth of 142 fathoms”; the station referred to being in lat. $66^{\circ} 49'$ N., long. $12^{\circ} 8'$ E.; but in that speeies the two pairs of gnathopods are deseribed as “very slender, with the hand very small and narrow,” and the first joint of the fifth peræopods is said to be at the extremity “almost vertieally truncate,” this expression referring to the lower margin behind, whieh in the Challenger speeies is very much rounded. In Sars’ figure the fifth and sixth pleon-segments are drawn as distinct, not coaleseed, but the eireumstanee is not referred to in the text. Aeeording to Buehholz, Die zweite deutsehe Nordpolarfahrt, 1874, p. 357, these segments are distinct in *Ampelisca eschrichtii*, Krøyer.

Ampelisca fusca, n. sp. (Pl. CV.).

Head sharply compressed on the dorsal line, in front emarginate at the top; from the lower angle of the emargination the sides slope backwards with a slightly sinuous outline; the baek is rounded as far as the third pleon-segment, which with the fourth is slightly keeled; the fourth segment has a transverse dorsal depression, a setule on the baek, the dorsal apex slightly projecting; the eoaleent fifth and sixth segments are seareely distinguished dorsally except by a slight transverse depression; the sixth segment carries a pair of dorsal setules, and the hinder angles on either side of the medio-dorsal line are slightly incurved; the lower hinder angles are as usual outdrawn; the postero-lateral angles of the first three pleon-segments are rounded.

Of the round simple *Eyes* one pair seem to project slightly beyond the margin of the head just below the lateral angles, while the other pair are a little above these angles, within the emarginate front border of the head.

Upper Antennæ rather longer than the lower. First joint rather short and thick, earrying several feathered elia; the seeond joint much longer than the first, longer than the head, with slender spines, some very long, on the under margin and on the surfacee;

the third joint less than a fifth the length of the second, widening a little distally, with a long but very slender terminal spine or seta; the flagellum much longer than the peduncle, consisting of thirty-four slender joints, the lengths varying irregularly, some of the apical setiform spines being of very great length.

Lower Antennæ.—First and second joints short, the second apically pointed on the side opposite to the short blunt gland-cone; the third joint as long as the preceding two united, its upper margin convex, the lower nearly straight; the fourth joint slender, longer than the second of the upper antennæ, with long slender spines or setæ on the under margin; the fifth joint shorter than the fourth, similarly furnished, as long as the second joint of the upper antennæ; the flagellum of eighteen slender joints, together shorter than the peduncle, and shorter than the flagellum of the upper antennæ, apically furnished with slender spines of various lengths.

Upper Lip.—The outer plate with flattened sides, the distal margin semicircular, with a little almost central emargination, on either side of which it is furred, the cilia as usual directed from either side towards the centre; the inner plate less advanced, its distal outline similar but without any notch, the central part strongly furred.

Mandibles.—The principal and secondary plates on the left mandible with five or six teeth apiece, those on the right with the usual modifications; the spine-row on the left mandible having thirteen spines, close set, curving backwards, most strongly denticulate near the apex; on the right mandible there are only ten spines, and of these the innermost is linear; the crown of the molar tubercle on the left mandible is almost pentagonal, with small marginal teeth on two of the sides and some transverse ridges; on the right mandible it was only observed in profile; the first joint of the palp is short, narrow at the base, with a few small marginal spines; the other two joints are as in *Ampelisca chiltoni*.

Lower Lip.—The principal lobes broad, much ciliated, the inner lobes rather tumid; the mandibular processes little prominent.

First Maxillæ.—The inner plate narrow, with two short setæ on the apex; the outer plate broad, with the eleven spines on the broad distal margin like those of *Ampelisca chiltoni*; there are spines at four points of the outer margin of the joint supporting this plate; the first joint of the palp is short, with a spine at the middle of the outer margin; the second joint is long, curved, expanding distally, the five teeth of the apical margin small, and its five spine-teeth neither long nor broad; there are seven slender spines below the distal margin and seven fringing the convex outer margin.

Second Maxillæ like those of *Ampelisca chiltoni*.

Maxillipeds closely resembling those of *Ampelisca chiltoni*; on the outer plates, which reach as nearly as possible as far as the long second joint of the palp, there are eighteen to nineteen spines, ten or eleven belonging as spine-teeth to the inner margin, the rest to the distal, the outermost four being setiform; on the inner margin of the finger near the nail there are some half-dozen spinules.

First Gnathopods.—Side-plates much wider below than above, directed forwards so as to cover the basal joints of the lower antennæ, the strongly convex lower margin closely fringed with long setæ, the hind margin nearly straight, ending in a sharp, curved apical tooth, which does not reach so low as the lower margin. The first joint not reaching the end of the side-plate, widening distally, armed as usual; the second joint having much of the hind margin fringed with feathered setæ; the third joint oval, apically pointed, with many spines along the hind margin and across the distal half of the inner surface; the wrist with the front margin little convex, the free hind margin convex, crowded with spines, many of which are conspicuously pectinate to the tip; the inner surface has rows of long spines near the hind margin, and smaller groups near the front; the hand is rather narrowly oval, longer than half the wrist, with the palm not well marked, the spines on the hind margin pectinate at the centre; the inner surface having half a dozen spines along the centre and others near the front margin; the apical spines are long; the finger is rather short, the nail narrowing almost abruptly, not half the length of the upper part of the finger; the spinules of the inner margin are four or five in number, pectinate, the series beginning near the base of the nail.

Second Gnathopods.—Side-plates elongate, widening a little distally, the hind margin with a small apical tooth, the very convex lower margin strongly fringed. The branchial vesicles widening from a narrow neck, for the most part of even breadth to the end, longer than the first joint. The marsupial plates narrow, no setæ present. The first joint not nearly reaching the end of the side-plate, curved forwards, a few long setæ on the lower half of the convex hind margin; the second joint with a couple of setæ on the apex of the hind margin; the third joint rather broad, the hind margin nearly straight, smooth, the truncate distal margin having one feathered seta; the wrist narrow, with only a few spines at intervals on the margins and inner surface; the hand narrow, more than half the length of the wrist, with the hind margin free from spines for more than half its length, then carrying six or seven; there are eight or nine spines or setæ on the inner surface, and as many on the front margin and its apex; the finger is short, with five pectinate setules on the inner margin close to the base of the not elongated nail.

First Peraopods.—Side-plates rather wider below than above, the hind margin with a small apical tooth, the lower convex, well fringed. The branchial vesicles shorter than the side-plates, as long as the first joint, tending to oval, but with the front side flattened. The first joint not reaching the end of the side-plate, the front margin straight, the hind convex, with the usual armature; the second joint short; the third long, nearly parallel-sided, fringed with many long plumose setæ; much of the upper part of the front margin appears to be bare, but there are setæ on the inner surface, which might project beyond this margin; the fourth joint, which is longer than broad, has eight groups of long plumose setæ on the hind margin, and one or two spinules on the front apex; the fifth

joint has many plumose setæ on the lower two-thirds of the convex front margin, the hind being nearly straight, with a spine and seta at three points near the centre, the lowest seta being the longest; the finger is longer than the two preceding joints united, not much curved.

Second Peræopods.—The side-plates broad for almost the whole length, the angle below the hinder excavation upturned, acute, the margin below it only slightly oblique except at starting, forming a rounded corner with the long nearly straight lower margin. The first joint a good deal curved forwards, much of the convex hind margin strongly fringed with setæ, the front margin also carrying them on the lower part; the second joint has five plumose setæ along the hind margin; the third joint is as usual longer than in the first pereopods, and densely fringed on both margins; the short fourth joint has many setæ on the hind margin and a group on the front apex; the fifth joint is longer than in the preceding pair, but is similarly armed on both margins; the finger is long and but slightly curved.

Third Peræopods.—The side-plates broad, the front lobe deeper than the hind one. The branchial vesicles large, bent forward across the top of the first joint, but not reaching beyond the margin. The marsupial plates short and narrow, without setæ. The large first joint resembling that in *Ampelisca chiltoni*, the front margin except the upper part fringed with plumose setæ, and below a little overlapping the second joint; the lower part of the hind margin having a few spinules; the second joint with two or three spinules on the front apex; the third joint with slender pectinate spines along the convex margin and two at the hinder apex, also a strong bent spine at the front apex; the fourth joint with five strong spines and several slender ones on the front margin, three or four surface groups near the hind margin, and a large apical group fringing the lower margin, with five small spines and three large ones which are of very differing lengths but all three distally denticulate; the fifth joint, which is nearly as long as the fourth, but much narrower, has three spines on the slightly concave hind margin, the insertion marks of nine or ten on the convex front, and two spines on the produced apex; the small sharp finger has two dorsal denticles more prominent than usual, and two little curved setules at what may be the base of the nail.

Fourth Peræopods.—The side-plates deeper in front than behind, the front margin carrying some spinules and setæ, the lower margin behind little curved, fringed with setæ. The branchial vesicles as in the preceding segment, but narrower. The large first joint, as usual, bowed out in front, and there carrying seven plumose setæ, the rest of the margin having small spines and spinules, below somewhat overlapping the second joint; the rounded lower margin projecting much behind the second joint, the hind margin for much of its course straight, armed with small spines; the second joint with apical spinules in front; the third joint fringed with spinules in front, and having a spine at the apex, the apex behind carrying a short stout spine and two that are setiform; the

fourth joint, longer than the fifth or the two preceding united, has five strong spines on the front margin and a dozen smaller ones, besides some spinules; at the apex behind, on the slope of the lower margin, there is the usual group, including eight stout spines and three or four that are very slender; the serrate convex front margin of the fifth joint has eleven strong spines besides those on the produced apex; there are two on the hind margin; the upturned finger has two or three dorsal teeth.

Fifth Peræopods.—The shallow side-plates seem to be quite coalescent in front with the segment which on its lower border carries some spinules; the lower margin of the side-plate is convex, fringed with slender spines, and forming an angle with the straight upper margin. The front margin of the first joint is nearly straight, set with spinules, and having some small spines at the apex; the lower margin crosses the top of the second joint, then descends nearly to the end of the third, whence with a much-rounded angle it ascends again, forming a continuous curve with the hind margin, from which it is probably to be distinguished by the commencement of the fringe of plumose setæ and spines which ends at the lowest point of the joint; the width of this joint is much less than its length, it is greatest a little above the apex of the front margin; the second joint is very short, with some apical spines in front; the third is longer, especially behind, where the apex is far decurrent; the front margin has two or three setules and an apical spine; the hind margin is fringed with thirteen long plumose setæ and some spinules; the front margin of the fourth joint is rather shorter than the hind margin of the third; it has four groups of spinules, the lower two having each a spine also; the hinder apex has spines and a long seta; the fifth joint is laminar, longer than the fourth, with smooth margins, except at the apices which have the usual short spines; the finger is lanceolate, shorter than the preceding joint, marked like it within the hinder margin as if for the insertion of setæ, the nail or its equivalent abruptly tapering, having at its base a setule.

Uropods.—The peduncles of the first pair rather longer than the rami, the lower ramus rather longer than the upper, each with the apex acute, curved; the peduncles of the second pair rather longer than the rami, the upper ramus a very little longer than the lower, on which the denticulate spine near the apex is only moderately elongate; the marginal spines are numerous; the peduncles of the third pair shorter than the rami, the lower margin apically produced, the upper carrying a prominent spine; the rami very broadly lanceolate, equal in length, the inner margin of the inner ramus nearly smooth, the other margins, except at the upper part, carrying numerous long plumose setæ, the outer margin of the outer ramus showing also a series of spines, and a strip of its surface being coated with denticles.

The Telson a little longer than the peduncles of the third uropods, nearly twice as long as broad, eleft four-fifths of the length, the sides converging to two almost acute, not dehiscent, apices, each furnished with a spine and feathered cilium, the

surfaee carrying on each side half a dozen or more setæ, not quite symmetrically arranged.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the apex of the third uropods, rather over half an ineh. Fully extended it would have measured a good deal more.

Locality.—Station 142, off Cape Agulhas, December 18, 1873; lat. $35^{\circ} 4'$ S., long. $18^{\circ} 37'$ E.; depth, 150 fathoms; bottom, green sand; bottom temperature, 47° . Three specimens.

Remarks.—The specific name refers to the colour of the specimens in spirits, which were dark, the branchial vesicles in particular being port-wine coloured.

Ampelisca zamboangæ, n. sp. (Pl. CVI.).

The Head as in *Ampelisca fusca*; the body more or less acutely compressed; the postero-lateral corners of the third pleon-segment almost right-angled, but with the points rounded; the fourth segment with a transverse dorsal depression, the earina at its apex raised above the succeeding segment; the fifth and sixth segments almost completely fused, the division marked by a transverse dorsal depression, the sixth segment with the usual dorsal and lower angles.

The Eyes small, the two pairs situated as in *Ampelisca fusca*.

Upper Antennæ.—First joint short and broad, with some feathered cilia on the upper margin, some groups of spines on the surface and at the apex, the lower surface adorned with seven or eight rows of long fine hairs; the second joint much narrower but not longer than the first, very much shorter than the head, furnished below with eight or nine groups of hairs like those of the first joint, but shorter; the third joint short, rather longer than broad; the flagellum of about twenty-four joints, together much longer than the peduncle, the first tapering, its upper margin straight, the lower oblique, armed with five groups of long and broad cylinders; on the third joint there is also a cylinder; the terminal joints are very long and slender.

Lower Antennæ much longer than the upper. The first two joints short; what appears to be the gland-cone of the second very inconspicuous; an acute apex on the opposite side; the third joint scarcely longer than broad, the serrate lower (or ? inner) margin closely set with nine or ten brushes of long hairs like those of the upper antennæ; the fourth joint nearly as long as the first and second of the upper antennæ united, with a few spines on the upper margin and thirteen tufts of hairs on the serrate lower margin; the fifth joint much longer, very slender, the spinules more thickly set on the lower than the upper margin; flagellum much longer than the peduncle, also much longer than the

flagellum of the upper antennæ, slender, with thirty-eight joints, of which the last is much shorter and narrower than the one preceding it.

Upper Lip not observed with sufficient distinctness for description.

Mandibles.—In the left mandible, which is drawn on the right hand of the Plate, the principal and secondary plates have each a border of four not very unequal teeth; on the right mandible the principal plate appears to have four or five teeth, the lowest being the longest, while the secondary plate is almost spine-like, having one prominent denticle on the side, while the denticles of the apical part are adpressed; the spine-row is of eight broad curved spines, which apically have a minutely fureate appearance, three spinules projecting between the longer front and shorter hind branch of the fork; the molar tubercle is prominent, with a lateral tooth on the forward side, and the crown bordered with comparatively few but broad denticles; the first joint of the massive palp is short but broad, widest distally; the second joint seems quite disproportionate to the trunk of the mandible, long, and of great breadth, its greatest breadth being nearer the base than the apex; it has slender spines at eight points on the front margin, and a few near the apex on the other; the third joint is of nearly the same length but much narrower, the outer margin convex, the inner carrying eight slender spines on its distal half, and two or three on the apex.

Lower Lip compact; the principal lobes broad and deep, ciliated on the inner margins and the inner part of the broadly convex distal margin; the inner lobes narrowly oval; the mandibular processes very little prominent.

The *First* and *Second Maxillæ*, so far as could be observed, are very like those of the preceding species; the inner plate of the first maxillæ apparently without setæ, the second joint of the palp having four spine-teeth on the dentate apical margin, besides slender subapical spines; the maxillipeds were not observed, having probably been lost during the dissection of the minute mouth-organs of this species.

First Gnathopods.—The side-plates directed forwards so as to cover the basal joints of the upper antennæ, much wider below than above, the hind margin produced into an apical tooth, between which and the very convex lower margin no interval is left; the fringe of the lower margin is not greatly developed. The first joint not reaching to the end of the side-plate, expanding a little distally, carrying six long setæ on the lower convex part of the front margin, three on the surface above the centre, five on the hind margin below it; the second joint not longer than broad, with five plumose setæ at the hinder apex; the third joint with a few spines on the hind margin and two large transverse groups on the inner surface at an angle with the oblique distal margin; the wrist rather broad, with many spines along the hind margin and on the inner surface near it, and a few spines near the front margin; the hand not very much shorter than the wrist, with spines at four points of the slightly convex front margin, besides the larger apical group; the hind margin is sinuous, bordered with spines of various lengths except for a

short space near the base ; the palm-like concavity is near the hinge of the narrow curved finger, which is rather more than half the length of the hand, with a spinule near the centre of the inner margin and another at the base of the nail.

Second Gnathopods.—The side-plates very little widened distally, the apical tooth of the hind margin as in the preceding pair. The branchial vesicles longer than the side-plates, not quite so broad, with many transverse folds or pockets. The first joint not reaching the end of the side-plate, with long setae on both margins, some of those on the lower part of the hind margin being extremely long ; the second joint longer than broad ; the third apically narrowed, with spines at one or two points of the lower part of the hind margin ; the wrist long and narrow, with a few spines along the almost straight front margin, and eight rather large groups along the serrate hind margin ; the hand narrow, half the length of the wrist, with six groups of spines along the hind margin, and about as many along the front ; on the inner distal surface some rows of small spines ; there is no pretence of a palm ; the finger is very small, half the length of the hand, with a spinule on the inner margin a little way from the inward-bent nail and two others at its base ; the dorsal cilium is close to the hinge.

First Peræopods.—The side-plates of almost even width throughout, the apical tooth of the hind margin as in the preceding pairs, the lower margin without any projecting fringe. The branchial vesicles longer than the side-plates, cylindric, with transverse folds. The first joint not reaching the end of the side-plate, straight, expanding a little distally, furnished only with a few marginal spinules ; the second joint short ; the third nearly as long as the first, the hind margin fringed with fourteen long plumose setæ, the front having two spinules on the upper part, and on the lower two slender spines and five long plumose setæ ; the fourth joint is much narrower than the third, scarcely longer than broad, with half a dozen setæ on the hind margin, and a seta and spinule on the front apex ; the fifth joint is scarcely twice as long as the second, much wider at the base than distally, with slender spines or setæ along the slightly serrate lower part of the convex front margin, and three feathered setæ standing out from the lower half of the hind margin ; the finger is slender, a little curved, very little longer than the two preceding joints united.

Second Peræopods.—The side-plates broad, with the front and hind margins almost parallel, the excavation behind shallow, but forming a produced angle, the lower margin slightly concave, its angles rounded, with some minute spinules near the edge. The branchial vesicles like the preceding pair. The first joint not reaching the end of the side-plate, distally dilated, with some long marginal setæ, chiefly on the lower part of the hind margin ; the second joint with four plumose setæ along the hind margin ; the third joint longer than in the preceding pair, both margins fringed with plumose setæ ; the remaining joints nearly as in the preceding pair.

Third Peræopods.—Side-plates with the front lobe deeper than the hinder one.

Branchial vesicles bent forward across the top of the first joint. The first joint large, with some long setæ at the prominent part of the front margin, the lower margin behind projecting a little beyond the second joint; the third joint longer than the second, with a spine at the apex behind; the front margin the longer; the fourth joint longer than the two preceding united, or than the fifth, with five spines on the front margin and an apical seta, three or four surface spines near the smooth hind margin, and on the inner slope of its apex six stout spines, one of which is nearly as long as the succeeding joint, apically minutely denticulate; the fifth joint with six spines along the pectinate front margin, a long one on the produced apex, three short ones on the hind margin; the finger is minute, pointed, probably with a dorsal denticle.

Fourth Peraopods.—The side-plates deeper in front than behind. The branchial vesicles directed forwards across the top of the first joint, but not or scarcely reaching beyond it. The first joint large, of the usual shape, the prominent part of the front margin carrying small feathered setæ, the long hinder and lower margins having some scarce perceptible spinules; the second joint with an apical spine and spinules in front; the third joint with three spines on the front margin, one on the hinder apex; the fourth joint much longer than the fifth, with five large spines on the serrate front margin, besides eleven smaller ones, three surface spines near the smooth hind margin, and a large apical group of six; the fifth joint has nine spines on the serrate and pectinate front margin and apex, the apical spine being long; the smooth hind margin has two spines projecting from the adjacent surface; the tiny finger has a series of three rather long dorsal teeth, beyond which it becomes very narrow, here carrying two dorsal setules.

Fifth Peraopods.—The small side-plates have some spinules on the convex lower margin. The large first joint has the front margin nearly straight; the lower margin crosses the top of the second joint, and behind descends to its lower end, where it makes a small curve and then obliquely ascends to join the smooth convex hind margin, being itself not very closely fringed with plumose setæ and spinules; the breadth of the joint is rather more than half its length; the second joint is longer than the third or fourth, and as long as the fifth; near the front apex it has a group of six short spines; the much shorter and narrower third joint has one or two spines on the slightly decurrent front apex, a spine and long seta on the hinder one; the fourth joint, which is a little shorter than the fifth, is slightly widened distally, and has an apical group of short spines in front, and of spines and setæ behind; the fifth joint is laminar, the hind margin a little more convex than the front, both smooth, the distal margin truncale, with some apical spinules at either side; the finger lanceolate, rather longer than the fifth joint, ending in an abruptly tapering limp sort of nail, with a minute setule at its base; near the hind margin of both fifth joint and finger there is a row of marks, as if the insertion-places of setules.

Pleopods.—The peduncles carrying plumose setæ; the coupling spines not examined;

the cleft spines four in number on the second and third pairs; the joints of the rami numbering from sixteen to eighteen.

Uropods.—The peduncles of the first pair subequal in length to the rami; the rami almost equal, with few marginal spines, the upper edges pectinate; the peduncles of the second pair scarcely reaching beyond those of the first pair, longer than the outer ramus, subequal in length to the inner; both rami have strongly pectinate edges, the upper and longer ramus having also five spines on one margin and one at the top of the other, the lower ramus having three spines on one margin and two near the top of the other; the peduncles of the third pair shorter than the rami, having two spines on the upper inner margin; the rami broad, lanceolate, the outer the narrower, not longer than the inner, but produced beyond it, with six or seven small spines along the outer margin, the inner margin serrate, pectinate, carrying nine or ten plumose setæ; the inner rami coming together like the plates of a cleft telson, the inner margin smooth, the outer serrate, furnished with spines and plumose setæ, few of which, however, were remaining in our specimen.

The Telson not twice as long as broad, widest at a little distance from the base, the convex sides then rapidly converging to the two acute apices, being notched for a spine a little before the apex is reached; cleft between four-fifths and three-quarters of the length, not dehiscent; the surface has a couple of spines not symmetrically placed, one on either side of the cleft.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the apex of the third uropods, just over a fifth of an inch.

Locality.—The single specimen was labelled as having been taken at the surface on February 18, 1875, off Samboangan, Philippine Islands.

Remarks.—The specific name refers to the place of capture.

From the other species here described the present is rather remarkably distinguished by the long fifth joint of the upper antennæ, and the great palp of the mandibles, but these differences do not seem to require the institution of a new genus.

Family PHOTIDÆ.

In 1870 Boeck made the Photinæ the eighteenth subfamily of the Gammaridæ; by a misreckoning in the Crust. amph. bor. et arct., p. 151, he calls it "Subfamilia XVII." and from the account which he gives of his earlier work in his later, De Skand. og Arkt. Amphipoder, p. 72, he omits the Photinæ altogether, perhaps owing to the previous miscalculation. In the later work itself he makes the Photinæ the second subfamily of a new family, the Photidæ, in which he also places the Leptocheirinæ and

the Microdeutopinæ. To the Leptocheirinæ he assigns the genera *Leptocheirus* and *Goësia*; to the Photinæ *Photis*, *Microprotopus*, and *Xenoclea*; to the Microdeutopinæ *Microdeutopus*, *Aora*, *Autonoë*, *Protomedieia*, *Gammaropsis*, *Podoceropsis*, and *Megamphopus*. In 1882 Sars made of the Microdeutopinæ the family Microdeutopidæ, including in it the genera just named, except that he does not specify *Megamphopus*; at the same time he united the Leptocheirinæ and Photinæ to form the family Photidæ, placing in it the genera *Ptilocheirus* [*Leptocheirus*], *Photis*, *Microprotopus*, and *Xenoclea*, presumably only omitting *Goësia* as not belonging to the fauna with which he was then concerned. By Gerstaecker, in 1886, all these genera except *Photis*¹ are placed in "Tribus I. Corophiina (Marcheurs, M.-Edw.)," "Fam. 3. Corophiidæ Dana," "2. Gruppe," while *Photis* is placed in "Tribus II. Gammarina genuina (Sauteurs, M.-Edw.)," "Fam. 6. Gammaridæ," "Subfam. 5. Gammarina."

Boeck defined the family Photidæ as follows:—

"Upper Lip broad, apically rounded.

"Mandibles strong, apically dentate; the secondary plate also dentate; the molar tubercle prominent; the palp three-jointed.

"First Maxillæ with the inner plate generally small or of moderate size.

"Second Maxillæ with the plates broad.

"Maxillipeds generally furnished on the inner margin [of the outer plates] with teeth, few, but strong, as they approach the apex longer and curved, sometimes furnished with slender spines; the last joint of the palp rarely not unguiform.

"The body more or less compressed, with the back rounded.

"Upper Antennæ with the accessory flagellum small or absent.

"First Gnathopods with a subcheliform hand.

"Second Gnathopods with the hand subcheliform, seldom scarcely subcheliform.

"The Fourth Peræopods as a rule much longer than the Third, and the Fifth than the Fourth.

"The Third Uropods biramous, rarely uniramous.

"Telson thick."

The distinctions which Boeck seeks to establish between the three groups which he calls subfamilies of this family are not very easy to appreciate. Indeed in my opinion *Xenoclea*, Boeck, the third genus of the Photinæ, is identical with *Podoceropsis*, Boeck, the sixth genus of the Microdeutopinæ. In *Photis* the inner ramus of the third uropods is minute, and in *Microprotopus* these uropods have but one ramus, so that there might be some reason for placing these two genera in a separate group, but if the Leptocheirinæ and Photinæ are combined, it seems impossible to formulate a definition that will separate them from the Microdeutopinæ. Boeck's Leptocheirinæ

¹ He does not name Norman's *Megamphopus*, which is only incidentally mentioned by Boeck, and has probably often escaped notice from the fact that the description has only been published in the British Association Reports.

have thin spines, not teeth, on the outer plates of the maxillipeds, and the side-plates of moderate size or large, while his Microdeutopinæ have teeth on the outer plates of the maxillipeds and the side-plates small, but Boeck's Photinæ agree with his Microdeutopinæ in the armature of the maxilliped-plates, and in point of fact some of the Microdeutopinæ have the side-plates well developed. In describing the family Photidæ, and also the subfamily Microdeutopinæ, Boeck says that the accessory flagellum of the upper antennæ is small or absent, whereas in reality among his Microdeutopinæ it is sometimes of considerable size; if therefore the term Photidæ be accepted as a sufficient heading for all the three groups, it will be necessary to modify the character by saying that this accessory flagellum is of variable size or absent. It will also, I think, be proper to state that the fifth pair of side-plates are nearly as deep as the fourth pair.

For the original definition of the genus, see Note on Krøyer, 1842 (p. 199); for Bate and Westwood's definition of *Eiscladus*, see Note on Bate and Westwood, 1862 (p. 340). In 1876 Boeck gives the following definition:—

"Upper Antennæ with the third joint of the peduncle elongate; accessory flagellum absent.

"First Gnathopods with a short wrist.

"First and Second Periopods with the first joint not thick.

"Third Uropods with the inner ramus minute.

"Telson apically rounded."

The new species, *Photis macrocarpus*, requires the cancelling of the second of these characters. Some of those characters which Boeck places in the definition of the subfamily Photinæ ought perhaps to be added to the generic account, if the subfamily itself is dropped. Of the mandibles he says that the spine-row consists of few (four)

spines, and that the third joint of the elongate palp is shorter than the second ; of the maxillipeds, that the plates are strong, the inner armed with three teeth, the outer armed on the inner margin with teeth few but strong, as they approach the apex longer and narrower, the series ending with curved setæ, and that the last joint of the elongate palp is not unguiform but apically armed with strong spines ; of the side-plates that the four anterior pairs are large, feathered on the lower margin, and that the fifth pair are larger than the fourth, incised on the hinder margin for the retroverted third peræopods. It is obviously only by a misprint or slip of the pen that he speaks of the fifth peræopods being *shorter*, instead of longer, than the fourth.

Photis macrocarpus, n. sp. (Pl. CVII.).

Rostrum quite small, lateral lobes of the head small and angular ; the postero-lateral corners of the second and third pleon-segments almost squared, with two little spinules within the hind margin.

Eyes small, round, situated on the lateral lobes of the head, the ocelli very few.

Upper Antennæ.—First joint rather long and stout, with one or two slender spines at the lower apex, the second joint longer and more slender, with slender spines at six points of the lower margin ; the third joint about as long as the first, with five pairs of spines on the lower margin, the lowest the longest ; the flagellum of fourteen slender joints, together about as long as the peduncle, and carrying similar spines.

Lower Antennæ subequal in length to the upper. The first two joints short, the gland-eone small, not very prominent ; the third joint as long as the preceding two united ; the fourth subequal to the second of the upper antennæ, proximally bent and thin, a little widened distally, with a few slender spines on the under margin ; the fifth joint shorter than the preceding, longer than the third of the upper antennæ, slightly curved, with spines at five points of the lower margin ; the flagellum of twelve slender joints tipped with longer or shorter spines. Many of the spines on both pairs of antennæ are slightly flattened on the concave border.

Upper Lip.—The front plate broad, its distal margin convex, unsymmetrically emarginate, furred with small cilia pointing inwards on either side of the shallow emargination.

Mandibles.—The trunk very small compared with the palp ; the cutting plate having its edge divided into five teeth ; the secondary plate on the left mandible has four teeth ; on the right mandible the secondary plate is smaller, ending in one prominent tooth, along the side of which are several denticles ; there are on the left mandible four, on the right mandible three, much bent dentieulate spines in the spine-row, followed by some plumose cilia ; the molar tubercle is tolerably strong, with the crown nearly round and closely set with fine denticles ; at its outer corner a small

thin plate projects, with a finely denticulate edge (this minute feature I left unfigured, supposing it due to an accidental laceration, but it is found also in *Autonoe*, *Gammaropsis*, *Podocerus*, *Cerapus*, *Platophium*) ; there is a process above the molar tubercle near the base of the palp ; the first joint of the palp is short, widening distally, rather longer than broad ; the second joint is large, armed on the inner margin or adjacent surface with about a dozen spines of different lengths ; the third joint is nearly as long, widening distally to considerably more than the width of the second joint, the lower part of the inner margin nearly straight, unarmed, the remainder as far as the apex curved, set closely with numerous long spines, some slightly plumose, most of them strongly pectinate ; the outer margin is very slightly convex ; adjacent to it on the inner surface some way below the apex is a row of four long spines, while on the outer surface, besides a continuation of this group, there are spines at five other points lower down and away from the margin, the set consisting of two pairs and three single spines.

Lower Lip.—The principal lobes ciliated round the distal and inner margins ; the inner plates thick, distally rounded and broad, narrowing to the base ; the mandibular processes small, rather divergent.

First Maxillæ.—The inner plate broad at the base (but a view of this breadth not easily obtained), with a setule on the narrowly rounded apex ; the outer plate carrying on the distal edge ten slightly denticulate spines ; the first joint of the palp very short, the second long, curving over the outer plate, its distal margin carrying four strong, variously cut spine-teeth, and a slender spine-tooth in the inner corner ; there are besides three submarginal spines, slender, pectinate on two edges.

Second Maxillæ.—The inner plate shorter and narrower than the outer, with thirteen setæ passing across from the base of the inner margin in a curve towards the outer apex, the upper part of the inner margin fringed with spines, the apical margin flattened and unarmed ; the outer plates broadest at the rounded apical margin, which is fringed with many spines.

Maxillipeds.—The inner plates short and broad, not quite reaching the distal end of the palp's first joint, fringed with setæ along the distal part of the inner margin, on the outer surface of which there is a spine-tooth just below the apex ; the broad straight distal margin has three irregular spine-teeth, and many slender feathered spines ; the outer plates do not reach the distal end of the palp's second joint, the inner margin has seven spine-teeth, the series being continued round the distal margin by six longer teeth or spines ; there is as usual a row of slender spines on the outer surface within the inner margin ; the first joint of the palp is short, the second long, with many long spines on the inner margin and outer surface ; the third joint is as long as the first, distally widened, set about the apex and surface with long spines, of which one at the apex is conspicuously pectinate ; the finger is longer than the third joint, if a long pectinate spine which appears to do duty for a nail be included ; this spine is as

long as the basal part of the finger, on the inner margin of which close by is another spine of almost equal length, and needle-like.

The *triturating organs* of the stomach show on one side about fifteen strong spines, wearing something the appearance of a set of Pandean pipes, but a little bent; on the other side are numerous slender spines.

First Gnathopods.—The side-plates wider below than above, the lower front corner being produced over the basal joints of the lower antennæ. First joint reaching beyond the side-plate, a little curved, the front concave margin having some spinules, the convex hind margin seven long setæ on the central part, besides some slender spines; four long setæ high up on the surface project beyond the front margin; the second joint is short, with several long spines at the apex behind; the third joint has convex sides converging to an acute apex, with long spines on the lower part of the hind margin and on the inner surface across the apex; the wrist is rather longer than the hand, fringed along the hind margin and at the front apex with many long spines, of which there are some also on the surfaces, chiefly on the inner; the hand oval, narrowing towards the hinge of the finger, the palm minutely pectinate, occupying more than half the hind margin, set with various spines; the two surfaces of the hand also are armed with many groups of spines; the finger is more than half the length of the hand, rather broad, curved, chiefly at the nail, which reaches just beyond the palm; the inner margin of the finger cut into seven decurrent teeth, and carrying a few small setules; the dorsal cilium rather long, placed very near the hinge.

Second Gnathopods.—Side-plates oblong, with rounded corners. Branchial vesicles narrow, not quite so long as the side-plates. The marsupial plates longer than the branchial vesicles, widening a little from the basal part, and fringed with sixteen setæ. The first joint reaching beyond the side-plates, the front margin straight, with a seta near the apex, the hind margin somewhat sinuous, armed with a few setiform spines; the second joint short, with one or two apical spinules; the third rather longer and more acute than in the first gnathopods, but similarly armed; the wrist shorter than the hand, distally broad, eup-like, with a few spines at the front apex, and many on the rounded corner behind as well as on the lower margin of the inner surface; the hand large and broad, the front margin gently convex; the hind margin, which is slightly serrate and set with spines, is almost straight and longer than the oblique palm, over which the finger closes as in the first pair; there are several surface groups of spines; the finger is dentate on the inner edge. In the male the first joint is much more dilated, and the hind margin of the hand is produced into a tooth carrying a palmar spine at the commencement of the palm, which is excavated.

First Peraopods.—Side-plates and branchial vesicles similar to the preceding pair. The first joint considerably longer than the branchial vesicle, straight, gradually dilated distally, with some long setæ at parts of both margins, those on the hind margin near the

middle five in number. The second joint is short, with an apical spinule, the third is long and broad, the hind margin smooth and nearly straight, the front convex, fringed with groups of long slender spines, the largest group being on the rounded apex; the fourth joint is of a similar shape, but much narrower, and only half the length; it has a few spines at each apex; the fifth joint is longer and much narrower than the fourth, slightly curved, tapering distally, with some spines at the middle and apex of the front margin, and a spinule at each of three points on the hind margin; the finger is narrow, curved, more than half the length of the fifth joint, with a small dorsal cilium near the hinge.

Second Peræopods.—Side-plates like the preceding pair, perhaps a little broader, as those are than the pair preceding; not excavate behind. The limb nearly the same as in the first peræopods.

Third Peræopods.—The side-plates broad, the front lobe less deep than the preceding pair, but of the same pattern, the hind lobe small. The branchial vesicles small, a narrow oval in shape. The marsupial plates narrower than the branchial vesicles, about as long, with six or seven setæ. The first joint of the limb much broader above than below, the upper part of each margin convex, the lower nearly straight, with few spines or setæ; the second joint short, its front margin like that of the three following joints convex, apically tipped with a setule; the third joint rather longer than the fourth and slightly broader, the hind margin straight, the fourth joint with a group of long spines at the apex of the straight hind margin; the fifth joint as long as the third, narrower than the fourth, the hind margin a little concave, the apex carrying a short spine and one or two long ones; the finger minute, sharply upturned, with a dorsal denticle. The last two joints, and perhaps the last four, in this pair of legs may be regarded as retroverted, facing, that is to say, in a direction opposite to that of the first two joints.

Fourth Peræopods.—Side-plates small. The limb similar to the preceding pair, but all the joints more elongate, particularly the third, fourth, and fifth; the first joint is a little more regularly narrowed towards the distal end, with the margins gently convex; the minute and upward-curved finger has a small tooth on the inner margin at the base of the nail, the dorsal denticle is very distinct, and there is a small dorsal cilium near the hinge.

Fifth Peræopods.—Side-plates small. The limb much more elongate than that of the preceding pair; the first joint not much dilated or especially at any one part, the front margin for the most part straight and smooth, the hind margin jutting out a little at the upper corner, the rest convex, carrying a few spinules; the third joint straight, longer than the fourth, but a good deal shorter than the fifth; the long fifth joint has two small groups of spines on each margin towards the distal end; the finger is slender, little curved, less than half the length of the fifth joint, ending in a minute nail.

Pleopods.—The coupling spines very small, curved, with a pair of lateral teeth similar to the flukes of the apex just beyond them; on some of the peduncles there were long

spines or setæ; I could not discover cleft spines on any of the pairs; the joints of the rami numbered from eight or ten.

Uropods.—Peduncles of the first pair¹ not reaching so far as those of the second, longer than the rami, one margin free from spines except at the apex; the outer ramus shorter and narrower than the inner, with several marginal spines and a nail-like one on the blunt apex; the inner ramus with five or six spines along one margin, and a large apical spine; the peduncles of the second pair only a little longer than the inner ramus, which is stouter and longer than the outer ramus, and has six spines on one of its margins; each of the rami has a strong apical spine; the peduncles of the third pair¹ about as long as the outer ramus, which is slender, curved, and has at the end a short second joint, tipped with a long straight spine; the inner ramus is minute, tipped with a spine.

The Telson is small, about as broad as long, not nearly reaching the end of the peduncles of the third uropods, the convex sides converging to a slightly rounded apex, near which there are one or two cilia on the surface close to the margin on either side.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the apex of the third uropods, three-tenths of an inch.

Locality.—The specimens were taken at Kerguelen, depth not mentioned. Several specimens were obtained, most of them apparently, like the one figured, being females, but one at least by the difference in the gnathopods appeared to be a male.

Remarks.—The specific name refers to the length of the wrist in the first gnathopods, to which it seemed the more necessary to call attention, since Boeck has included in the generic character of *Photis*, the statement “pedes 1mi paro carpo brevi.”

Photis brevicaudata, n. sp. (Pl. CVIII.).

Rostrum small, lateral lobes of the head sharply angled; the postero-lateral corners of the first three pleon-segments squared, the points rounded.

Eyes small, round, situated on the angular lateral lobes, with many rather broad ocelli, the median line of each being in this, as in the preceding species, very distinct; the colour is dark in the specimen preserved in spirit.

Upper Antennæ.—The first joint rather thick, not twice as long as broad, tapering a little distally, carrying two spines and some cilia on the lower apex; the second joint considerably longer, much thinner, with slender spines at five points of the lower margin, the apical the longest; the third joint intermediate in length between the first and second, with spines at six points of the lower margin, the apical very long; the flagellum of seven or eight joints, moderately slender, together shorter than the peduncle, the lower apex carrying long spines, which like many of those on the peduncle are pretty

¹ On the Plate the numbers *ur.3.* and *ur.1.* should be interchanged.

strongly feathered on the eoneave margin; the last joint has a pair rather stronger and shorter than those on the other joints, besides several slighter appendages.

Lower Antennæ.—The first two joints very short, the gland-eone not prominent; the third joint as long as the two preceding united, or a little longer, with several slender spines at the lower apex; the fourth joint as long as the seeond of the upper antennæ, curved at the base, bordered with spines below; the fifth joint as long as the fourth, similarly fringed with spines, feathered on the eoneave margin, and attaining their greatest length at the apex of the joint; the flagellum of six joints is shorter than the peduncle, and rather shorter than the flagellum of the upper antennæ; the apical spines of the last two joints are stouter than the others, but feathered in the same manner.

Mandibles scarcely differing from those of *Photis macrocarpus*, except that the third joint of the palp is very little widened distally, and has not so many spines on the apical margin.

Lower Lip as in *Photis macrocarpus*.

First Maxillæ.—Inner plate small, oval; outer plate broad, the broad distal margin carrying ten spines, with but few lateral denticles, three of them having a single denticle on the outer convex side, two having two denticles on the inner eoneave side; the five spine-teeth on the distal margin of the palp's seeond joint much resemble those in the other species, the outermost rather narrow, the innermost very narrow, the three between broad, fureate, with the outer edge dentate.

Second Maxillæ like those in *Photis macrocarpus*, but without the flattened distal edge of the inner plate.

Maxillipeds similar to those of the species just mentioned; the distal margin of the inner plates slopes a little inwards, and has the spine-teeth regular in shape, the slender spines fewer in number; the outer plates have five spine-teeth on the inner margin and four on the inward-sloping distal margin; the third joint of the palp is longer than the first.

First Gnathopods.—Side-plates rather deep, not expanded below. The first joint with some long setæ at various points of the convex hind margin, and others on the surfacee projecting on the front margin; the seeond joint short, with a large group of long, more or less feathered, setæ near the hinder apex; the third joint very little longer than the second, with numerous long spines crossing the inner surface a little above the apex; the wrist broad, in length nearly equal to the hand, with a group of spines on the front apex, many more or less peetinate on the hind margin, and groups near it on the inner surfacee; the hand is oval, broad at the base, narrowing towards the hinge of the finger, the front margin smooth, but with two large groups of spines on the inner surfacee near it and an apieal group, the hind margin occupied chiefly by the finely peetinate palm, which is bordered by various spines singly and in groups; there are at intervals two or three strong palmar spines, and on both surfacees there are spines remote from the margin; the

finger is broad, the inner margin pectinate and cut into four strong decurrent teeth; the dorsal cilium near the base is rather long; there are also some setules at the base of the nail, which is curved and scarcely reaches the extremity of what may be considered as the palm-border.

Second Gnathopods.—The side-plates deep, wider below than above, the hind margin slightly concave. The branchial vesicles much shorter and narrower than the side-plates. The marsupial plates rather longer than the branchial vesicles, narrow at the basal part, carrying fifteen setæ on the lateral margins and apex. The first joint not reaching beyond the side-plate, the convex hind margin having some long setæ at the apex; the short second joint with an apical group of setæ, one long and plumose; the third joint rather longer than in the first gnathopods, similarly armed; the wrist much shorter than the hand, broader than long, distally eup-like, with long spines at the front apex and on the narrow hind margin, and some on the lower margin of the inner surface; the hand broad, between oval and oblong, with a single seta-like spine above the middle of the front margin, a group between that and the apex and another at the apex, these spines being slightly plumose; the hind margin bordered with more or less pectinate spines, and produced into a tooth at the commencement of the palm, within which the finger closes down against a strong palmar spine; the palm is obliquely excavate for some distance, bordered with several spines, of which there are also various groups on both surfaces of the hand; the finger is broad, with five decurrent teeth on the inner margin.

First Peræopods.—Side-plates rather deeper than the preceding pair, a very little wider below than above, with the front margin convex and the hinder concave. The branchial vesicles narrow, widening a little distally. The marsupial plates as in the preceding segment. The first joint not reaching the end of the side-plate, with four long setæ on the lower part of the hind margin, the lowest conspicuously plumose; near the apex is a shorter plumose seta; the second joint short, with a long plumose seta at the hinder apex; the third joint stout, longer than the fourth, its convex margin fringed with about fourteen long plumose setæ, the hind margin almost straight, with some setules at the apex; the fourth joint with a group of setæ at the apex of the convex front margin, and some very slender setæ or setules at the apex of the straight hind margin; the fifth joint as long as the third, tapering distally, the convex hind margin with six or seven groups of long slender setæ, the straight front margin with a spinule at the apex and another higher up; the finger curved, rather more than half the length of the fifth joint.

Second Peræopods.—These in all respects closely resemble the preceding pair; the side-plates a little broader, and an extra setule perhaps on the hind margin of the fifth joint of the limb.

Third Peræopods.—Side-plates scarcely less deep and much broader than the preceding, the front and hind margins both convex, the hind lobe very small. Branchial

vesicles small, oval. Marsupial plates short and narrow, longer and narrower than the branchial vesicles, with half a dozen setæ. The first joint of the limb much smaller than the side-plate, much dilated, broader below than above, fully as broad as long, with the margins almost unarmed ; the second joint short, not longer than broad ; the third a little longer than the second, and the fourth than the third, all three with the front margin convex, and some apical spinules, the fourth with a long straight spine on the hinder apex ; the fifth joint much narrower than the fourth, almost as long, the front margin convex, with an apical spine and spinules, the hind margin tending to concave, with a setule at the centre, a strong spine at the apex, accompanied as in the preceding species by a much shorter one ; against these the minute finger bends upwards and backwards, it is very thick at the base, with a small dorsal cilium, and a strong dorsal denticle, the apical part beyond the denticle being comparatively narrow.

Fourth Peræopods longer than the third. Side-plates small. Branchial vesicles narrow, shorter than the first joint. The first joint as long as in the third peræopods, but not so broad, wider above than below, the margins carrying a few setules ; the rest of the limb like that of the preceding pair, except that the joints are more elongated, and the fifth decidedly shorter than the fourth ; the finger is produced to a very sharp apex.

Fifth Peræopods very little longer than the fourth. The first joint a little longer, but narrower than in the preceding pair, most narrowed at the junction with the second joint ; the second joint longer than broad ; the third longer than the second, the fourth scarcely longer than the third, each of these two with a spine on the hinder apex ; the fifth longer than the fourth, with a group of slender setæ on the apex of the convex hind margin, two small setules and a small apical spine on the straight front margin ; the finger curved, half the length of the fifth joint, with a strong dorsal cilium close to the hinge, and a small dorsal denticle over the base of the nail.

Pleopods.—The coupling spines very small and slender, curved, with apparently two lateral retroverted hooks below the apex ; the peduncles have also many long setæ. I have not been able to discover any cleft spines ; the joints of the rami number from seven or eight to nine.

Uropods.—The peduncles of the first pair are much longer than the rami ; the outer ramus is rather shorter than the inner and has a series of five spines beginning above the middle of the outer margin, and a stronger spine at the blunt apex ; the inner ramus has a like apex and two or more distant spines on the inner margin ; the peduncles of the second pair are slightly longer than the inner ramus, which has four spines along the inner margin and a strong apical spine flanked by two small ones ; the outer ramus is considerably shorter, with a similar apex, and two spines on the side. The peduncles of the third pair are a little longer than the outer ramus, which does not reach back so far as the rami of the other two pairs ; it is slightly curved, tapering distally to the short second joint, which is tipped with a long spine ; the inner ramus is

very short, yet twice as long as broad, its edges peetinate, as seems to be the case with all the rami, the apex narrowed to two sharp points, between which is a little spine.

The Telson is very short, broader than long, the sides converging to a broadly rounded apex.

Length.—The specimen, in the position figured, measured, from the rostrum to the apex of the second uropods, three-twentieths of an inch.

Locality.—Station 161, off Melbourne, April 1, 1874; depth, 33 fathoms; bottom, sand. One specimen, female.

Remark.—The specific name refers to the shortness of the telson.

For the original definition of the genus, see Note on Krøyer, 1845 (p. 211); for that of *Lalaria*, see Note on Nicolet, 1849 (p. 231); for that of *Lonchomerus*, see Note on Spence Bate, 1857 (p. 294), and for that of *Autonoë*, see Note on Bruzelius, 1859 (p. 312). Boeck in 1876 gives the following definition:—

“ *First Gnathopods* larger than the *Second*; in the male the third joint produced behind into a long stiliform process; the wrist elongate, narrow; the hand also elongate, oval; in the female the third joint not produced at the lower hinder angle; the wrist short; the hand broad.

"As to other points almost as in the genus *Microdeltopus*."

In describing the subfamily Microdeutopinæ, Boeck says that the third joint of the elongate mandibular palp is apically obtuse, rounded; that the first maxillæ have the inner plate small, and the second maxillæ the plates very broad, that the maxillipeds have the outer plates armed with teeth, and the last joint of the palp apically armed with two strong curved spines; that the flagellum of the lower antennæ is not very long, that the uropods are biramous and the telson thick. In the definition of *Microdeltopus*, Costa, he says (see p. 1082) that the upper antennæ have the third joint of the peduncle short, and that the third uropods have rami of almost equal length. Mr. Chilton is of opinion that *Microdeltopus* ought to become a synonym of *Aora*, the females being practically undistinguishable. M. Chevreux, on the other hand, hopes to be able to publish characters by which the very similar females of *Aora*, *Microdeutopus*, and *Stimpsonia* may be discriminated.

Aora kergueleni, n. sp. (Pl. CIX. figs. A. ♂, D. ♀).

Rostrum minute, lateral lobes of the head broadly convex, little prominent, lower angles of the head acute; postero-lateral angles of the first three pleon-segments rounded.

Eyes small, tending to oval, situated on, but by no means filling, the lateral lobes of the head.

Upper Antennæ.—First joint long and thick. The other joints missing in the specimen figured, but in a second specimen resembling those of *Aora trichobostrychus*, the flagellum with thirty-three joints.

Lower Antennæ.—The first two joints short, the gland-cone decurrent; the third joint longer than the preceding two united, with some small stout spines at the apex; these three joints united not as long as the first of the upper antennæ. The other joints missing in the specimen figured; in another specimen the fourth and fifth joints were equal in length; the flagellum of eleven joints, was scarcely so long as the fifth joint of the peduncle.

Upper Lip.—The distal margin describes a broad curve, much projecting at the central part, the middle of which is smooth, except that straight spine-like cilia project a little from the inner surface, while a brush of cilia is directed towards it from the margin on either side.

Mandibles.—The cutting edge has six teeth; the secondary plate of the left mandible probably has five; that of the right mandible, fig. m. A., is very narrow, showing only two distinct teeth, but it probably has two or three denticles as well; the spine-row consists of four broad overlapping spines, the oblique distal margin of which is cut into denticles; the spines are followed by two or three plumose setæ; the molar tubercle is prominent, the crown surrounded with long teeth, and its

surfacee covered with small dentieles; it has a plumose seta at one corner; the first joint of the palp is twice as long as broad; the second about twice as long as the first, with three spines on and two near the front margin; the third joint shorter than the second, with more than half of each margin clear of spines, of which there are two planted close to the eonvex hind margin a little above the centre, while on the straight front margin there is a row of half a dozen long and strongly peetinate spines passing up to the narrow apex, and parallel with these are two rows of short peetinate spines.

Lower Lip.—Both the prineipal lobes were widely dehiseent, eausing the mandibular proeesses to appear nearly parallel; it is however obvious that if the lobes came nearer together, the mandibular proeesses would beeome proportionately divergent; the prineipal lobes have their distal margins fringed with spines, set close together and very numerous, as many as thirty, the inner margins are as usual eliated, as are those of the inner lobes, whieh apieally are narrow; the mandibular proeesses are long and aeute, the outer margins convex, the inner tending to eoneave.

First Maxillæ.—The inner plate very small, closely pressed against the outer plate, earrying a single very long thin plumose seta on the apex; the ten spines on the apieal margin of the outer plate seem in no ease to have more than three lateral dentieles; of the three outermost one showed no dentiele, of the next pair one was apieally fureate, of the remainder two had a single dentiele apiee on the outer side; the first joint of the palp is rather longer than broad, the seeond, expanding from the base, curves beyond the outer plate, with a spine below the middle of the very eonvex outer margin, seven or eight serrate spine-teeth on the apieal border, and several slender spines, perhaps a dozen, beginning near the middle of the eoneave inner margin, and passing aeross to the outer apex.

Second Maxillæ.—The inner plate shorter and mueh narrower than the outer, with a series of about twenty-four plumose setæ, beginning low down on the inner margin, and passing in a curve on the surfacee aeross towards the outer apex; there are spines at intervals round mueh of the inner margin, and densely set on the rounded, rather narrow, apieal margin; the outer plate, of almost uniform breadth, has the outer margin eonvex, the inner tending to eoneave, the distal almost trunateau, with an outward slope; on the inner corner are many spines, and some long ones in a series, commeneing on the inner margin and passing aeross the inner apex; the rest of the distal margin is oeeupied by six or seven smaller spines not closely set.

Maxillipeds.—The inner plates, reaehing as far as the apex of the first joint of the palp, having many plumose setæ on the inner margin, and a spine-tooth near its apex; the irregular apieal margin, whieh slopes abruptly at the outer eorners, earries four spine-teeth and many slender plumose spines; the outer plates reaehing the apex of the seond joint of the palp, with eleven spine-teeth on the serrate inner margin, and eight spines

round the distal margin, of which three are spine-teeth, the rest slender or setiform; the first joint of the palp short, the second not greatly elongate, twice as long as the first; the third joint not much longer than the first, distally expanded, produced in a little apical cap over the base of the finger, and carrying many spines about the distal half; the finger little shorter than the third joint, not stout, with some setules on the inner margin, close to the short apical spine which does duty for a nail. The long slender spines or setae on the inner margin of the first, second, and third joints of the palp show little or no feathering.

First Gnathopods.—The side-plates not large either in this or the following segments; in this pair the lower front corner is directed strongly forwards towards the base of the lower antennæ, the oblique front margin tending to concave. The first joint almost free from the side-plate, narrow at the neck, then widening, but not greatly, the margins almost entirely smooth; the second joint stout, but longer than broad, with some spinules at the hinder apex; the third joint an elongate triangle, about as long as the wrist, but not quite reaching the end of it, attached to the wrist by less than half its front or inner margin, carrying on its surface or margin only two or three slender spines or spinules; the wrist a long oval, broader than the first joint, and almost equal to it in length, the hind margin and the surface carrying groups of slender spines not very closely set; the hand shorter than the wrist, but long and narrow, widening a little distally, with groups of slender spines along the surface near, and at the apex of, the convex front margin; the slightly serrate hind margin, which tends to concave, has also several spaced groups of slender spines on and near it, and some little way above its apex a strong projecting palmar spine; the palm is almost too short to deserve the name, with irregular edge, bordered with slender spines; beyond the palm the curved finger projects, with its inner margin denticulate, and apparently adapted to impinge against the third joint rather than against the hand or wrist, while the point of the third joint is well adapted to hold objects pressed against the hand; the dorsal cilium is very small, near the base.

Second Gnathopods.—Side-plates rather larger than the preceding or following pair, with the margins convex, especially the lower one. The first joint furnished with a few marginal spinules; the second with two or three at the hinder apex; the third with several slender spines on the oblique distal margin; the wrist rather longer than the hand, with nine or ten groups of pectinate spines along the serrate hind margin, two or three groups on the adjacent surface, one more remote consisting of five spines in a row; there are also a couple of groups near the apex of the front margin, and a spinule or two higher up; the hand almost oblong, a little widened at the palm, with nine or more groups of pectinate spines on the serrate hind margin and a palmar spine at the apex, six groups of spines near or on the convex front margin, and four or five on the surface between the two margins; the convex scarcely oblique finely pectinate palm is bordered with spines and spinules; the finger has the inner margin cut into teeth, the

nail, with two or three setules at its base, projects beyond the palm; the dorsal cilium near the base is small.

First Peræopods.—Side-plates rather smaller than the preceding pair, with the hind margin tending to convex. The first joint packed with gland-cells, almost entirely free from the side-plate, in length exceeding the fourth and fifth joints united, with some slender spines and spinules on the margins, of which two at the upper part of the hind margin are longer than the rest, the second joint with one or two setules at the apex behind; the third joint widening distally, longer than the fourth, subequal in length to the fifth, with spinules and slender spines at three points of the hind margin; the fourth joint with a spinule almost at the top of the hind margin, then a group, then two separate spinules, and a large group near the apex; there is also a group at the apex of the convex front margin; the fifth joint, tapering distally, has a spinule high up on the hind margin, three near the apex, and on the convex front margin above the centre one or two spinules and at the apex a small spine and a spinule; the finger is long and tapering, slightly curved, more than half the length of the fifth joint, with a small dorsal cilium close to the base, and an opening within the apex. The other peræopods were missing in the specimen figured, and are therefore described from a different specimen.

Second Peræopods.—Side-plates similar to the preceding pair, but a little smaller. The limb as in the first peræopods.

Third Peræopods.—Side-plates broader than the preceding pair, the front lobe nearly as deep, the hind lobe shallow. The branchial vesicles oval, longer than the depth of the side-plate. The first joint elongate, wider above than below, with small spines at distant unequal intervals on the margins, of which the front is rather more convex than the hinder; the second joint longer than broad, with spinules at the front apex; the third joint longer than the fourth, shorter than the fifth, with a spine at the hinder apex and spinules at some other points; the fourth joint not conspicuously spined; the fifth with spines at four or five points of the serrate front margin; the finger slender, curved, a little more than half the length of the fifth joint.

Fourth Peræopods.—Side-plates and branchial vesicles like the preceding pair but smaller. The limb very much larger than in the third peræopods, especially the third, fourth, and fifth joints, and the finger much more elongate; the first joint more widened at the top; the third joint much longer than the fourth, subequal to the fifth, with small spines at three or four points on the hind margin; the fifth joint with spines at six or seven points on the front margin and three on the hind margin; the finger much more than half the length of the fifth joint.

Fifth Peræopods.—The side-plates scarcely bilobed. The limb like that of the fourth peræopods but considerably longer; the first joint more widened at the top; the third joint not very much longer than the fourth, shorter than the fifth, with spines at six or seven points of the hind margin; the nail more than half the length of the fifth joint.

Pleopods.—Coupling spines small, bent, with two pairs of retroverted teeth below the apical pair; the margin of the peduncles at the corner below these spines a little serrate; the cleft spines three in number; on one ramus of one pair there were four; the joints of the rami numbering from twelve to thirteen, the outer ramus a good deal shorter than the inner.

Uropods.—The peduncles of the first pair rather longer than the rami, with some strong spines along the under and two upper margins, and a large curved spine at the lower apex; the rami nearly equal, with the marginal spines not numerous, and a group at the apex; the peduncles of the second pair not longer than the rami, reaching as far as the preceding peduncles; the rami not reaching so far as those of the preceding pair, the armature similar, the outer ramus rather shorter than the inner; the peduncles of the third pair reaching beyond the preceding peduncles, shorter than or subequal to the rami, which do not reach so far as the preceding rami; the outer ramus rather longer than the inner, with some marginal spines, and at the apex two, below and behind which there is a little seemingly jointed cap, which is not represented on the inner ramus.

The Telson about as broad near the base as the extreme length, the sides converging from the convex upper part to the acute corners of the distal margin, which is convex in the centre; the raised line which runs obliquely from each outer corner on to the upper surface carries a small spine and a cilium by its side.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the extremity of the uropods, two-fifths of an inch. The second specimen which has contributed to the description was a little longer. Both were distinguished from the specimens attributed to the next species by darker colours, but this distinction did not apply to other specimens, which appear in other respects to belong to the present species.

Locality.—The specimen figured was labelled as having been obtained at Kerguelen Island, off Cape Maclear, from a depth of 30 fathoms; the second specimen was also labelled from Kerguelen Island, Royal Sound; depth, 38 fathoms.

Remarks.—The specific name refers to the locality.

A specimen which is probably the female of this species, has in the first gnathopods the second joint with a group of slender spines at the hinder apex, the third joint with a group low down on the hind margin, the oblique distal margin fringed with many spines, the front apex acute, resting on the wrist, not produced along it; the wrist about as long as the hand, fringed along the convex hind margin with long slender spines, of which there are three or four groups on the surface, as well as one at and another near the front apex; the hand widens distally, and has on the front margin three spaced groups of spines, then a long palmar spine, and finally a fourth group of slender spines; near the front margin there are five or six groups, and three or four

on the surface nearer the front, the finger has its inner margin cut into eleven denticles, and the long sharp nail curves across the palmar spine beyond the obliquely convex finely pectinate palm, so as to become parallel with the hind margin. In the second and smaller gnathopods, the long spines of the third joint cross the surface at an angle with the distal margin; the spines along the serrate hind margin of the wrist and hand are more numerous and closely set than in the first gnathopods, the hand is oblong, rather longer than the wrist, the palm is only slightly oblique, and the short finger fits it, its tip when closed only just appearing beyond the spine which defines the palm; the inner margin of the finger is cut into small teeth; the spines on the surface and front margin of both wrist and hand are nearly as in the first gnathopods.

The peræopods seem to agree in shape and proportion with those of the males above described, and in particular the fifth joint of the second peræopod showed the same armature as that figured for the male, *ppr.p.1. A.*, differing from that of *ppr.p.1. C.* the female, as I suppose, of the other species. The great size of the finger in the fifth peræopods may also be noticed as a distinguishing characteristic.

Locality.—The specimen came from Kerguelen Island, the depth not specified. The figure of the upper antenna and part of the lower in the Plate, *a.s. D.*, was drawn from a female specimen which seems to belong to this species, a specimen also taken at Kerguelen, and labelled as coming from a depth of 120 fathoms.

Aora trichobostrychus, n. sp. (Pl. CIX. figs. B. ♂, C. ♀).

The resemblances between the species of the genus *Aora* as yet described are so great as to suggest the possibility of their in fact constituting but a single true species, widely distributed, and subject to local variation.¹ The difference between male and female in this genus is sufficiently well known, and it is easily understood that there will be variations in the form of the male according to its age, while there is the further possibility that even the adult male may show some variety of form. The probability that the different specimens of *Aora* from Kerguelen Island all belonged to a single species, induced me to figure on a single Plate parts of different specimens which showed variation, and it was not till I had written most of the description, including all the specimens under one species, that the complication of the narrative brought me to a halt. Upon carefully reviewing the different characteristics, I at length came to the conclusion that less confusion was likely to arise from giving two names to one species, if so it should eventually prove, than by describing two distinct species under one and the same name. The following description is intended chiefly to bring out the points of distinction, real or supposed, between this species and *Aora kergueleni*.

Upper Antennæ.—First joint long, slightly curved, moderately thick, with some slender spines at the apex; the second joint longer and much thinner, also slightly

¹ See especially Mr. Chilton's paper, *Ann. and Mag. Nat. Hist.*, ser. 5, vol. xvi. p. 369.

curved, with some slender spines and spinules here and there, the third joint less than a fourth the length of the second; the flagellum much longer than the peduncle, slender, with about thirty-four joints; the secondary flagellum of four slender joints, the last very small, the four together about equal to three of the primary; on one antenna the secondary flagellum had five joints, the first two being short.

Lower Antennæ.—The fourth joint elongate, rather longer than the first of the upper antennæ, with some slender spines on the margins; the fifth a little longer than the fourth, similarly armed; the flagellum of seven joints, together about equal to the fifth joint of the flagellum, the first joint the longest, the joints carrying at the side and tips some stout spines and some that are setiform.

Upper Lip.—The distal margin a little less protruded than in the other species.

Mandibles.—The cutting edge of the left mandible with five strong teeth visible and probably a small sixth tooth on the side of the largest of the others; the secondary plate with five teeth; the cutting edge on the right mandible having three small and four large teeth; the first joint of the palp widens distally, the second joint has on the front margin four groups of spines, that near the apex forming a row of four; the third joint is longer than the second, and near the hind margin below the middle has two spines on the outer surface; rows of pectinate spines, large and small, are on or near the front margin and apex, fringing more than half the joint. The palp therefore is not very like in its armature to that of *Aora kergueleni*.

Lower Lip.—The principal lobes rather narrow at the top, the flattened distal margin carrying about half a dozen spines; the mandibular processes very acute and much curved, strongly divergent.

First Maxillæ.—The second joint of the palp has no spine on the outer margin, on the apical it has nine spine-teeth, and the slender spines below these do not seem to be more than five or six; the inner plate, though not shown in the figure, *mx.1. C.*, is as in other species.

Maxillipeds.—The inner plates have in a male specimen only three spine-teeth on the distal margin, but in a female specimen they have four, so that this is no doubt a variable character.

First Gnathopods.—The side-plates are not so strongly produced forwards as in the other species. The first joint rapidly widens from the narrow neck; the hind margin is furnished with nine or ten tufts of very long setæ, which at the lower part are so large and so close together as to make a dense brush; the second joint is not stout, and has a group of several slender spines at the hinder apex; the attachment of the third joint to the wrist is very much less than half its length, and beyond the attachment the process of the third joint is exceedingly narrow; near the commencement of the process the third joint has more than a dozen slender spines; the spines of the wrist are much more numerous than in the other species; the hand widens more at the distal end,

having consequently a rather longer palm, which at the same time is more oblique; over this the finger closes, bending down beyond the palmar spine and approaching but not reaching the margin beyond it.

Second Gnathopods.—The branchial vesicles narrow, much longer than broad, shorter and narrower than the first joint. The first joint has many slender marginal spines, two longer than the rest near the top of the hind margin; on the wrist and hand near the front margin the spines are longer, more numerous, and more setiform than in the other species, the hand is more slender and the palm more oblique, the finger more curved, with its nail not projecting, but passing the base of the palmar spine and resting within the hind margin.

First Peraopods.—Branchial vesicles rather wider than in the preceding segment. The first joint not longer than the third and fourth united, the front margin straight, with spinules at intervals, the hind margin carrying some slender spines, and one longer than the rest near the top; the third joint quite as long as the fifth and scarcely longer than the fourth; the fourth joint having near the top of the front margin a very small spine, below this in succession a longer one, two small groups, a spinule, and a group of several slender spines; the fifth joint has on the upper half of the hind margin four slender spines, graduated in length, the longest lowest.

Fourth Peraopods.—The third joint with slender spines at two points of each margin, and a spinule at two other points of each margin; the fourth joint with very small slender spines at two points and hairs at two points of the front margin, with a large group of long slender spines at the apex, at the apex behind there is a group of three short bent spines and some that are setiform; the fifth joint has some small spines at six points of the front margin, a large group of setiform spines at the apex behind, and higher up one or two spines and one or two spinules; the nail is less than half the length of the fifth joint.

Fifth Peraopods.—The margins of the first joint not serrate nor carrying stout little spines as in the other species, but in both male and female almost absolutely smooth except for a few little setules; the third joint subequal in length to the fifth; the nail much less than half the length of the fifth joint.

Pleopods.—One of the rami examined had only two eleft spines; the joints numbered from eleven to twelve.

Uropods.—In none of the pairs are the peduncles longer than the rami; the outer ramus of the third pair has, besides the two small spines and the cap, three more slender spines apically feathered; that these are not represented in either specimen of the other species, may, however, be accidental.

The Telson longer than its breadth.

Length.—The female specimen, in the position figured, measured, in a straight line from the front of the head to the extremity of the uropods, three-tenths of an inch

Locality.—Off Christmas Harbour, Kerguelen. Two specimens, male and female.

Remarks.—The specific name is derived from the Greek $\tau\rhoιχο\betaόστροψ$, a word meaning *with locks or clusters of hair*, and here referring to the ornamentation of the gnathopods.

That which I suppose to be the female of this species is fig. C of the Plate. It differs little from the female of the other species, except in the proportions of the joints of the peræopods, the fourth and fifth pairs having here a much smaller finger; the fifth joint in the first and second pairs is armed as in the male of this species and not as in *Aora kergueleni*; the more elongate telson is another characteristic. The marsupial plates are here, and no doubt in the other species also, very broad as well as long, being longer as well as greatly broader than the first joint in the first or second peræopods.

For the original definition of the genus, see Note on Bruzelius, 1859 (p. 312). *Gammarus longipes*, Liljeborg, 1852, is the only one of the five species placed by Bruzelius in the genus which Boeck allows to remain in it. With this Boeck identifies the *Microdeutopus websterii* of Spence Bate. Norman in discussing the latter (Shetland Dredging Report, 1869, see Appendix) says—"I question whether there are sufficient

¹ M. Jules Bonnier's Catalogue only reached me on December 12th, 1887, or it would have been referred to in earlier lists of synonyms, as accepting the generic names *Stenothoe*, *Halirages*, *Tritæta*, *Elasmopus*.

grounds for separating the genus *Aora* from *Microdeuteropus*. We have seen that the females of [the] two are almost undistinguishable; and if *Aora* be divided from *Microdeuteropus* because the tooth-like projection proceeds from the meros [third joint] and not the carpus [wrist], *M. Websterii* must in justice have a similar distinction conferred upon it, because in that species the tooth-like projection does not spring from either meros or carpus, but from the hand." Mr. Chilton in 1885 definitely unites the genera *Aora* and *Microdeutopus*, and would, it may be presumed, make *Autonoe* also a synonym of *Aora*. Boeck adopted the other alternative suggested by Mr. Norman, and allowed *Gammarus longipes* to have the distinction of a separate generic name on account of the hand of the first gnathopods; his definition is as follows:—

"First Gnathopods larger than the Second; the fifth joint in both sexes forming the hand, which is stronger in the male than in the female.

"The Third Uropods with the outer ramus longer than the inner.

"In other points almost as in the genus *Microdeutopus*."

Practically the generic character must be reduced to the description of the first gnathopods, since in the description which Boeck gives alike of *Autonoe longipes*, Liljeborg, and of his own *Autonoe plumosa*, it is clear that the difference in length between the two rami of the third uropods is insignificant. None the less I am much more doubtful than I formerly was of the expedience of combining the three genera *Aora*, *Microdeutopus*, and *Autonoe*, since the character of the first gnathopods in the male of *Aora* is so peculiar, that, as more and more species in the group become known, there will be a continual tendency, I imagine, to draw the *Aora*-form apart from the other two, and then the severance also of those two becomes, as Norman points out, a logical consequence.

The definition of *Microdeutopus*, to which Boeck refers in defining both *Aora* and *Autonoe*, is as follows:—

"Upper Antennæ longer than the Lower; the third joint of the peduncle short.

"First Gnathopods larger than the Second; the wrist of the male very dilated, produced at the lower hinder angle; the fifth joint or hand narrower than the wrist and together with the finger forming a two-jointed thumb (una cum ungue pollicem 2articulatum formanti); the fifth joint in the female very dilated and forming the hand.

"The First and Second Peræopods with the finger shorter than the fifth joint.

"The Third Uropods with the inner and outer ramus almost equal in length."

Autonoe philacantha, n. sp. (Pl. CX.).

Rostrum scarcely perceptible, lateral lobes of the head small, acute, lower angles still more acute; the postero-lateral angles of the first three pleon-segments rounded, especially those of the third segment.

Eyes narrow and small, reniform, set obliquely on the lateral lobes of the head.

Upper Antennæ.—The first joint longer than the head, tapering distally, with spines at five points of the lower margin, a row of feathered cilia near the base of the convex upper margin; the second joint thinner, but much longer than the first, with slender spines at intervals on the lower margin; the third joint scarcely half as long as the first; the flagellum of numerous joints, more than eighteen, together longer than the peduncle; the secondary flagellum slender, of seven slender joints, together equal in length to the first four of the primary, the first and last joints the shortest; the slender spines, both short and long, as well on the flagellum as on the peduncle, have a conspicuous accessory thread near the apex.

Lower Antennæ shorter than the upper; the peduncle longer than that of the upper antennæ; the first two joints short, the gland-cone narrow, decurrent; the third joint longer than the preceding two united, with two groups of spines on the under side and another at its apex; the fourth and fifth joints thinner, much longer, about equal to one another, a little shorter than the second of the upper antennæ, armed with long spines on the lower margin, and with short ones on both; the flagellum of nine joints, together not much longer than the fifth joint of the peduncle, tipped with setæ or setiform spines and strong curved spines, which on the upper joints are long; there are also short spines on the sides of the joints.

Upper Lip.—The distal margin broad, very slightly convex, and almost imperceptibly emarginate at the centre, being furred within and on either side of the emargination.

Mandibles.—Cutting edge broad, with six teeth, of which one is especially prominent; the secondary plate has four unequal teeth, which are strong on the left mandible, and long on the right; the spine-row of twelve long, strongly denticulate spines; the molar tubercle prominent, with long denticles surrounding the somewhat narrowed crown, and several rows or ridges of smaller ones crossing the surface; on the outside of the tubercle, above the plumose seta, there is a small plate or process with a denticulate edge; near to the base of the palp there rises a prominent process with rounded apex; the first joint of the palp short; the second long, fringed on two edges with numerous spines of various lengths; the third rather shorter and much narrower, the apex acute, carrying one or two long feathered spines, the front margin nearly straight, fringed with many spines, most of them pectinate; the outer margin convex, but a little below the centre somewhat bent in, there being here a great group of cilia and pectinate spines, which give the joint the appearance of being divided into two; there are on the outer surface other groups of spines both above and below the bushy group.

Lower Lip.—The principal lobes are distally rather narrow and dehiscent; from the curve which may be reckoned either to the distal or inner margin projects a row of seven close-set spines on one lobe and eight on the other, the two or three lowest having curved

tips. The inner lobes are strongly ciliated; the mandibular processes are very long, thin, and divergent, but with a slight inward curve.

First Maxillæ.—The inner plate small, with a long plumose seta on the apex; the outer plate broad, having on the truncale distal margin ten denticulate spines, of which one is simply fureate, two have one denticle apiece on the outer margin, the rest have from two to six denticles on the inner margin not very near to the apex; the first joint of the palp very short, the second long, not distally widened, curving over the outer plates, the distal margin carrying on one maxilla seven, on the other eight, spine-teeth, the outermost the longest; a series of seven slender spines begins on the outer surface a little way down the inner margin, and passes across towards the outer apex.

Second Maxillæ.—The inner plate rather shorter than the outer, with a series of plumose setæ beginning near the base of the inner margin and passing across the surface towards the outer apex; a series of spines begins below the middle of the inner margin and passes round the margin nearly to the outer distal corner; the outer plate has the distal margin fringed with long spines, and some shorter ones descend the outer margin for a short space.

Maxillipeds.—The inner plates broad, reaching nearly as far as the apex of the first joint of the palp, the distal margin broad, sloping away a little at the outer corners, carrying three spine-teeth and several slender feathered spines, the inner margins having plumose setæ and a spine-tooth close to the apex; the outer plates very broad, not reaching the end of the second joint of the palp, fringed on the serrate inner margin with about a dozen spine-teeth, the series being continued by five spines on the distal margin, below which on the very convex outer margin are three more, spaced, the lowest shorter than the preceding; the first joint of the palp short, the second long and rather broad, carrying spines at the outer apex and along the inner margin; the third joint longer than the first, expanding distally, and produced in a small pointed cap over the base of the finger, armed with feathered or pectinate spines before and behind, on the surface and at the apex; the finger is slender, slightly curved, tapering, tipped with a small very sharp nail, near the base of which the inner margin carries two or three setules.

First Gnathopods larger than the second. The side-plates small. The first joint reaching much beyond the side-plate, with small groups of spines at points of the hind margin and spinules in front; the short second joint with an apical group of several small slender pectinate spines; the third joint small, with many spines on the hind margin and its rounded apex, and on the surface near the front, the apex in front acute; the wrist massive, not quite so broad as long, nor so long as the hand, with five groups of spines on the convex front margin, the serrate hind margin thickly fringed with serrate spines, of which there are also groups on the surface and broad lower margin; the hand massive, with some seven rows of long spines at or near the convex front margin; the serrate hind margin is fringed with several groups of spines, and apically forms a triangular tooth the

inner side of which is serrate, and within which is set a strong palmar spine projecting beyond the tooth, and from this the finely but irregularly denticulate palm takes an oblique sinuous course to the hinge of the finger; besides the marginal groups of spines there are others on the surface and adjoining the palm, which is also fringed with short spines; the finger is much curved, and its sharp tip closes on to the surface at the base of the palmar spine, leaving a narrow space between the concave part of the palm and the distal inner margin of the finger; the inner margin almost to the nail is cut into numerous decurrent teeth, with spinules at the base of some of them, the dorsal cilium is lightly feathered, short but rather stout, near the base of the finger.

Second Gnathopods.—Side-plates small, rather broader and deeper than the preceding pair. First, second, and third joints of the limb much as in the first peræopods; the wrist nearly as long, but a good deal less broad, similarly armed, the spines of the hind border forming nine groups; the hand is as long as the wrist, almost oblong, with several groups of spines at or near the convex front margin, twelve groups along the serrate hind margin, which is not as in the first gnathopods very much shorter than the first; there are several other groups of spines along the surface and near the palm; the hind margin on one of the limbs produced into a small tooth, on the other it is not produced into a tooth, but it forms a definite angle, almost a right angle, with the slightly sinuous, finely pectinate, spine-bordered palm; the finger is stout, curved, of a length to fit the palm, the inner margin cut into teeth with a setule to every second or third tooth, and two or three longer setules near the base of the sharp nail, in respect to these and the dorsal cilium resembling the first gnathopods.

First Peræopods.—Side-plates like the preceding pair. First joint reaching much beyond the side-plate, pretty evenly broad except at the neck, packed with gland-cells, with some spinules along the front margins, some small spines along the hinder, and some moderately long setæ at the upper part of both; the second joint short, with a slender spine or two at the apex; the third joint much longer than the fourth or fifth, like the two preceding joints having abundance of gland-cells, which are dark in the preserved specimen; there are spinules and slender spines on both margins but in no great numbers; the fourth joint is much broader but a little shorter than the fifth, having the almost straight hind margin fringed with slender spines, the front margin more convex and carrying a spinule above and two or three small groups of spines below; the fifth joint narrows a little distally, and has nine or ten groups of slender spines on the hinder and two on the front margin; the finger is slightly curved, not half the length of the fifth joint, with a feathered cilium near the base, and an opening within the apex for the excretion from the gland.

Second Peræopods.—Side-plates wider than deep. The limb nearly as in the preceding pair.

Third Peræopods.—Side-plates broad but shallow, the front lobe a little deeper but

not much broader than the hind one, having many setæ on the inner surface, the hind lobe having a few, and a small spine at the further corner of its flat lower margin. The branchial vesicles broad, shorter than the first joint of the limb. The first joint little more expanded than in the preceding pairs, the spines few and small on either margin; the second joint with a small apical group in front; the third joint longer than the fourth but scarcely so long as the fifth, with two groups of slender spines and two of spinules on the slightly convex front margin, the hind margin interrupted at two points to receive short stout spines, and, besides one or two on the adjoining surface, having such with some long slender ones at the apex; the fourth joint with some mixed groups in front and at the apex behind, and some stout spines on the surface; the fifth joint with four groups in front, others near the hind margin, and a large tuft of long slender spines at its apex; the finger short, sharp, bent upwards, with a dorsal cilium near the hinge and another near the base of the nail.

Fourth Peræopods broken. The first two joints similar to those of the preceding pair.

Fifth Peræopods.—Much longer than the third. The first joint long but little expanded, with thirteen or fourteen spines along the hind margin, and rather fewer and smaller ones along the front; the second joint with setiform spines at the front apex; the third joint long and slender, with six prominent groups of spines on the hind margin and single spines at two or three other points; the front margin has some spinules and setiform spines; the fourth joint long, but considerably shorter than the third, with spines at intervals on both margins, but more prominent on the hinder; the fifth joint broken.

Pleopods.—The peduncles carrying numerous plumose setæ; the coupling spines bent, the heads much broader than the shafts, with three lateral retroverted teeth on each side below the apex; the cleft spines five in number in each pair; the joints of the rami nineteen in number on each ramus; the outer ramus, having a shorter first joint than the inner, is in each pair shorter than its companion; on the first joint of the inner ramus in the third pair some surface spinules were observed, one of which appeared to be cleft.

Uropods.—The peduncles of the first pair longer than the rami, with many spines along the two upper margins, and a large curved apical spine; the outer ramus a little shorter than the inner, six spines on the outer margin, two that are more slender low down on the inner, and a group of five at the blunt apex; the outer ramus has five and four spines on the margins and five at the apex; the peduncles of the second pair subequal in length to the rami, armed like the first pair; of the subequal rami one has seven spines on one margin, three on the other, and five at the apex; the other ramus has five and four on the margins and five at the apex; the peduncles of the third pair shorter than the rami; the rami short, the shorter with slender spines at two points of the outer and one point of the inner margin, and a group of five at the rounded apex, three being

long and setiform; the longer ramus has three spines on the outer and four on the inner margin, and half a dozen setiform spines at the rounded apex; of these rami, it is the outer apparently that is the shorter, not the inner as would be required by Boeck's account of this genus.

Telson not reaching beyond the peduncles of the third uropods, scarcely longer than broad, the apical margin forming three points, of which the central is a little the most produced; at each outer corner there is a cilium, and along the raised line which runs obliquely from each corner upon the upper surface there are on each side five setiform spines.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the extremity of the uropods, nine-twentieths of an inch.

Locality.—Station 162, off East Monceur Island, Bass Strait, April 2, 1874; depth, 38 fathoms; bottom, sand and shells. One specimen.

Remarks.—The specific name, from the Greek *φιλέω*, I love, and *ἄκανθα*, a spine, seems justified by the bush of spines on the mandibular palp and the row of spines on the lower lip, as well as the more usual spininess of the gnathopods.

The species has much resemblance to *Autonoë plumosa*, Boeck, from which, however, the antennæ and first gnathopods separate it, and likewise to *Microdeutopus australis*, Haswell, from Port Jackson, which is likewise an *Autonoë*, but distinguished from the present species by having the third joint of the peduncle of the upper antennæ "very short," by the first gnathopods, in which the wrist is described and figured as being larger than the hand, by having "second pair of pereiopoda longer than the first; dactylos in both long, slender," and lastly by having the rami of the third uropods "lanceolate."

Autonoë kergueleni, n. sp. (Pl. CXI.).

Rostrum small, lateral lobes of the head small, acute; in the first three pleon-segments the lower lobe of the hind margin taking the place of the postero-lateral angles, the separation between the lobe and the true lower margin being marked by a minute notch and setule; the third pleon-segment is longer than either of the two preceding segments; the fourth segment has a transverse dorsal depression.

Eyes small, situated on the lateral lobes of the head.

Upper Antennæ.—The first joint large, longer than the head, with some spinules and spines, chiefly on the under margin. The remainder of these antennæ broken off.

Lower Antennæ.—The first two joints short, the gland-cone small, acute, decurrent; the third joint broad, not twice as long as broad, armed with some slender spines; the fourth and fifth joints long, subequal in length, the fifth the thinner, both equipped with

slender spines, some of them long; the flagellum of seven joints, together not equal to the fifth joint of the peduncle, several of them tipped with curved spines, which on the last joint are short.

Upper Lip as in *Autonoc philacantha*.

Mandibles.—The cutting edges do not appear to have more than five teeth, the secondary plates four, or on the right mandible, perhaps only three; the spines of the spine-row five on the left, six on the right, mandible, slender, not very conspicuously dentieulate, curved, and directed backwards; the molar tubercle prominent, with strongly dentieulate crown and a plumose seta; the first joint of the palp a little dilated distally, the second joint with a few long and short spines along the front; the third joint as long as or longer than the second, and nearly as broad for much of its length; the front margin carrying four and the apex two long pectinate spines, the distal half of the inner margin being fringed with some fifteen short pectinate spines, the length slightly increasing as they approach the apex; besides these there is below the centre a transverse row of four unequal but very long curved pectinate spines near the outer margin, and above the centre a spine on the surface near the inner margin.

Lower Lip.—The principal lobes rather broad distally, the inner part of the distal margin and the inner margin ciliated, without spines; the inner lobes ciliated; the mandibular processes long, pointed, divergent.

First Maxillæ.—The inner plate small, with a long, not strongly plumose, seta on the apex; the outer plate with ten spines on the distal margin, constructed on the same general plan as those in *Autonoc philacantha*, but seemingly with only two or three lateral denticles where in the other species there were three or four; the first joint of the palp short, with a small spine on the outer apex, the second joint curving over but not much beyond the outer plate, a good deal broader distally than at the base, the indentured distal margin in one maxilla having six, in the other five, spine-teeth, the outermost the longest; there are five slender spines on the surface nearer to the inner than to the outer apex.

Second Maxillæ.—The inner plate shorter but slightly broader than the outer; a row of twenty-one setæ passes almost from the base of the inner margin across in a curve towards the outer apex; there are also some slender spines on the inner margin and round part of the apical margin; the outer plate has a straight inner margin, near the apex of which begins a series of half-a-dozen subapical spines, the apical margin itself, which is rounded with an outward slope, carrying several more.

Maxillipeds.—The inner plates broad, reaching as nearly as possible the distal end of the first joint of the palp, with several long setæ along the inner margin, and a bent spine-tooth just below the apex; the distal margin broad, occupied by three strong spine-teeth and a few slender setiform spines; the outer plates very broad, not reaching the end of the palp's second joint, with seven spine-teeth on the inner margin, and

two longer ones on the broad distal margin, followed by four successively more and more setiform; the first joint of the palp short, the second much longer, fringed with long slender spines on the inner margin; the third joint little longer than the first, dilated distally, the convex outer margin longer than the inner, but not produced over the base of the finger, the inner margin without spines, except near the apex; the finger, including the spine-like nail, is as long as the third joint, it has a couple of setules on the inner margin near the base of the nail, and a small dorsal cilium so close to the base that it might almost be supposed to belong to the third joint.

First Gnathopods larger than the second. The side-plates small, directed forwards at the front lower corner. The first joint almost entirely free from the side-plate, the front margin straight, unarmed, the hind margin convex, with a solitary seta high up; the second joint short, with a group of slender spines on the hinder apex; the third joint a little longer than the second, its two convex margins meeting at an acute apex, with groups of spines on the hind margin and on the inner surface above the apex; the wrist stout, much shorter than the hand, the hind margin closely fringed with spines in groups; the hand broader than the wrist, widening a little from the base, the front margin very convex, with a few spines on the apex, and groups on the surface at a little distance; the hind margin straight, carrying two or three groups of spines at intervals, and apically produced into a long tooth, with a spine on the outer side; there is a deep cavity on the inner side, of which the further margin is sinuous, apically forming a small tooth, beyond which the remainder of the palm is sinuously denticulate; the finger is short, curved, with seven or eight minute spine-teeth at intervals along the inner margin; it closes tightly against the denticulate part of the palm, but leaves open part of the cavity above-mentioned before the nail reaches the tooth-process of the hind margin; about the palm and on the surface of the hand near the hind margin there are various spines, slender and not numerous.

Second Gnathopods.—Side-plates small, rather wider above than below, the front margin a little concave. Branchial vesicles small, narrowly oval. The first joint almost entirely free from the side-plate, dilated after the manner usual with the last three pairs of peræopods, and as found also on the second gnathopods of *Gammaropsis exsertipes*; narrow at the base, and to a less extent distally, the margins having a few spinules, and the hind margin a setiform spine above the centre; the second and third joints nearly as in the first pair, but the third having its lower margin much more distinct from the hinder; the wrist little shorter and broader than the hand, with seven groups of spines on the convex hind margin, and some groups on the surface near it; the convex front margin armed along the lower two-thirds with many long curved spines; the hand, which is somewhat curved, of nearly even width throughout, has the long convex front margin armed with numerous long spines in many groups; the serrate and nearly straight hind margin carries four groups of slender spines, and has one or two stout palmar spines at

the slightly blunted angle which it makes with the finely pectinate, nearly straight palm; the finger is stout and short, with a rather long dorsal cilium near the base; its inner margin cut into teeth, the tip of the nail projecting just beyond the palm; the surface of the hand has several slender spines besides those on the margins.

First Peræopods.—Side-plates smaller, branchial vesicles larger, than in the preceding segment. The first joint of the limb nearly free from the side-plate, well packed with gland-cells, the front margin straight, the hinder slightly convex, both armed with small spinules, the hinder having also a seta or setiform spine high up; the second joint short, with apical spinules; the third longer than either the fourth or fifth, dilated a little distally, with slight spines at either apex, and a spinule on each margin; the fourth joint shorter than the fifth, with spines at two points on the hind margin and at the apex in front; the fifth joint with slender spines at three points on the upper half of the straight hind margin and one of the convex front, some spinules on either side of the narrowed rounded apex; the finger narrow, more than half the length of the fifth joint, with a dorsal cilium near the base, and an opening at the tip.

Second Peræopods not materially differing from the first.

Third Peræopods.—The side-plates broad, the front lobe deeper than the hinder, as deep as the preceding side-plates. The branchial vesicles narrowly oval, much shorter and narrower than the first joint of the limb. The first joint not greatly expanded, more than twice as long as broad, the sides slightly convex, with some slight spines at the front apex and spinules elsewhere; the short second joint with similar spines at the front apex; the third joint broader and longer than the fourth, not longer than the fifth, with some small spines at each apex, and one or two spinules on the front margin; the fourth joint with strong spines at two points near the hind margin and two at its apex with a slender spine; the fifth joint with spines at four points of the front margin, these being stronger than those of the upper joints, and with a group of longer spines at the apex of the convex hind margin; the finger upward bent, less than half the length of the fifth joint.

Fourth Peræopods much longer than the third. The side-plates and branchial vesicles smaller than in the preceding pair. The first joint with several plumose setæ or setiform spines on the hind margin, otherwise like the first joint of the preceding limb, but longer and wider; the third joint elongate, much longer than the fourth, subequal in length to the fifth, with slender spines at four points of the hind margin, slenderer spines at two points of the front margin, and spinules elsewhere; the fourth joint similarly armed in front, but behind having a strong spine at two points near the hind margin, and two strong spines and some slender ones at its apex; the fifth joint with spines at five points in front and some spinules behind; the finger acute, upward curved, not half the length of the fifth joint, with a long dorsal cilium at the base.

Fifth Peræopods much longer than the preceding pair, and twice as long as the third

pair. Side-plates small. All the joints of the limb longer than in the fourth peræopods, but the third, fourth, and fifth joints especially so; the third joint is longer than the fourth but shorter than the fifth; the fourth joint is elongate, with spines at four points of the hind margin or near it; the fifth joint has spines not regularly spaced at seven points of the front margin; the finger is scarcely one-third the length of the fifth joint.

Pleopods.—Coupling spines slender, bent, with an apical pair of retroverted teeth and a similar pair a little below the apex; the cleft spines are three in number on the first pair and two only on the third; there are some small surface spines on the first joint of the inner ramus; the joints of the inner ramus ten in number, of the outer and shorter only nine.

Uropods.—The peduncles of the first pair a little longer than the rami, with few marginal spines, a large spine at the lower apex; the rami equal in length, or nearly so, the inner with five spines along one upper margin, two or three near the top of the lower, and a large apical group, the outer ramus with two spines low down on one margin and an apical group; the peduncles of the second pair not so long as the inner ramus, with two spines at the inner apex and a large one at the outer; the longer ramus has four spines on one of the upper margins, two on the other, two near the top of the lower margin, and a large apical group of five; the shorter ramus has three spines on the upper margin and an apical group of five; the peduncles of the third pair shorter than the short rami; the inner ramus rather the shorter, with two rather elongate spines below the centre, and five at the blunt apex, one with a setiform termination; the outer ramus similarly armed, but with the terminal spines longer, three of them with setiform ends.

The Telson very little longer than broad, reaching beyond the peduncles of the third uropods, the centre of the distal border convex, the extremities acute, with a long setiform spine projecting from the surface above and within each; there is also a marginal cilium or two a little higher up.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the extremity of the uropods, one-fifth of an inch.

Locality.—Station 149H, off Cumberland Bay, Kerguelen, January 29, 1874; depth, 127 fathoms; bottom, volcanic mud. One specimen.

Remarks.—The specific name refers to the place of capture. A female specimen from the same locality, which I regard as probably belonging to this species, has the wrist of the first gnathopods nearly as long as the hand, the hand itself dilated at the palm, which has no dental process, but is finely pectinate as in the second gnathopods, the nail of the finger reaching beyond it and antagonising with a long palmar spine.

For the original definition of this genus, see Note on Liljeborg, 1855 (p. 286). For the definition of *Eurystheus*, see Note on Spence Bate, 1857 (p. 294). For the definition of *Paranænia*, see Note on Chilton, 1884 (p. 550). It was rather for a subdivision of the genus *Gammarus* than for an independent genus that Liljeborg gave the name *Gammaropsis*, and this is confirmed by the circumstance that he does not include the name *Gammaropsis* in the table of genera which he drew up for the Gammaridæ in 1865. It is therefore perhaps an open question whether the name *Eurystheus* which Spence Bate proposed for the genus in 1855, though he did not define it till 1857, should not have been allowed priority. As matters stand, it will be, I think, convenient to give the preference to *Gammaropsis*, which has obtained the more general acceptance. Boeck gives the following definition :—

- “ Upper Antennæ with the third joint of the peduncle very long.
 - “ Hypostome produced in front and acuminate.
 - “ Fourth pair of side-plates the largest.
 - “ First and Second Gnathopods in both sexes like one another, but the Second the stronger; the fifth joint constituting a subcheliform hand.
 - “ First and Second Peræopods with the finger of moderate size.
 - “ Third Uropods with the outer ramus a little shorter than the inner.”
- To these characters should be added the presence of a well-developed accessory

flagellum on the upper antennæ, while the similarity in shape between the first and second gnathopods is, to say the least, too slight and vague to be worth insisting on ; the new species, *Gammaropsis afra*, has the outer ramus of the third uropods a little longer, instead of a little shorter, than the inner.

To complete Boeek's view of this group, I give his definition of Kröyer's *Protomedeaia*, which is as follows :—

“ *Second Gnathopods* stronger than the *First* and in the male more robust than in the female.

“ *Third Uropods* with the inner ramus shorter than the outer.

“ *First and Second Peræopods* with the finger tolerably elongate.

“ In other respects almost as in the genus *Microdeutopus*. ”

Gammaropsis exsertipes, n. sp. (Pl. CXII.).

Rostrum little developed, lateral lobes of the head narrow, acute ; postero-lateral angles of the first three pleon-segments rounded.

Eyes small, nearly round, situated on the lateral lobes of the head, retaining a little colour in spirits.

Upper Antennæ.—First joint as long as the head, moderately thick, with several setiform spines on the lower margin and upper apex, and a stouter short spine at the lower apex ; the second joint thinner but much longer than the first, the lower margin fringed with many slender curved spines, the longest at the distal end ; the third joint intermediate in length between the first and second, fringed like the second ; the flagellum of seventeen unequal joints, together not as long as the peduncle, the first the longest, all carrying slender spines, and most of them cylinders, the terminal joint tipped with some setæ and a short stiff spine ; the secondary flagellum of four very slender joints, together not quite equalling in length the first three of the primary.

Lower Antennæ not quite so long as the upper ; the first two joints short, set far back on the underside of the head, the gland-cone narrow, decurrent ; the third joint longer than the preceding two united, widening a little distally, with slender spines on the margin, and a short stiff spine at the lower apex ; the fourth joint prismatic rather than cylindrical, nearly as long as the second of the upper antennæ, and with similar spines ; the fifth joint a little shorter than the fourth, similar ; the flagellum of twelve unequal joints, the first the longest, the spines of the various joints and the terminal armature much as in the upper antennæ.

Upper Lip rather unsymmetrically bilobed.

Mandibles.—The cutting edge with four large teeth and probably two small ones ; the secondary plate of the left mandible (figured on the right hand of the Plate) with four strong teeth ; the secondary plate of the right mandible apically bifid, its upper or

outer edge denticulate; the spine-row of four denticulate spines and a small seta; the molar tubercle prominent, the crown set with numerous denticles which appear to be stronger round the margin than over the concave surface; there is a feathered seta on the side; in the right mandible the molar tubercle has, attached to the margin on its outer surface, a small thin plate expanding distally, striated, with finely pectinate edge, similar to that observed in *Photis macrocarpus*; a broad-limated process rises near the base of the palp; the palp is of great size compared with the trunk of the mandible; the first joint short, widening a little distally; the second joint long, with seven groups of spines on the hind margin, the front fringed for its whole length with a double row of spines of various lengths, at the lowest part having a row of five which are straight and graduated in length, the lowest the shortest; the third joint shorter than the second, but long, widening distally, with four spines on the outer surface near the base and the outer margin, three on the inner surface also near the outer margin but a little way below the apex, the apex itself set about with many long feathered and pectinate spines, groups of which descend the inner margin for three-quarters of its length.

Lower Lip.—The distal and inner margins of the principal lobes rather flattened, not strongly ciliated; the inner plates distally broad; the mandibular processes long, narrow at the tips.

First Maxillæ.—The inner plate small, with the outer margin convex, the inner straight, armed near the apex with a spine-like seta, below which is a much shorter one, the apex narrow and unarmed; the outer plate has only nine spines on the apical border, three of them apically forked, the rest with one or two lateral teeth on the inner margin; the long second joint of the palp expands distally, curving over the outer plate, the distal edge having five spine-teeth followed by three more slender, which descend the inner margin, while a series of nine slender plumose spines, beginning on the upper part of the inner margin, crosses the surface towards the outer apex.

Second Maxillæ.—The inner plate shorter and narrower than the outer, fringed with spines round the apex and down the inner margin below the middle; the broad, slightly convex distal margin of the outer plate fringed with long spines, one series of which passes a little way down the inner margin; there are none on the outer margin.

Maxillipeds.—The inner plates oblong, distally a little widened, not quite reaching the apex of the first joint of the palp; a series of a dozen plumose setæ beginning near the middle of the inner margin passes across the inner surface towards the apex; the slightly convex distal margin has three spine-teeth and six or seven feathered spines; the outer plates not nearly reaching the distal end of the palp's second joint, with nine spine-teeth along the inner margin, and seven longer spines round the distal border; the first joint of the palp short; the second long with many spines on the inner margin, and one or two at the apex of the outer and at a point below it; the third joint not longer than the first; scarcely expanded distally, with long spines about the apex and the distal half of the

inner margin ; the finger nearly as long as the third joint, narrowing very gradually till the apical part, which carries four slender spines on the oblique inner margin, and at the tip no nail but a strong spine, which is long but not nearly so long as the body of the finger, nor so long as a slender spine next to it.

First Gnathopods.—Side-plates small, directed forwards, but not covering the base of the lower antennæ. The first joint narrow at the neck, extending much beyond the side-plate, with many long setæ on the convex hind margin, and others along the surface ; the second joint with a large apical group of spines ; the third joint with the two convex margins converging to a pointed apex, carrying many groups of spines on the surface and along much of the hind margin ; the wrist almost as long as the first joint and distally wider, the long front margin little convex, with a group of spines at the apex, and some spinules elsewhere, the convex serrate hind margin fringed with numerous groups of spines, of which there are several also on the surface and hinder apex ; the hand rather shorter than the wrist, the front margin convex, with six or seven groups of spines in rows on the adjacent surface ; the hind margin much more convex than the front, the major part of it, which may be regarded as the palm, being finely pectinate, the surface immediately adjacent and at a little distance carrying several groups of spines, besides which there are many single spines and spinules at intervals along the margin ; the finger is of great size, in the larger specimen (but not in the female) longer than the hand, and no doubt adapted for impinging against the wrist or to hold fast an object pressed against the wrist ; the dorsal cilium is small, near the base ; the inner margin is cut into seventeen little teeth, resembling spine-teeth, with a hair or cilium adjacent to each, or with few exceptions ; at a little distance from the base of the sharp nail two or three setules are inserted.

Second Gnathopods not much longer, though very much broader, than the first pair. The side-plates deeper and much broader than in the preceding segment, broader than deep, the lower margin rather concave in the middle. The first joint almost entirely free from the side-plate, and expanded in a very abnormal manner, more like the first joint of one of the hinder peræopods than like that of a gnathopod ; the breadth is greatest a little way below the narrow neck or point of attachment, from which the upper margin at once spreads out on either side ; the hind margin, which is slightly convex, has some long setæ at the upper part, and two or three spinules below these ; the front margin is crenulate, with setules in the notches ; the lower margin projects for some distance in front of the second joint, but is much narrower than the upper margin ; the second joint has a group of slender spines at the hinder apex ; the third is more squared, and with fewer spines than in the first gnathopods ; the wrist is short, triangular, distally cup-like, as broad as long, narrower than the hand, with a few spines at and near the front apex, many round the apex of the hind margin, some on the lower margin ; the hand is very large, widening from the base, considerably longer than its greatest breadth, which is at

the commencement of the oblique palm ; the front margin a little convex, with several groups of spines on or near the distal half, the hind margin nearly straight, carrying some seven large groups of spines, and apically ending in a long narrow tooth, within which is a very small palmar spine ; from this the palm runs in a very oblique but even course towards the hinge of the finger, before reaching which it forms a second tooth-like process smaller than the first, by means of the small cavity which precedes the broad irregular process that extends to the hinge ; the margin of this long palm is set with spinules and some of the groups of spines which are dispersed upon the broad surface of the hand ; there seem to be no strong or broad spines in any part of the limb, the little palmar spine not constituting an exception ; the finger is very much curved, and when closed does not reach the small palmar spine, but rests against the surface at some distance from it ; its inner margin as in the finger of the first gnathopods.

In the female the first joint, though tolerably broad, is not abnormally so ; there is only a small acute tooth process at the commencement of the palm, having a palmar spine at its side, followed by another further on ; the second process is wanting, the oblique margin is finely pectinate. The marsupial plates are rather broad and long, with many setæ.

First Peræopods.—The side-plates with the lower margin convex. The first joint rather long, narrow only at the neck, with gland-cells down each side, some moderately long setæ and some spinules on the margins ; the second joint rather longer than broad, with a spine or two at the hinder apex ; the third joint much longer than the fourth, widening distally, with small groups of spines at three points of the straight hind margin, and at the apex and one other point of the slightly convex front margin ; the fourth joint with spines at three points behind and the apex in front ; the fifth joint nearly as long as the third, with spines at five points behind and two in front ; the finger slender, curved, more than half the length of the fifth joint, with an opening on the inner side of the tip for the excretion from the gland.

Second Peræopods almost the same as the preceding pair.

Third Peræopods.—The side-plates broad, with the front lobe very deep, the hinder quite small. The limb missing in the large specimen, in the smaller resembling in structure the following pairs, but notably shorter.

Fourth Peræopods.—Side-plates very small, scarcely bilobed. The first joint of the limb not greatly dilated, wider above than below, with some small spines along the slightly convex front margin, the hind margin nearly smooth, with a few setules, the convexity chiefly at the upper part ; the second joint with some small apical spines in front ; the third joint much longer than the fourth, with spines at three points on each margin, those behind in general stronger than those in front ; the fourth joint widening like the third distally, with a group of spines at each apex ; the fifth joint longer than the third, with spines at five points of the front margin and three of the hinder ; the

finger acute, curved at the tip, a little more than half the length of the fifth joint, with a dorsal feathered cilium very near the hinge, and a small hair near the base of the nail.

Fifth Peræopods.—Side-plates very small, not bilobed, the limb scarcely differing from that of the fourth peræopods, but rather longer, and the first joint having the hind margin more flattened at the top.

Uropods.—The peduncles of the first pair longer than the rami, with nine spines on one and ten on the other of the upper margins, a large curved spine on the apex below; the outer ramus shorter than the inner, with a row of eight marginal spines and an apical group of four, the marginal spines of the longer ramus only seven in number; the peduncles of the second pair longer than the outer ramus, but scarcely so long as the inner, with a long spine on the lower apex; the outer ramus with six spines on one margin, three on the other, and the apical group as in the first pair; the inner ramus with seven spines on one margin and four on the other, besides the apical group; the peduncles of the third pair reaching beyond the peduncles of the two preceding pairs, longer than the rami, with one apex acute, and seven spines on one margin including the apex, and four on the other, the two lowest being side by side; the rami are small, subequal, not reaching so far back as the inner ramus of the second pair, each having two marginal spines, and probably one at the apex; the inner ramus slightly longer than the outer.

Telson not nearly reaching the end of the peduncles of the third uropods, a little longer than broad, widest at a little distance from the base, then with the sides almost straight, converging rapidly towards the triangular apex; at about the centre on either side, at a little distance from the margin, there is a strong spine on the surface, and between this and the margin a feathered cilium; the margin below as far as the angle at which the apical triangle begins is armed with little spines or scales, about forty in number on either side.

Length.—The longer specimen, in the position figured, measured, in a straight line from the front of the head to the extremity of the uropods, two-fifths of an inch.

Locality.—Kerguelen Island; depth not specified. Three specimens, two males and one female.

Remark.—The specific name refers to the remarkable prominence of the second gnathopods, especially in the male.

Gammaropsis afra, n. sp. (Pl. CXIII.).

Rostrum small, lateral lobes of the head narrow, acute; postero-lateral angles of the first three pleon-segments not much rounded.

Eyes deeper than broad, close to the front margin, occupying the space between the rostrum and the front part of the lower border of the lateral lobes.

Upper Antennæ similar to those of *Gammaropsis exsertipes*; but the first joint of the primary flagellum not the longest, and the secondary flagellum not so slender, consisting of six joints, together equal in length to the first four or five of the primary, the terminal joint minute.

Lower Antennæ in general as in *Gammaropsis exsertipes*, but with the fifth joint longer than the fourth, the spines stronger, especially on the flagellum, the three terminal joints of which have each a pair of short spines with accessory threads, the upper joints having both longer and shorter spines similarly furnished.

Upper Lip.—The distal border appears to be evenly convex.

Mandibles.—The cutting edge with five or six teeth; the secondary plate on the left mandible with four teeth, that on the right mandible slighter, with the edge much subdivided, with two principal teeth below, and several denticles above on the edge facing the principal plate; the worn plate has more denticles than the one in preparation; the spine-row has on the left mandible ten, on the right nine, long bent denticulate spines, those nearest the cutting plate very broad; the molar tubercle prominent, with long denticles round the crown; the first joint of the palp short, widest distally; the second joint long, the front margin fringed with many spines of different lengths, the hind margin also having five or six groups; the third joint not so long as the second, but long, expanding distally, with many groups of long spines along the hind margin, and having the rather broad distal margin set with many long spines, the series also passing down nearly to the base of the inner margin, many or most of the spines of the third joint being strongly pectinate.

Lower Lip.—The principal lobes forming a definite angle at the meeting of the distal and inner margins, at which point there are two small spines; the inner lobes widest below the distal margin; the mandibular processes long and narrow.

First Maxillæ.—Inner plate small, with eleven plumose setæ along the sinuous inner margin and a short seta at the narrow apex; the outer plate with nine or ten spines on the distal margin, variously denticulate, some on the outer and some on the inner margin, and some apically; the first joint of the palp short, with a spine near the apex of the outer margin; the second joint long, slightly widening from the base, reaching beyond the outer plates, the distal margin having seven spine-teeth, the outermost the longest, the rest serrate on the outer margin; on the surface below these are seven slender feathered spines.

Second Maxillæ.—The inner plate shorter and a little narrower than the outer, with a series of twenty plumose setæ beginning near the base of the inner margin and passing across the surface towards the outer apex; the inner margin is also fringed with spines from below the middle, and feathered or pectinate spines pass almost round the apex; the outer plate has the apex set with many long spines, but there are none on the lateral margins.

Maxillipeds.—The inner plates widening distally, not reaching quite to the apex of the palp's first joint, with setæ and spine-teeth as in *Gammaropsis exsertipes*, but the spine-teeth broader at the base; the outer plates not nearly reaching the end of the second joint of the palp, with seven spine-teeth on the serrate inner margin, and five or six long curved spines round the serrate apieal margin, the two lowest almost setiform; the first joint of the palp short, the second long, with many spines along the inner margin, and a group above the middle, and another at the apex, of the outer margin; the third joint as long as the first, expanding a little distally, set round the apex, the distal half of the inner margin, and on the surface with many spines; the finger very short, with a strong spine projecting from its apex, the spine longer than the body of the finger, the inner margin of which carries four slighter spines near the large one.

First Gnathopods.—Side-plates not produced at the lower corner, neither reaching nor directed towards the basal joints of the lower antennæ. The first joint reaching considerably beyond the side-plate, narrow at the point of attachment but presently widening, with setæ on the upper part of the convex hind margin, and groups of slender spines below, channelled in front and having the front margins a little eoneave; the second joint with a group of spines near the hinder apex; the third joint with several groups of spines along the hind margin and round the apex; the lower margin eoncave, forming an aeute front apex; the wrist not quite so long as the first joint, subequal in length to the hand, and almost as broad, the front margin having two groups of spines, the surface several broad rows of them, the hind margin numerous groups, some of the spines being strongly pectinate; the hand longer than broad, broadest at the beginning of the slightly oblique and convex pectinate palm, both margins having numerous rows of spines on the adjacent surfaces; smaller groups occupy the centre of the surface, and the palm margin has scattered spines as well as groups. The finger fits the palm, reaching as far as the point where a palmar spine is inserted, not on the margin, but the surfaces; its inner margin is divided into small decurrent teeth, and there are some setules near the base of the nail.

Second Gnathopods.—Side-plates a little broader and deeper than the preceding pair, with small setules round the convex lower margin. Marsupial plates short, surrounded with long setæ. The first joint reaching much beyond the side-plate, the front channelled, eoncave, carrying spinules at intervals, the hind margin convex, fringed with groups of long spines or setæ; the second and third joints as in the first gnathopods, but with fewer spines on the hind margin of the third joint; the wrist much shorter than the hand, distally eup-like, with spines at the apex in front, and along the lower margin on the inner surface, and in six or seven groups along the serrate hind margin; the hand not twice as long as broad, with seven or eight groups of spines along or near the convex front margin on the inner surface, nine large groups along the serrate hind margin, which is not produced into a tooth at the commencement of the oblique palm, which forms an angle with it, and is for a short space eoneave, then convex,

minutely pectinate, fringed with small spines ; the finger is curved, with the usual dorsal cilium ; the nail closes down against a palmar spine, set on the surface at some distance from the hind margin. There are scattered groups of spines on the surface besides those already mentioned.

First Peræopods.—The side-plates very similar to the preceding pair. The first joint of the limb reaching much beyond the side-plates, well packed with gland-cells, the hind margin fringed with long spines, the front with short ones ; the second joint with an apical group of spines ; the third joint much longer than the fourth, with spines at three points behind and the apex in front ; the fourth joint like the third widening distally, the hind margin fringed with numerous slender spines, the apex in front carrying a small group ; the fifth joint longer than the fourth, shorter than the third, narrowing distally, with some six groups of slender spines on the straight hind margin, a group at the apex of the front convex margin, and another high up on it ; the finger more than half the length of the fifth joint, with an opening at the tip, and near the base a long dorsal feathered cilium.

Second Peræopods not specially examined ; similar to the preceding pair.

Third Peræopods.—The side-plates broad, the front lobe large, nearly as deep as in the preceding pair, the hind lobe small. The first joint of the limb scarcely longer than broad, dilated above, narrowing distally, with spines, but not stout ones, at intervals on the slightly convex front margin and the upper margin adjoining ; the hind margin very convex above, carrying a few spinules, and near the apex a stout spine ; the second joint with an apical group of slender spines ; the third joint broader than the fourth, but about as long, with spines at the apices ; the fourth joint bordered with some short stout spines ; the fifth joint much longer than the fourth, with stout spines at three points in front, slender ones at two points behind ; the finger short and strong, very much curved, with a dorsal feathered cilium near the hinge, and a smaller cilium near the base of the sharp nail.

Fourth Peræopods.—Side-plates very shallow. The limb missing.

Fifth Peræopods.—Side-plates small and shallow. The limb a good deal longer than that of the third peræopods. The first joint broader above than below, but not greatly dilated at any point, much longer than broad, with spinules on the slightly convex front margin, and setules on the almost straight hind margin, which has a stout spine near the apex ; the second joint longer than broad, with an apical slender spine ; the third joint longer than the fourth, with stout spines at three points of the hind margin, one at the apex in front, with other slenderer spines on that margin ; the fourth joint with spines at two points on the hind margin, and two or three in front ; the fifth joint longer than either of the preceding, with four groups of spines in front, and three of slenderer spines behind ; the finger not nearly half the length of the fifth joint, longer and less strongly curved than in the third peræopods, but similarly armed.

Pleopods.—The pair examined had many groups of long spines or setæ on the peduncles; the coupling spines small, bent, with an apical pair of retroverted teeth and a similar pair just below the apex; the cleft spines four in number; the joints numbering eleven on the inner, and thirteen on the outer, ramus.

Uropods.—The peduncles of the first pair longer than the rami, with a very large apical spine besides the small ones on the margins; the outer ramus shorter than the inner, with five spines on one margin, three that are more slender on the other, and an apical group of five; the inner ramus with six on one margin, four on the other, and the apical group; the peduncles of the second pair about as long as the inner ramus, armed with some very stout spines; the outer ramus a little shorter than the inner, with four very stout spines on one margin, three more slender on the other, and the apical group; the inner ramus with four spines on one margin, six on the other, and the apical group; the peduncles of the third pair a little longer than the rami, reaching beyond the peduncles of the preceding pairs; the outer ramus a little longer than the inner, with a stout spine on the outer margin, at the blunt apex two stout spines with accessory threads and three more slender which are distally feathered; the inner ramus with two spines on the outer margin, three on the inner, and one at the almost acute apex. In the figure *Pl.*, the inner ramus of the first pair on the left side, and the inner ramus of the second pair on both sides, have been accidentally left without mark of separation from the respective peduncles.

The Telson short, scarcely longer than broad, not reaching the end of the peduncles of the third uropods, the sides converging very slightly, the lower margin forming a broad shallow triangle, with a stout spine just within each outer corner, the apex tolerably sharp; there are some feathered cilia on the lateral margins.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the extremity of the third uropods, three-tenths of an inch.

Locality.—Station 142, off Cape Agulhas, December 18, 1873; lat. $35^{\circ} 4'$ S., long. $18^{\circ} 37'$ E.; depth, 150 fathoms; bottom, green sand; bottom temperature, 47° . One specimen.

Remark.—The specific name refers to the place of capture, just at the south of Africa.

Gammaropsis atlantica, n. sp. (*Pl. CXIV.*).

This species I was long inclined to identify with *Gammaropsis afra* from the south of Africa, but a minute comparison has induced me to establish it as a separate species.

Rostrum very small, lateral lobes narrow, acute, strongly produced; the postero-lateral angles of the first three pleon-segments rounded; the fourth and fifth carrying the

usual pair of dorsal setæ or spines. The animal covered in many parts of the mouth-organs, as well as the exterior, with dark stellate markings, an enlarged figure of one of which is given in the right hand lower corner of the Plate.

Eyes of very peculiar shape, lageniform, occupying the front of the lateral lobes, and produced upwards in a narrow neck round the part of the concave margin between the rostrum and the lateral lobes.

Upper Antennæ.—The third joint about equal in length to the first; the principal flagellum of seventeen joints; the secondary flagellum of six joints together equal to the first five of the principal.

Lower Antennæ.—The third joint a little upward bent; the fourth and fifth joints equal or nearly so; the flagellum of ten joints.

Mandibles.—On the left mandible there are twelve spines in the spine-row; the secondary plate of the right mandible has four clearly cut teeth followed by one or two denticles; the second joint of the palp has only two groups of spines near the outer margin; the third joint is as long as the second and distally a good deal broader, with spines singly or in groups at five points near the outer margin.

First Maxillæ.—The apex of the inner plate is still more narrowly produced than in the other species; the ten spines on the apex of the outer plate are as in that species.

Second Maxilla.—The row of plumose setæ on the inner plate numbers twenty-six; the distal margin is flattened and more than half of it devoid of spines.

Maxillipeds.—On the outer plates the inner margin has six spine-teeth, the distal margin has six spines, of which the first is a strong spine-tooth, the three outermost are setiform, the other two of intermediate character; the first joint of the palp has slender spines on the outer apex; the second joint has a similar group, but no others on the outer margin; the third joint has surface spines at about the middle; the spine at the tip of the finger is a little shorter than the body of the finger.

First Gnathopods.—The side-plates are produced at the lower front corner and reach the base of the lower antennæ. The finger reaching beyond the palm.

Second Gnathopods.—The side-plates directed a little forwards. The branchial vesicles (not observed in the other species) very small and narrow. The marsupial plates much longer and broader than the branchial, gradually narrowing downwards, surrounded by long setæ. The first joint with only a few setæ on the convex hind margin; the hand oblong, but slightly narrowing towards the palm and with the front margin convex, the hind margin serrate, produced into a long tooth at the commencement of the palm, which is not very oblique, irregularly convex, and erinate; the much-curved finger reaches with the nail quite beyond the process which defines the palm; it has just within the inner margin a beaded appearance, seemingly caused by the presence of nine or ten minute spine-teeth which do not project beyond the margin.

Fourth Peraopods.—The first joint pear-shaped, with some spinules along the almost

smooth margins, a slender spine near the apex behind; the third joint longer than the fourth, these and the fifth and sixth being, as it were, reversed, the hind margin of the third and fourth nearly straight, each with strong spines at two points, the third with slender spines at two points in front, the fourth with spines at the apex of its convex front margin; the fifth with strong spines at four points of the straight hind margin and slender ones at four points of the convex front; the finger short, strongly bent, with a cilium at the base of the sharp nail.

Pleopods.—The pair examined resembling those of *Gammaropsis afra*.

Uropods and *Telson* in very close agreement with those of the species just named, yet not without minute differences, such as that the spines on the telson are not at the outer corners of the apieal triangle, but further in upon the surfacee.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the extremity of the uropods, three-tenths of an ineh.

Locality.—Off St. Vincent, Cape Verde Islands. One specimen, female.

Remark.—The specific name refers to the habitat.

Gammaropsis thomsoni, n. sp. (Pl. CXV.).

Rostrum scarcely pereetible, lateral lobes narrow, almost angular, with the lower margin long, convex at first; the postero-lateral angles of the third pleon-segment forming a little slightly upturned point, which does not project beyond the lower lobe of the hind margin; the corresponding points on the first and second segments are minute; the fourth segment has a small dorsal tooth in the centre of a postero-dorsal emargination, which is flanked by sharp points and has a seta or spine in each angle; the fifth segment has a similar emargination with the spines, but without the central tooth; the sixth segment is provided on either side of the telson with one or two short apical spines.

The Eyes are eomparatively large, with numerous oeelli, closely fitted to the margin of the lateral lobes.

Upper Antennæ.—First joint rather long and thick, with some slightly feathered setæ on the lower margin and a spine at its apex; the remainder missing.

Lower Antennæ.—First and second joints short, gland-cone small, decurrent, aeute at the tip; third joint longer than the preceding two united, with several spines, some of them long, setiform, and slightly feathered, on the lower margin and apex, and with two or three short spines on the upper margin. The remainder missing, but a detaehed joint, which probably is the fourth of the lower antennæ, is long, slightly curved, narrower at the base than elsewhere, and fringed with numerous spines, some of which are of great length.

Upper Lip.—The distal margin broad, furred, rather unsymmetrically insinuate.

Mandibles.—The cutting-edge divided into six or seven unequal teeth; the secondary plate on the left mandible divided into four or five teeth like those on the principal plate; on the right mandible the secondary plate is more ribbon-like, obliquely cut into four sharp teeth facing the principal plate, the lowest of the four much the longest; the spine-row is long, containing eleven or twelve long denticulate spines; the molar tubercle is very prominent, with finely dentate somewhat rounded crown; the palp is large, the first joint short, widest distally; the second joint of moderate length, carrying in front two rows of spines, many of which are very long; near the middle of the hind margin is a group of three, and a smaller group above, and another below, the middle; the third joint is as long as the second and distally wider; on the outer surface near the base are seven or eight long spines, and two others above them on the inner surface close to the outer margin; this margin is convex, interrupted a little before reaching the apex, and at that point shows a transverse group of several long, curved, slightly feathered spines; the apex itself is broad, fringed with similar spines, and there are many spines down much of the convex inner margin, but these spines are smaller than those at the apex.

Lower Lip.—The principal lobes distally broad, strongly ciliated along the inner margin, at the distal part of which there are two little spines; the oval inner plates are broad distally and strongly ciliated; the mandibular processes are very narrow and divergent.

First Maxillæ.—The inner plate with a sinuous inner margin, fringed with nine spaced setæ; the apex acute, tipped with a stule; the inner plate having ten spines on the distal margin; the innermost has a single lateral denticle low down; this is followed by three which have two lateral denticles on the outer side, the lower of the two exceedingly small, one spine is apically furcate; the remainder appear to have few denticles on the inner margin; the first joint of the palp is short, the second long, curved, widening a little from the base, having seven serrate spine-teeth on the distal margin, and about ten slender spines on the distal part of the inner margin and submarginal to the apex.

Second Maxillæ.—The inner plate shorter than the outer and a little less broad, with a row of twenty-six long plumose setæ passing from the base of the inner margin across the surface towards the outer apex; much of the inner margin fringed with spaced spines, and the front part of the rounded apex with close-set spines; the outer plate with many spines round the apex.

Maxillipeds.—The inner plates oblong, reaching beyond the first joint of the palp, with numerous plumose setæ on the inner margin, three spine-teeth and several feathered setæ or spines along the broad distal margins, which slope a little inwards near the inner angle; the outer plates not nearly reaching the end of the palp's second joint, the inner

margin carrying nine spine-teeth, the distal margin four longer spine-teeth and three or four setiform spines; the first joint of the palp very short, the second long, with slight spines at three points of the outer margin, and very many long ones along the inner margin and adjoining surface; the third joint longer than the first, widening distally, the distal half carrying numerous spines; the finger short, broad, with long apical spines instead of a nail, the principal spine longer than the body of the finger; the distal half of the finger's lower margin fringed with long slender spines; the dorsal cilium small, very near the hinge.

First Gnathopods.—Side-plates small, about as broad as deep, directed a little forwards. The first joint almost free of the side-plate, with some spinules along the slightly concave and pectinate front margin, and a slender spine and spinules at the apex of the convex hind margin; the second joint short, with a small group of spines at the middle of the hind margin and a group of several long ones near the apex; the third joint with spines on both margins, and on the inner surface, especially across the distal margin; the wrist longer than the hand, widening distally, the hinder margin fringed with many long spines, and the inner surface carrying many groups; the hand a little broader than the wrist, the hind margin, palm included, much more convex than the front, fringed with six groups of long spines; the inner surface carrying six groups of long spines in the neighbourhood of the front margin, and four or five smaller groups near the centre; the palm finely pectinate, set with some palmar spines and many spinules in addition to the groups of long spines; the finger broad, curved, the inner margin having about eight decurrent teeth, and fitting closely to the palm; the dorsal cilium small, near the base.

Second Gnathopods.—Side-plates small, much larger than the first pair, breadth and depth about equal, with some spinules along the lower and hinder margins. The branchial vesicles about as long as the first joint, and rather wider. The marsupial plates narrower than the branchial vesicles, a little longer, fringed with about forty setæ. The first joint nearly free from the side-plate, with spinules along the margins; the second and third joints less strongly spined than in the first pair; the wrist and hand together as long as the wrist and hand of the first gnathopods, but here the wrist smaller and shorter, the hand longer and larger; the wrist triangular, rather longer than broad, distally cup-like but not broadly, with spines at the apex of the front margin, three large groups along the serrate hind margin, and a still larger group about its apex and on the lower margin adjacent; the hand longer than broad, widening out from the wrist, the greatest breadth at the commencement of the palm, which is long, oblique, forming an obtuse angle with the hind margin, defined by four palmar spines, fringed with spinules and groups of long spines, and denticulate, two larger teeth rising amidst the smaller; besides some surface groups, there are spines at intervals along the convex front margin of the hand, and the serrate hind margin has nine or ten groups; the finger is strong

and curved, just reaching the end of the palm; the inner margin smooth, but forming a tooth just in front of the nail and bordered with a few small setules and tiny spine-teeth, neither series projecting beyond the edge; dorsal cilium as in the first gnathopods.

First Peraopods.—Side-plates, brachial vesicles, and marsupial plates rather larger than in the preceding segment, otherwise very similar. The first joint rather longer and broader than in the second gnathopods, showing closely-packed gland-cells; the second joint short, with spinules at two points of the hind margin and a small group of slight spines at its apex; the third joint broad, well-packed with gland-cells, widest distally, longer than the fourth joint, with spinules or spines at two points in front and three behind; the fourth joint not nearly twice as long as broad, with spines at four points of the hind margin and the apex of the front; the fifth joint longer than the third, with spines at six or seven points along the hind margin and two on the convex front margin, which like the preceding joint has also a spinule high up; the finger curved, more than half the length of the fifth joint, with an obvious aperture at the tip for the exudation from the gland.

Second Peraopods.—Side-plates, brachial vesicles, marsupial plates, and limb scarcely distinguishable from those of the preceding segment.

Third Peraopods.—Front lobe of the side-plates deeper than the hind one. Front joint not much dilated, broader above than below; the front margin only slightly convex, carrying small spines at intervals, and an apical group; the hind margin very faintly serrate and armed with spinules, and at the lower end a slender spine; the second joint with spines at two points of the front margin; the third joint not long, but longer than the fourth, with spines at two points of each margin, besides spinules at two points in front; the fourth joint with spinules at the centre and slender spines at the apex of the front margin and spines and spinules at the apex behind; the fifth joint longer than the third, with tolerably strong spines at four points in front and at two points behind; the finger strongly curved, half the length of the fifth joint, with a cilium at the base of the very acute nail.

Fourth Peraopods.—The front lobe of the side-plates a little deeper than the hinder, with some spinules in front; the hinder with a spine and spinule at the back. The limb similar in many respects to that of the preceding pair, but with the joints longer; the first joint with the hind margin concave below; the second with spines only at the apex; the third with spines at four points of each margin, the hinder being serrate and with strong spines; the fourth joint with two groups of strong spines in front, and a group at the apex behind, one of short, the next of slender, the lowest two of long and strong, spines; the finger is much less than half the length of the fifth joint.

Fifth Peraopods.—The side-plates small, not bilobed. The limb scarcely differing from that of the fourth peraeopods; the first joint rather longer, with the hind margin

more eoneave; and the spines at the baek of the fifth and perhaps at one or two other points rather stronger.

Pleopods.—Coupling spines small, slightly bent, the retroverted hooks including the apeial being three on one side and two on the other; the cleft spines four on the first and second pairs, three on the third; but in the seeond pair one inner ramus had five cleft spines though its fellow had but four; the joints of the rami number from twelve to fourteen.

Uropods.—Peduncles of the first pair a little longer than the rami, with seven or eight spines along each of the upper margins and a very large curved spine at the lower apex; the inner ramus with a row of six spines on the upper margin and a group at the blunt apex; the outer ramus similar but shorter; the edges of both finely pectinate; peduncles of the second pair about as long as the outer ramus; the rami similar to those of the first pair, but a little shorter; peduncles of the third pair shorter than those of the second, but reaching beyond them, with thrcce spines on the inner margin, and near the outer margin one on the surface and two at the apex; the rami equal in length to the peduncles, and one to the other, not reaching so far back as the outer ramus of the second pair, the edges obscurely pectinate, the inner ramus with four spines on the inner margin, two on the outer, and one at the apex, the outer ramus with three on the inner margin, one or two near the outer, and apparently a small group at the apex.

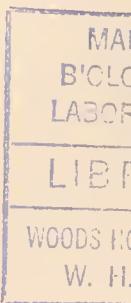

The Telson very little longer than broad at the base; the sides eonvex above, then converging to the broad distal margin which is a little eonvex in the eentre and eoncave at either side, with a small fold of the integument running obliquely along the surfacee from either angle, the fold on either side carrying a small spine, which projects beyond the distal concavity (too faintly shown in the figure of the pleon).

Length.—The speeimen in the position figured, measured, in a straight line from the front of the head to the extremity of the uropods, a quarter of an ineh.

Locality.—Station 168, off New Zealand, July 8, 1874; lat. $40^{\circ} 28'$ S., long. $177^{\circ} 43'$ E.; depth, 1100 fathoms; bottom, blue mud; bottom temperature, $37^{\circ}.2$. One specimen, female.

Remarks.—The specific name is given in compliment to Mr. G. M. Thomson, rector of the High School, Christchurch, Dunedin, an accomplished carcinologist.

I have been unable to identify this species with any of the three, likewise from New Zealand, which my friend Mr. Chilton assigns to his genus *Paranænia*, nor ean I perceive any very clear marks to distinguish that genus from *Gammaropsis*, of Liljeborg and Boeek.

Genus *Podoceropsis*, Boeck, 1860.

1860. *Podoceropsis*, Boeck, Forh. ved de Skand. Naturf. Sde Møde, p. 666.
 1862. *Nænia*, Spence Bate, Brit. Mus. Catal. Amph. Crust., p. 271.

 1869. *Nænia*, Norman, Last Report on Dredging among the Shetland Isles, p. 285.
 1869. *Megamphopus* (?), Norman, Last Report on Dredging among the Shetland Isles, p. 282.
 1870. *Xenoclea*, Boeck, Crust. amph. bor et arct., p. 154.
 1870. *Podoceropsis*, Boeck, Crust. amph. bor. et arct., p. 162.
 1871. *Nænia*, Metzger, Einundzwanziger Jahresbericht Naturh. Ges. zu Hannover.
 1876. *Xenoclea*, Boeck, De Skand. og Arkt. Amph., p. 561.
 1876. *Podoceropsis*, Boeck, De Skand. og Arkt. Amph., p. 583.
 1877. " Meinert, Crust. Isop. Amph. et Decap. Daniae, p. 151.
 1878. *Nænia*, Spence Bate, Crustacea in Couch's Cornish Fauna revised and added to, p. 58.
 1878. *Podoceropsis*, Stebbing, Ann. and Mag. Nat. Hist., ser. 5, vol. ii. p. 367.
 1879. *Nænia*, Stebbing, Trans. Devonshire Assoe., p. 520.
 1882. *Podoceropsis*, Sars, Oversigt af Norges Crustaceer, p. 30.
 1886. " Gerstaecker, Bronu's Klassen und Ordnuugen, Bd. v. Abth. ii. p. 496.
 1887. " Bonnier, Catal. Crust. Malac. Concarnneau, p. 108.
 1887. " Chevreux, Catal. Crust. Amph. Bretagne, p. 27.

For the original definition of the genus, see Note on Boeck, 1860 (p. 324); for the definition of *Nænia*, see Note on Spence Bate, 1862 (p. 336); for that of *Megamphopus*, which I only with hesitation make a synonym of the present genus, see Note on Norman, 1869 (in Appendix); for the definition of *Xenoclea*, see Note on Boeck, 1870 (p. 402). In 1876, as in 1870, Boeck defines it as follows, as third genus of the Photinae:—

"Upper Antennæ with the third joint of the peduncle elongate; accessory flagellum wanting.

"First Gnathopods with the wrist elongate.

"First and Second Peræopods with the first joint very broad.

"Third Uropods biramous, the rami about equal to one another in length.

"Telson apically sinuate."

Of *Podoceropsis*, as sixth genus of the Microdeutopinæ, he gives the following definition:—

"Upper Antennæ with the third joint of the peduncle elongate; accessory flagellum wanting.

"Second Gnathopods larger than the First, and in the male much stronger than in the female.

"First and Second Peræopods with the finger small.

"Third Uropods with the rami equal to one another."

To *Podoceropsis* Boeck assigns the one species, *Podoceropsis sophiae*, to which he makes *Nænia tuberculosa*, Spence Bate, a synonym; to *Xenoclea* he assigns the one species, *Xenoclea batei*, which is almost certainly the same as *Nænia rimapalmata*, Spence Bate. In *Nænia rimapalmata*, Spence Bate, in *Megamphopus cornutus*,

Norman, as in the new species *Podoceropsis kermadeci*, there is a rudiment of a secondary flagellum on the upper antennæ, and the presence of this might be noted among the generic characteristics ; in the neighbouring genus *Gammaropsis*, the secondary flagellum is far from rudimentary.

Podoceropsis kermadeci, n. sp. (Pl. CXVI.).

Rostrum small, lateral lobes of the head acute, not very prominent ; the head and peraeon-segments hairy to a certain extent.

No *Eyes* perceived.

Upper Antennæ.—First joint elongate, with nine groups of slender spines on the lower margin, the longest at the apex, and five groups on or near the upper margin ; the second joint thinner, a little longer, similarly furnished, but with the spines on the lower margin longer ; the third joint thinner than the second, very little shorter than the first, with eight groups of long spines on the lower margin, four or five on the upper ; the flagellum of six joints, together scarcely longer than the second of the peduncle, the first as long as the three following united, and with three groups of long spines and one of spinules on the lower margin, the fifth joint short, conical, and the sixth minute, all having long apical spines. There is a mere rudiment of a secondary flagellum, with two apical setules. Some of the long spines are distally very finely pectinate.

Lower Antennæ shorter than the upper, the first and second joints short, placed behind and below the lateral lobes of the head, the gland-cone small, but acute, decurrent ; the third joint longer than the preceding two united, distally a little dilated, with spines along the lower margin and at the apex of the upper ; the fourth joint elongate and furnished like the second of the upper antennæ ; the fifth joint resembling the third of the upper antennæ ; the flagellum of five joints, together scarcely longer than the fifth joint of the peduncle, the first joint carrying several long spines, its length exceeding that of the other four united, the last two and especially the last being very small, all carrying spines that are long, very slender, some pectinate.

Upper Lip.—The broad distal margin gently and almost symmetrically emarginate, faintly ciliated.

Mandibles very small compared with the length of the palp. The cutting edge divided into six unequal teeth, the three at the top and the lowest small, the other two rather large. The secondary plate on the left mandible rather broad, with an edge of five teeth, the lowest the largest ; the secondary plate on the right mandible feebler, with two rather long and sharp teeth and some lateral denticles ; in the spine-row there are on the left mandible three, on the right two, curved denticulate spines ; the molar tubercle is very prominent, narrowed at the crown, of which the denticles are small and

sharp; there is a plumose seta on the side; in the right mandible the crown of the tubercle has two or three acute points independent of denticles; the first joint of the palp little longer than broad; the second long, bent forward at a little distance from the base, then straight, having three small spines standing out straight on the lower part of the front margin, and higher up several long pectinate spines on or near both margins; the third joint narrower and shorter, straight, with the hind margin slightly convex, the front margin and narrow apex carrying about twenty spines, most of them long, curved, and pectinate; the hind margin having quite near the base a very long and a shorter curved spine.

Lower Lip.—The rounded distal margins of the principal lobes not strongly ciliated, the inner lobes distally a little narrowed; the mandibular processes divergent.

First Maxillæ.—Inner plate small, oval, with three plumose setæ at intervals on the distal part of the inner margin, followed by two setules on the apex; the outer plate with probably ten slender spines on the rather broad truncate distal margin, several of which have five little lateral teeth, while three are distally furcate, in two the hinder branch the shorter; the first joint of the palp a little longer than broad; the second joint reaching much beyond the outer plates, undilated, the apical border armed with five spine-teeth, none of them broad, the outermost the longest; there are also some slender spines below the apical border and along the upper part of the inner margin.

Second Maxillæ.—The plates about equally broad, the inner the shorter, with many slender spines round the distal margin, and some setæ descending the inner margin for a little distance; the spines on the distal border of the outer plate longer, as usual, than those on the inner, with a few feathered spines on each side below the distal margin.

Maxillipeds.—The inner plates not quite reaching so far as the distal end of the palp's first joint, fringed with long plumose setæ on the upper part of the inner margin, which has a very small spine-tooth near the apex; the distal margin sloping slightly outwards, carrying two small spine-teeth and several slender spines; the outer plates not nearly reaching the end of the palp's second joint, the inner margin faintly serrate, unarmed (unless by spines on the adjacent surface) until near the apex when the margin is serrate for the insertion of three slender spine-teeth; on the distal margin there are three long curved setiform spines; the first joint of the palp is very short, the second long and narrow, with many spines along the inner and some along the outer margin; the third joint is longer than the first, expanded distally over the base of the finger, with many long spines about the apical part; the finger is short and broad and blunt, tipped with long spines instead of a nail, and having along the distal half of the inner margin six or seven spines of great length.

First Gnathopods.—The side-plates small and rhomboidal, the lower corner directed forwards but not reaching the base of the lower antennæ; it carries a single setule or

small spine, and the rounded hinder corner has three. The first joint is almost wholly clear of the side-plate, distally a little widened, the convex hind margin carrying on the lower part three serrate seta-like spines and some spinules; the second joint short, with an apieal group of spines; the third joint with the front margin very convex, the hind margin serrate, carrying three groups of pectinate spines; there are two acute apices, between which more pectinate spines protrude from the inner surface; the wrist is as long and broad as the hand, the front margin with only an apical group of spines, the hind margin serrate, closely fringed with long spines pectinate on two edges, the inner surface also carrying several groups; the hand is dilated towards the palm, has four groups of spines along the serrate hind margin, and six groups along the convex front margin, besides scattered spines on the inner surface and groups near the palm-border; many or most of these spines are pectinate; the palm-border is almost at right angles with the hind margin, finely pectinate, slightly convex; the finger is curved, the inner margin smooth, with half-a-dozen minute submarginal setules, followed by two longer setules such as are commonly found at the base of the nail, the inner margin of the finger being here doubled, though there is no transverse mark to indicate the commencement of the nail; the termination is formed by a sharp spine, only half of which projects beyond the apex of the finger.

Second Gnathopods.—Side-plates broader than deep, with eonvex lower margin. First joint almost entirely free from the side-plate, much shorter and narrower than the hand, the hind margin convex, the front a little concave, with a group of spines a little above the apex, which projects beyond the short second joint, the third joint oblong, with some small spines at the apex of the straight hind margin; the wrist not nearly so broad as the hand, much broader than long, distally eup-like, with a group of spines at each apex, the short hind margin as well as the longer front one being otherwise smooth; the hand of great size, widest at the palm, where the width falls not far short of the length, the hind margin nearly straight, with some small groups of spines; the front margin on leaving the wrist very convex, afterwards straight and carrying some small groups of spines; the palm at right angles to the front and hind margins, much sculptured, beginning with the apical tooth of the hind margin, the interval between this and the following tooth being occupied by one or two small palmar-spines and a group of short slender spines; there is then a rather deep cavity with four or five spinules on its border, the remainder of the palm being convex, deeply serrate so as to form four rather distant teeth, the oblique intervals being set with several slender spines and spinules; the finger curves over the palm to its extremity and has a smoothly coneave (perhaps in part microscopically spinulate) inner margin with submarginal setules, while the convex outer margin has at intervals five or six groups of small and slender spines besides a dorsal cilium near the base; the nail is not slender, but apieally acute; there are some scattered spines singly or in small groups on the surfacee of the hand.

First Peræopods.—Side-plates rather smaller than the preceding pair. First joint reaching much below the side-plates, with a few small spines on the almost straight front margin, and at the apex of the hinder; the second joint short; the third longer than the fourth, not quite so long as the fifth, with two spinules and two groups of spines on the convex front margin, and two groups of spines on the straight hind margin; the fourth joint with three groups on the hind margin, the apical containing many spines; the fifth joint with spines at five points of the hind margin, and at the apex and a point near the middle of the convex front margin; the finger curved, half the length of the fifth joint, with a long dorsal feathered cilium near the base, a smaller cilium at the base of the nail, and on the inner margin, at a little distance from the nail, a spine with a flexible tip directed towards the nail.

Second Peræopods like the first, but rather shorter, the difference being chiefly in the length of the first joint; there is an additional spinule on the front margin of the fourth joint.

Length.—After the fourth segment of the peræon the specimen was defective; the existing portion, from the rostrum to the end of the fourth segment, measured one-fifth of an inch.

Locality.—Station 170A, north of the Kermadec Islands, July 14, 1874; lat. $29^{\circ} 45' S.$; long. $178^{\circ} 11' W.$; depth, 630 fathoms; bottom, volcanic mud; bottom temperature, $39^{\circ} 5$. A fragment only.

Remark.—The specific name refers to the place of capture.

Family PODOCERIDÆ, Leach, 1814.

In 1814 Leach instituted the Podoceridæ as the fourth family of the Gammerides, assigning to it the genera, *Corophrium*, *Podoerurus*, *Jassa*. In 1870 Boeck made the Amphithoinæ the twentieth [numbered as XIX] subfamily, and the Podocerinæ the twenty-first [numbered as XX] subfamily of the Gammaridæ; in 1872 to 1876, he made these two respectively the first and second subfamilies of the Podoeridæ, a family which he defines as follows:—

“Mandibles strong, apically much dentate; the secondary plate also dentate; the molar tubercle prominent; the spines of the spine-row numerous, often strong, serrate on the convex margin; the palp elongate, three-jointed, often very strong.

“Lower Lip with the inner plate large.

“First Maxillæ with the inner plate little.

“Second Maxillæ with broad plates.

“Maxillipeds having the outer plates armed on the inner margin with strong teeth; the fourth joint of the palp not unguiform, but apically armed with two curved spines.

- “ Body compressed or subdepressed, with the back rounded.
- “ *Upper Antennæ* with the accessory flagellum short or absent.
- “ *First Gnathopods* smaller than the *Second*, with the hand subeheliform.
- “ *Second Gnathopods* with the hand subeheliform, sometimes eheliform.
- “ The *Fourth Peraopods* longer than the *Third*, the *Fifth* than the *Fourth*.
- “ *Third Uropods* uniramous or biramous.
- “ *Telson* thick.”

To the Amphithoinæ Boeck assigned only the genera *Amphithoë* and *Sunamphithoë*; to the Podocerinæ *Podocerus*, *Janassa*, and *Cerapus*, of which *Janassa* is pretty certainly a synonym of *Podocerus*, and *Cerapus* not the true *Cerapus* but a synonym of *Erichthonius*, Milne-Edwards. In 1882, Sars, dropping the subfamilies, accepted the family Podoceridæ for the genera of both, naming them *Amphithoë*, *Sunamphithoë*, *Podocerus*, *Janassa*, *Erichthonius*.

For the original definition of the family Podoceridæ, see Note on Leach, 1814 (p. 86).

- 1840. *Amphithoe*, Lucas, Hist. Nat. des Crust. Arachn. et Myriap., p. 229.

¹ Since the very general acceptance of the form *Amphithoë*, I have considered that it would be inconvenient and pedantic to revert to the oddly spelt form *Ampithœ*, which Leach adopted at the first suggestion of the genus in 1813, and continued to use in his later writings.

² If the genus *Sunamphithoë*, Spence Bate, should be united to *Amphithoë*, as being separated by only one mark of distinction of doubtful generic value, *Anisopus*, Templeton, 1836, would then have to be included in the synonymy of *Amphithoë*.

¹ *Pleonexes* is probably a synonym of *Sunamphitoe*, which White spells as *Synamphithoe*, and if that genus be retained as distinct from *Amphithoë*, *Pleonexes* had a kind of claim to priority, being placed in front of *Sunamphitoe* both in 1856 when the two genera are first mentioned, and in 1857 when they are first defined.

1884. *Amphithoë*, Blanc, Die Amph. der Kieler Bucht, pp. 51, 77.
 1885. *Amphithoe*, Carus, Prodromus Faunæ Mediterraneæ, pars ii. p. 395.
 1886. *Amphithoë*, Gerstaecker, Brönn's Klassen und Ordnungen, Bd. v. Abth. ii. p. 496.
 1887. *Amphitoe*, Bonnier, Catal. Crust. Malac. Concarneau, p. 108.
 1887. *Amphithoe*, Chevreux, Catal. Crust. Amph. Bretagne, p. 27.

For the original definition of the genus, see Note on Leach, 1814 (p. 86). *Cymadusa*, Savigny, was never defined, and has been identified by the figures. For the definition of *Pleonexes* (and for that of *Sunamphithoë*), see Note on Spence Bate, 1857 (p. 294). Boeck's definition of the genus is practically included in that which he gives for his subfamily *Amphithoinæ*, from which I omit what has been already given in the character of the family.

“Lower Lip with the outer lobes deeply incised at the apex; the inner lobes large.

“Body compressed; side-plates of moderate size, not plumose on the lower¹ margin; fifth pair as deep as the fourth and broader, incised on the hinder margin for the retroverted third peræopods.

“Upper Antennæ slender; third joint of the peduncle very short; flagellum long; accessory flagellum absent.²

“Lower Antennæ with very short flagellum.

“First and Second Gnathopods with subcheliform hand; the hand of the first pair of the same shape as that of the second; the second pair stronger in the male than in the female.

“Third Peræopods retroverted.

“Uropods biramous; third pair with the rami little; the outer ramus furnished with two hooks (ungvibus).”

For the genus itself he says:—

“Mandibles with the third joint of the palp not very dilated, almost equalling the length of the second joint.

“First and Second Gnathopods with the finger dentate; the second pair stronger than the first.”

It may be observed that it is only the four terminal joints of the third peræopods that are retroverted, and that the third joint of the mandibular palp sometimes even exceeds the second in length. For the generic character of *Sunamphithoë*, Boeck says, “Last three pairs of peræopods with the last [meaning the fifth, not the sixth] joint dilated downwards and constituting a subcheliform hand; other points almost as in *Amphithoe*.”

¹ *Interiore* is no doubt a misprint, copied from the earlier of Boeck's works into the later, *inferiore* being intended as in the account of the Leptocheirinae and Photinæ.

² It is this character which separates *Amphithoe* from *Grubia*, Czerniavski, and *Amphithoides*, Kossmann.

Amphithoë kergueleni, n. sp. (Pl. CXVII.).

Rostrum inconspicuous, lateral lobes of the head not very prominent, with rather irregular outline; the postero-lateral angles of the first three pleon-segments almost squared. The animal in many parts covered with dark stellate markings.

Eyes rounded oval, situated on the lateral lobes of the head close to the margin.

Upper Antennæ.—First joint rather thick, about as long as the head, with some spinules on the under margin, and at the apex a group of small stiff spines and longer slender ones; the second joint much narrower but longer than the first, slightly bent, with spinules along the margins, and some slender spines on the lower one; the third joint more than a third the length of the second, similarly armed; the flagellum much longer than the peduncle, with thirty-three slender joints, tipped with setiform spines, alternately longer and shorter on the upper joints.

Lower Antennæ shorter than the upper. First two joints very short, gland-cone small, acute, decurrent; third joint short and broad, longer than the preceding two united, with some spinules on the margin, and a large group of setiform spines on the lower apex; the fourth joint abruptly narrower, about as long as the first joint of the upper antennæ, slightly bent, with setiform spines at four or five points of each margin; the fifth joint similar, a little shorter and narrower; the flagellum of twenty joints equipped as in the upper antennæ, and the last joint being, as in that pair, minute.

Upper Lip.—The centre of the distal margin rounded, prominent, the cilia there being straight, spine-like, projecting; the cilia on either side long, directed towards the centre; the margins between the rounded sides and rounded centre of the plate being nearly straight.

Mandibles.—The cutting edge divided into eight strong teeth; the secondary plate into five or six on the left mandible, and on the right mandible into four that are alternately long and short; the spine-row consisting of nine long bent spines, denticulate prominently on the outer convex side; the inner spines longer than the outer; the molar tubercle prominent, with long teeth round the crown of it, and a long plumose seta, two of the teeth by its side on the right mandible being almost setiform in their length; there is a process near the base of the palp; the first joint of the palp rather longer than broad; the second joint not very long, with spines at three points of its front margin; the third joint rather longer and broader than the second, with about fourteen long pectinate spines, of which four or five may be reckoned to the front margin, the rest are crowded round the apical curve, those at the extreme apex being the longest; the outer margin is a little convex, without spines.

Lower Lip.—The principal lobes narrow, finely ciliated on the outer margins, with a little conical process at the inner apex, the inner margin deeply sinuous, ciliated on the

upper and lower prominences, strongly on the lower; the inner lobes narrowed below, strongly furred above; the mandibular processes divergent, apically rounded.

First Maxillæ.—The inner plate having the inner margin fringed with many slender plumose setæ; the outer plate with ten spines on the distal margin, of which two have a single tooth on the outer side, one a single tooth on the inner side, the rest having from two to five denticles apiece, except one of the outermost, which is apparently without teeth; the second joint of the palp of nearly equal breadth throughout, curved, with nine spine-teeth round the curve of the apical margin, most of these being pectinate on the outer margin; there are on one maxilla six, on the other seven, setiform spines passing across the surface from the inner margin towards the outer apex.

Second Maxillæ.—The inner plate a little shorter and much narrower than the outer, with a long row of three and twenty plumose setæ passing from near the base in a gentle curve towards the outer apex; there are also spines along the slightly serrate nearly straight inner margin and many on the narrow apex; on the outer plate a row of sixteen or seventeen long spines singly or in pairs, beginning on the upper half of the straight inner margin, passes towards the apex, keeping near the margin; about as many more encircle the broadly rounded apex and its outer slope; this plate is narrower at the base than above, the reverse being the case with the inner plate.

Maxillipeds.—The inner plates reaching just beyond the first joint of the palp, with many plumose setæ along the inner margin, and several feathered spines along the distal margin and a spine-tooth at the inner apex; the outer plates rather narrow, not quite reaching the apex of the second joint of the palp, with sixteen serrate spine-teeth (graduated in size) on the inner margin, three on the apical, followed by nine long setiform spines which reach a long way down the hind margin, all the spine-bearing margins being serrate; the first joint of the palp short; the second long, well fringed on the inner margin with long spines; the third joint a little longer than the first, widening distally, both margins and the apex being set about with spines, two at the apex being strongly pectinate; the finger, including the unguial spine, is nearly as long as the third joint, its inner margin nearly straight, with two rows of pectination; the spine which does duty for a nail is also pectinate, shorter than the trunk of the finger, and is accompanied by another spine and a spinule near the base on the inner margin of the finger.

First Gnathopods.—The side-plates much wider below than above, the lower front corner being strongly produced towards the base of the lower antennæ; there are several setæ on the lower margin, chiefly on the hinder part; the integument is marked with little dots, which are bright when seen by transmitted light; these, however, are not confined to the side-plates. The first joint reaching beyond the side-plate, carrying a few setiform spines at different points of both margins; the second joint short, with some slender spines at the apex behind; the third joint broader above than below, the hind margin straight, carrying several spines, especially on the serrate part

near the slightly produced apex ; the free part of the hind margin is curved and forms an angle with the oblique portion which lies against the wrist and is apically acute ; the distal margin is concave between the two apices ; the wrist is elongate, almost as long as the hand, the hind margin serrate, bordered by a row of about fifteen spines ; it has also some spines upon the surface and at the apex of the long front margin ; the hand widens slightly towards the obliquely curved palm ; it has near the slightly convex front margin four large groups of spines ; on the straight hind margin there are five groups of slender spines, followed by a large palmar spine and then by another group of slender spines ; the finely peetinate palm joins the hind margin by a smooth curve, and is bordered by many submarginal spines of various lengths ; the finger is broad, slightly curved, with a very small cilium near the base ; its inner margin is cut into fourteen teeth, and there are one or two setules at the base of the nail, which projects considerably beyond the palm.

Second Gnathopods.—The side-plates deeper than in the preceding pair, but not so broad, of nearly even width throughout, the front margin convex, the lower also convex, fringed with setæ. The first joint reaching beyond the side-plate, with some setæ on the upper part of the convex hind margin, the front margin concave till near the distal part which forms a projecting round lobe carrying a spine and spinule ; the second joint is short, with the front margin very convex, the hind margin only slightly convex, carrying one or two spinules and at the apex a group of slender spines ; the third joint is more regularly oblong than in the preceding pair, with many spines about the distal margin, and a group a little way above the apex of the hind margin ; the wrist is triangular, a good deal shorter than the hand, distally cup-like, with spines at five points of the slightly convex front margin, and a bush of spines about the rounded apical portion of the hind margin. The hand is broad, with six or seven groups of spines along the slightly convex front margin and others near it ; the hind margin is also slightly convex, with seven groups of slender spines ; it forms a rounded angle with the oblique very sinuous palm, which is set with numerous slender spines of different lengths, and over which the broad curved finger closes, so as to reach the angle with its tip, the dentate inner margin leaving a small cavity between itself and the concave commencement of the palm ; the palmar spine is set rather deeply on the surface and projects beyond the palmar angle.

First Peræopods.—Side-plates rather broader and deeper than the preceding pair. Branchial vesicles as long as the side-plates, but much narrower. Marsupial plates long and narrow, surrounded by very numerous setæ, the surface appearing as if striped with lines of tubercles, the appearance perhaps due to the internal vessels. The first joint reaching a little beyond the side-plate, packed with gland-cells, carrying some setæ or setiform spines and spinules at various points of both margins, but especially on the hinder ; the second joint rather longer than broad, with some slender spines at the apex

behind ; the third joint widening distally, rather longer than the fourth, scarcely so long as the fifth, with slender spines at several points of the hind and two or three of the front margin ; the fourth joint has many slender spines along the nearly straight hind margin, on the more convex front a spinule high up and a small apieal group ; the fifth joint with seven or eight sets of slender spines on the hind margin, a spinule high up on the convex front margin, a group of slender spines below the spinule and another at the apex ; the finger short, not half the length of the fifth joint, with a dorsal cilium near the base, and an opening on the inner side of the apex.

Second Peræopods.—The side-plates rather broader than in the preceding pair ; the branchial vesicles and marsupial plates similar ; the limb also similar, with the fifth joint slightly shorter and having rather fewer spines.

Third Peræopods.—The side-plates with the front lobe about as large as the preceding plates, having some setæ on the hinder part of the lower margin, the hind margin convex ; the hind lobe shallow, with two setæ at the hind corner and the hind margin rounded. The limb short, easily detached ; the first joint much smaller than the side-plate, widest above, the length and breadth equal, the front margin convex, with a short thick spine near the top, and four or five rows of slender spines at intervals ; the hind margin very convex at the upper part, with some spinules at the apex, otherwise almost unarmed ; the second joint with a slender spine and some spinules at the apex in front ; the third joint scarcely longer than the fourth, shorter than the fifth, with some slender spines and spinules at the centre of the convex front margin, a group at its apex, and somewhat stouter spines at two points of the hind margin ; the fourth joint is equipped like the third, both with the two following joints having, as is usual in this genus, the true hind margin in front ; the fifth joint having a spinule high up on the convex front margin, followed by three groups of slender spines ; on the serrate hind margin there are large stout spines at four points, accompanied by setæ ; at the distal end in the cavity which it forms with the very short extremely upward bent finger there are some small stout spines ; the finger is sharp at the tip, and has a strongly feathered dorsal cilium at the base.

Fourth Peræopods.—Side-plates shallow, the front lobe a little deeper than the hind one. Branchial vesicles not as long or as wide as the first joint. The first joint longer but narrower than in the preceding pair, the front margin evenly convex, with a spinule here and there, the hind margin convex at the upper part, almost unarmed, the lower part a little concave, with one or two small spines ; the second joint short ; the third longer than the fourth, shorter than the fifth, with slender spines at two points of each margin ; the fourth joint similarly armed, but with an additional spinule high up on the hind margin ; the fifth joint with slender spines at three points of the hind margin and four of the front, there being likewise some stouter spines at the apex in front ; the finger short, curved, less than half the length of the fifth joint, with a feathered dorsal cilium.

Fifth Peræopods.—Side-plates smaller than in the preceding segment. The limb scarcely differing from that of the fourth peræopods, but rather longer, especially with respect to the first joint.

Pleopods.—Coupling spines thin, with broad much-bent apices; cleft spines four in number on the first two pairs, three on the third pair; the joints of the rami numbering from fifteen to nineteen, the outer ramus rather shorter than the inner and curved.

Uropods.—The peduncles of the first pair longer than the rami, with the usual curved spine at the lower apex; the outer ramus shorter than the inner, with four spines on the outer margin, three at the upper part of the inner, and a group of five at the truncate apex; the inner ramus with three spines on the outer, six on the inner margin, and the apical group; the peduncles of the second pair reaching a little beyond those of the first, not quite so long as the inner ramus, which has five spines on the inner margin, three on the outer, and the apex as in the preceding pair; the outer ramus a little shorter, with four spines on the outer margin, three on the inner and the apical group; the peduncles of the third pair longer than the rami, reaching much beyond the other peduncles, having on the apical margin four little stout spines and three or four that are setiform; the outer ramus having on the straight outer margin a stout spine, and at the broad apex two strong much-curved spines, the outer the broader, the inner the longer; the oval inner ramus has a spine near the middle of the inner margin, and about the apex four short stout spines and a row of nine setiform spines of different lengths.

The Telson is small, broader than long, much wider above than below, not nearly reaching the end of the peduncles of the third uropods, the distal margin nearly straight between the two acute corners, each of which carries a cilium; on the surface a little way from each apex is a long seta or setiform spine, and there are two setæ on each lateral margin near the centre.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the extremity of the uropods, rather over one-fifth of an inch.

Locality.—The single specimen, a female, was obtained at Kerguelen Island, whence the specific name.

Amphithoë flindersi, n. sp. (Pl. CXVIII.).

Rostrum inconspicuous, lateral lobes of the head little prominent; the postero-lateral angle of the first three pleon-segments more or less rounded, but with a little notch where the curve of the hind margin meets that of the lower margin; the fourth segment with a transverse dorsal depression.

The Eyes oval, small, with many small ocelli, the position rather horizontal than vertical.

Upper Antennæ.—The first joint rather thick, more than twice as long as broad,

not so long as the head, with some small slender spines about the distal end. The remaining joints missing. Fig. *a.i.* should be *a.s.*

Lower Antennæ.—The first two joints short, the gland-eone decurrent, the third joint not as long as the preceding two united, having three or four small groups of spines about its distal end. The rest of the joints missing. Both figures *a.s.* should be *a.i.*

Mandibles.—The cutting edge broad, with seven well-defined but unequal teeth on each mandible; the secondary plate on the left mandible with the broad distal edge cut into five teeth; on the right mandible this plate has two obvious teeth, with perhaps two or three denticles in addition, and as usual does not easily lend itself to a broadside view, except when seen through the transparent skin in preparation for the next moult; the spines of the spine-row are six in number, slender, much bent, and the distal half strongly denticulate especially on the front convex side; on the right mandible the sixth spine is diminutive; the molar tubercle prominent, with long teeth encircling the crown, and a long plumose seta at one corner of it. The process near the base of the palp is small; the first joint of the palp a good deal longer than broad; the second joint about twice as long as the first, with a spinule near the apex; the third about as long and broad as the second, with five long spines on the broad apex. The right mandible is figured on the left, and the left mandible on the right, in the Plate; the large uppermost tooth of the cutting edge has beside it a less prominent tooth not shown in the figures.

Lower Lip.—The principal lobes distally narrow, with the inner corner produced in a little rounded point, the inner margin strongly sinuous, with cilia on the slightly convex distal part and on the very convex lower part, which is near the strongly ciliated distal margin of the inner lobes; the mandibular processes are large, distally narrow but not acute.

First Maxillæ.—The inner plate small, in one maxilla with two, in the other with three, plumose setæ on the inner margin; the outer plate broad, with ten spines on the broad trunate distal margin, the innermost with three lateral denticles, two of the three next with a single lateral tooth on the outer side, some but not all of the others having, as far as could be seen, two or three lateral teeth on the inner side; the first joint of the palp very short, the second widening from the base, curving, and reaching a little beyond the outer plate, its apical margin with sloping sides cut into four teeth and carrying five spine-teeth; there are three slender spines on the surface at some distance from the apical as well as from the outer and inner margins.

Second Maxillæ.—The inner plate nearly as long but not so broad as the outer, with a series of thirteen setæ passing from near the base of the inner margin in a curve towards the outer apex; the apical margin is narrow, with a group of close-set spines, and a few descend the distal part of the inner margin at intervals; the outer plate has a straight inner margin, at the upper part of which is a series of four spines, there

are three that are subapical, ten on the inner apical corner, close-set, and two more spaced on the outward sloping part of the distal margin.

Maxillipeds.—The inner plates reach a little beyond the first joint of the palp; they have seven plumose setæ along the inner margin, three or four on the surface adjacent; and a spine-tooth just below the apex; the distal margins slope a little outwards and carry five or six feathered spines, but not more, so far as I could see, than one spine-tooth; the outer plates reach beyond the second joint of the palp, and have on the erenate and finely pectinate inner margin eight spine-teeth, two more on the distal margin, followed by three setiform spines on the outer curve; the first joint of the palp is short, with a small spine on the outer margin a little below the rounded apex; the second joint is not twice as long as the first, its inner margin is fringed with not numerous spines; the third joint is not longer than the first, with some spines along the front margin, and a group of five at the outer apex, of which two are conspicuously pectinate for part of their length; the finger is almost as long as the third joint, if the unguial spine or nail be included; there is a minute dorsal cilium near the base, and on the inner margin near the origin of the nail, which is pectinate on the inner side, there are two setules, one shorter, the other longer than the nail.

First Gnathopods.—Side-plates almost triangular, the rounded front corner being strongly produced forwards towards the base of the lower antennæ. The first joint reaching a little distance below the side-plate, with three long setæ on the upper part of the convex hind margin, and a few others on the surface; the front margin tending to concave; the second joint short; the third with a very short front margin, the hind margin convex, with a spinule below the middle, and a slender spine near the apex; the wrist not quite so long as the hand, but as broad, the convex front margin smooth, the hind margin also smooth, furnished with half a dozen slender slightly feathered spines, the surface having three or four more; the hand widens from the base to the palm; the long front margin is very slightly convex, with three or four small groups of spines at or near it; the hind margin is also but slightly convex, at first smooth, but near the palm carrying three little groups of spines followed by a palmar spine, where with a smooth curve it passes into the oblique palm border, which is set with several submarginal slender spines of different sizes; the finger is short, stout, and curved, with a small dorsal cilium near the base; the inner margin is at first finely pectinate, then cut into five teeth of gradually increasing size; there is one small setule near the first of these, and three near the last, which is followed by the sharp curved nail.

Second Gnathopods smaller than the first. Side-plates narrower but rather deeper than the preceding pair, with a long seta at the hind corner of the convex lower margin. The branchial vesicle much shorter and narrower than the side-plates. The first joint is armed with long setæ as in the first pair; it does not reach so far beyond the side-plate, that being deeper; the third joint with the front margin straight, almost wholly applied

against the wrist, apically pointed, the hind margin distally rounded, distal margin distinct, set with spines; the wrist scarcely longer than the third joint, triangular, distally a little cup-like, with eight or nine geniculate spines on the lobe which is constituted by the hind margin; there are one or two small spines on the apex of the front margin, and one or two spines or setæ on the surface; the hand is longer than the wrist, and at the palm a little broader; there are spines at three points near the smoothly convex front margin, and a group at its apex; the hind margin is slightly convex, smooth, with one spine and three pairs of spines submarginal along the distal half; these are followed by a palmar spine, where the hind margin joins the palm by a curve; the palm itself has a minutely pectinate edge, and is bordered but not thickly by several slender spines of various lengths; the finger is short, in structure corresponding with that of the first gnathopods; there are two small spines on the surface of the hand. The gnathopod on one side with fewer spines and with a smaller hand and finger than on the other, probably abnormal.

First Peræopods.—The side-plates broader than the preceding pair; with two setæ on the lower margin near the hind corner. The branchial vesicles larger than in the preceding segment. The first joint reaching a little beyond the side-plate, broader at the upper part than the lower, packed with gland-cells, with some long setæ or setiform spines at intervals along the hind margin and a few on the surface at the upper part; the second joint short, with a slender spine and spinules at the apex behind; the third joint similarly armed at each apex, and with a slender spine higher up on the hind margin; this joint widens distally, is longer than the fourth, not longer than the fifth, none of the joints being elongate; the fourth has slender spines at three points of the hind margin and at the apex in front; the fifth joint has a group at either apex, and a single slender spine above the centre on the convex front margin, and one below the centre on the straight hind margin; the finger is short and broad, curved, longer than half the fifth joint, with a dorsal cilium near the base, and an opening within the blunt apex.

Second Peræopods similar to the first.

Third Peræopods.—Side-plates broader than the preceding, but not quite so deep, the front lobe very large, the hind lobe shallow. The branchial vesicles smaller than in the preceding segment. The limb missing.

Fourth and Fifth Peræopods.—The side-plates small. The limbs missing.

Pleopods.—Coupling spines small, with only the apical pair of hooks; eleventh spines two in number; the joints of the rami numbering from eight to nine, the outer ramus being a little shorter than the inner.

Uropods.—The peduncles of the first pair very little longer than the inner ramus, with three spines on each of the upper margins, and a large spine at the lower apex; the outer ramus the shorter, with two lateral spines and an apical group of four or five spines,

one of which is large and a little denticulate ; the inner ramus is similarly armed ; the peduncles of the second pair as long as the inner ramus, with a spine at the apex of each of the upper margins ; the outer ramus shorter than the inner, with a spine on each margin and an apical group as in the preceding pair ; the inner ramus with three spines on one margin, one on the other, and the apical group ; the peduncles of the third pair longer than the rami, reaching much beyond the peduncles of the preceding pairs, having four small spines and a couple of setæ on the distal margin ; the rami very short, the outer with a slender spine just below the middle of the outer margin and two short hooked spines at the rounded apex, the outer spine the stouter ; the inner ramus oval, slightly longer than the outer, with a spine near the middle of the inner margin, and at the apex two short spines and a long and a short slender spine.

The Telson of about equal length and breadth, much rounded, not reaching nearly so far as the peduncles of the third uropods, with a pair of setæ or setiform spines on the surface, one on either side the centre of the telson, another pair lower down but some way above the distal margin, each of the latter pair being attended by a setule ; there is also a cilium or setule at the upturned corner on each side of the distal margin, and perhaps some small cilia elsewhere.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the extremity of the uropods, three-twentieths of an inch.

Locality.—Station 186, Flinders Passage, September 8, 1874 ; lat. $10^{\circ} 30'$ S., long. $142^{\circ} 18'$ E. ; depth, 8 fathoms ; bottom, coral mud. One specimen.

Remark.—The specific name refers to the place of capture. There is a great similarity between this species and *Amphithoe brevipes* as figured and described by Dana, but the two species do not seem to agree in respect to the uropods and telson. *Amphithoe brevipes* was also taken in a very different climate, "near Hermite Island, Tierra del Fuego; brought up with kelp in 5 fathoms water." With *Amphithoe brevipes*, Dana, *Amphithoë falklandi*, Spence Bate, seems to be in close agreement, since in the description of the upper antennæ of the latter species, "third joint of the peduncle longer than the preceding," third is probably only a misprint for second.

Amphithoë japonica, n. sp. (Pl. CXXXVIII. A).

In general appearance this species is in close agreement with *Amphithoë rubricata*, Montagu.

Rostrum obsolete, lateral lobes of the head not strongly advanced, the sides of the head excavate below the lateral lobes for the base of the lower antennæ ; the postero-lateral angles of the first three pleon-segments with produced points, not upturned and scarcely acute.

The Eyes small, irregularly round, situate on the lateral lobes of the head.

Upper Antennæ.—The first joint about as long as the head, with a short stiff spine at the lower apex, and slender spines there and elsewhere; the second joint longer and much thinner, with several groups of slender spines and spinules; the third joint about one-third the length of the second, similarly curved; the flagellum much longer than the peduncle, having (on one of the specimens) forty-six joints, very slender towards the distal end of the flagellum. There is on the distal end of the third joint of the peduncle a little setuliferous (seemingly jointed) tubercle, that may be regarded as a remnant of a secondary flagellum. This, however, is not so long as what Czerniavski figures, in 1868, for the secondary flagellum of *Grubia taurica* and describes as *minutissimo*. In *Amphithoides longicornis*, Kossmann, 1880, the secondary flagellum though not as long as the first joint of the primary, consists of a long and a short joint.

Lower Antennæ.—The first two joints very short, closely coaleseed, the gland-cone decurrent; the third joint short, but longer than the coaleseed first and second, carrying some slender spines of various lengths; the fourth joint much thinner and longer than the third, rather longer than the second of the upper antennæ, carrying several slender spines; the fifth joint thinner and a little shorter, similarly furnished; the flagellum of about five and twenty joints, together longer than the fourth and fifth of the peduncle united, the terminal joints long and slender.

Upper Lip rather broad, the distal margin not quite evenly convex, since the broad central part projects slightly, this part being strongly furred all round.

Mandibles.—The cutting edge divided into seven or eight teeth; the secondary plate with four teeth on the right mandible, and five on the left; the spine-row consisting of nine very slender spines, curved and dentieulate; the molar tubercle strong, with sharp slender teeth round part of the crown, broad teeth or transverse plates on the side, and at one corner a slender spine; the first joint of the palp not quite twice as long as broad, the second about twice the length of the first, widening a little distally, with some spines at the apex in front; the third joint rather longer and broader than the second, widening a little distally, and on the convex sloping apical border carrying about twenty long dentieulate spines, the longest on the apex of the hind margin; there are also one or two spines on the surface very near the apex of the front margin, which is shorter than the hinder one.

Lower Lip.—The principal lobes dehiscent, strongly ciliated on the inner margin, at the top of which there is a wide and deep emargination, by which a narrow distal lobe is formed, directed inwards, the outer or distal border smooth, but the sinuous inner border ciliated; the inner lobes are long, much wider at the oval distal part, which is very strongly ciliated, than at the squared base; the mandibular processes large, divergent, with the outer margin very convex.

First Maxillæ.—The inner plate small, widening from a narrow base, the inner

margin straight, with a slender spine standing out stiffly from about the middle, the outer margin very convex, and the distal slightly so; the outer plate broad, curved, the distal margin carrying ten spines, the innermost and two or three others with two or three small lateral denticles, two that are near to the innermost more slender than the rest, and having each a minute denticle on the outer side, and in one of the maxillæ having another little denticle on the inner side; the outermost two or three stouter than the rest and seemingly smooth; the first joint of the palp short, yet longer than broad; the second joint reaching beyond the outer plate, and having six slender spine-teeth along the distal half of the inner margin, three on the apical, and some slender spines crossing the surface.

Maxillipeds.—The inner plates not reaching the distal end of the palp's first joint, long and narrow, tending to oval, the inner margin set with about two dozen long plumose setæ, one, two, or three together; the distal margin narrowly rounded, set with several feathered setiform spines, but seemingly without spine-teeth; the outer plates large, reaching beyond the second joint of the palp, with fourteen spine-teeth, not close-set, on the serrate inner margin, two larger ones on the distal margin, and seven long spines passing far down the serrate convex outer margin; there are dark stellate markings on this plate; the first joint of the palp is not very long, with two or three spines on the short inner margin; the second joint is not twice as long as the first, widening distally, with spines on the inner margin, which are numerous round the apical part; the third joint subequal in length to the first, with four groups of spines on or near the hind margin, some of them strongly pectinate; the convex inner margin fringed for the distal two-thirds with slender spines, the apical pectinate coarsely for part of their length and finely for the remainder; the finger short and narrow, having the inner surface thickly set with irregular rows of little prickles; there is no nail, but instead, at the rounded tip of the finger, a strong spine, not quite two-thirds the length of the base, distally pectinate on the inner margin; the usual couple of setules, one long, the other short, are placed near it.

First Gnathopods.—The side-plates much broader below than above, the front margin oblique, a little concave, the front corner much produced forwards. The first joint reaching a little below the side-plate, the margins nearly straight except at the base of the hind margin and at the lower end in front, which is produced in a rounded lobe overlapping the following joint; there are some slender setiform spines on the upper part of the hind margin, and a few long ones on the surface; the second joint rather longer than broad, with a small group of slight spines near the apex behind; the third joint longer than the second, narrowing distally, with slender spines at two points below the middle of the hind margin, some across the short, concave, pectinately furred, apical margin, and others near the convex front margin; the wrist triangular, twice as long as broad, with short spines at two points near the middle of the slightly convex front margin, and

longer spines at its apex; the hind margin microscopically pectinate or furred, fringed with slender spines in six or seven small groups; there are three groups also on the inner surface at a distance from the hind margin; the hand between oval and oblong, nearly as long as the wrist, with four groups of spines at the slightly convex front margin, five or six along the almost straight hind margin, which makes an obtuse angle at the oblique slightly convex palm; the palm is defined by a palmar spine, and bordered with slender spines of various lengths, its edge like that of the hind margin being microscopically furred or pectinate; there are setiform spines at six points of the inner surface, distant from the hind margin; the finger is broad and strong, the outer margin much curved, with a small dorsal cilium near the base, the inner margin fitting the palm, cut into sinuous decurrent teeth, and ending in a very sharp nail, which projects beyond the palm.

Second Gnathopods.—The side-plates a little broader below than above, deeper than the preceding pair, and much wider above, but scarcely so wide below. The marsupial plates long and rather narrow, longer and a little wider than the first joint; distally tapering to a point, closely set all round with a vast number of very long setæ. The first joint reaching beyond the side-plate, rather larger and stouter than the first joint in the preceding pair, and less constricted at the base, with several groups of long spines on the hind margin, the front produced below in a rounded lobe; the second and third joints nearly as in the preceding pair, but rather broader, and the third with more spines, and the distal margin less contracted; the wrist shorter than the hand, but distally wider, the distal width being almost equal to the length; the convex hind margin smooth, but the distal margin, where it projects beyond the hind margin of the hand, carrying an immense brush of long slender spines; the hand almost oblong, very similar to that of the first gnathopods, but wider, the width scarcely varying from near the base to the origin of the palm; the armature of the hand and the finger are similar to those in the preceding pair.

First Peræopods.—The side-plates larger than the preceding pair, tending to oblong, but broader above than below, and with the corners rounded, especially the lower front one. The branchial vesicles large and inflated, rather longer than the first joint. The marsupial plates similar to the preceding pair, longer than the branchial vesicles. The first joint reaching beyond the side-plate, containing rows of dark gland-cells, of nearly uniform breadth except at the base, much wider as well as much longer than any of the following joints, with many groups of long spines along the hind margin, the front margin fringed with spines and setæ; the second joint scarcely longer than broad, with spines at the apex behind; the third joint widening distally, broader but scarcely longer than the fourth joint, with spines or spinules at four points of the straight pectinately furred hind margin, spinules at two points in front and long slender spines at the apex; the fourth joint narrowing a little distally, with slender spines at five points of the straight scabrous

hind margin, those near the apex forming a broad row of very long thin spines; the slightly curved front margin is slightly armed at three points; the fifth joint is longer than the third or fourth, narrowing a little distally, with seven groups of slender spines behind, with spinules at two points high up on the slightly curved front, and a group of setæ or setiform spines at the apex; the finger is about half the length of the fifth joint, and has an opening in the apex.

Second Peræopods.—These, with their side-plates, are in close agreement with the preceding, but a little longer; the third joint has six or seven groups of spines, the fourth has five, and the fifth has eight, on the front margin.

Third Peræopods.—The side-plates nearly as deep as the preceding pair, and full as broad even below, considerably broader above by the addition of the small hind lobe. The branchial vesicles as broad as the first joint. The marsupial plates are similar in general character to the preceding pairs, but considerably shorter, and more continuously tapering. The first joint irregularly shaped, about as broad as long, the front and hind margins both very convex, the front with seven short, stout spines, followed by some on the lower part that are more slender; the second joint short, longer behind than in front, with some small spines in front at the apex; the third joint rather longer than the fourth, with spines at three or four points behind and two in front; the fourth joint with spines at two points on each margin, those at the apices being long; the fifth joint longer than either the third or fourth, with six groups of spines along the hind margin, comprising strong and slender spines in each group, the apex of the joint on the inner side forming two small laminar projections, on the outer side set with numerous slender setæ much longer than the finger; the finger curved, acute, about half the length of the fifth joint.

Fourth Peræopods.—The side-plates shallow, with several setæ on the front edge of the front lobe; the hind lobe less deep but broader than the front, with a spine in a notch at the lower hind corner. The branchial vesicles large and inflated. The limb longer than the preceding pair.

Fifth Peræopods.—The side-plates not bilobed, rather deeper behind than in front. The limb longer than the preceding pair; the first joint pear-shaped.

Pleopods.—The peduncles (at least of the first pair), instead of the more usual pair of coupling spines on each peduncle, have a row numbering about a dozen; they are short and small, with one pair of retroverted hooks at the apex; the eleventh spines form a row of nine; the joints of the outer ramus number twenty-two, of the inner twenty-three; the second and third pairs are very like the first, but perhaps with fewer coupling spines, seven or eight eleventh spines in a series, and a joint less in each of the rami.

Uropods.—The peduncles of the first pair longer than the rami, with strong spines on the inner or upper margins, and slight ones on the lower or outer margin; the outer ramus a little shorter than the inner, both with stout spines along the inner margin and

an apical group; the peduncles of the second pair reaching a little beyond those of the first, a little longer than the rami, with strong spines on the lower half of the inner margin; the outer ramus shorter than the inner, both armed as in the preceding pair, but with rather stronger spines, the rami themselves rather broader, and respectively reaching a little beyond the other two; the peduncles of the third pair much longer than the rami, reaching beyond the telson, and carrying some short stout marginal and apical spines and some lateral groups of long slender spines; the rami short and subequal, the outer narrowing distally, with two apical spines, stout and curving upwards, the outer the stronger; there is a short stout spine at the upper part of the upper margin; the lower margin is convex; the inner ramus tapers less, has four stout spines and three slender ones fringing the truncate apex, two small spines on the straight upper margin, and some small stout surface spines.

The Telson is scarcely longer than broad, widest near the base, the sides then converging with a straight course to the still wide distal margin, which forms an angle with each of the sides, but is itself convex; at each angle there is a little tooth on the surface; there are two slender spines near each margin, two pairs wide apart on the surface some way above the distal margin, one in each pair very long, and some spinules at different points.

Length.—The length of the specimen, without the antennæ, was eleven-twentieths of an inch.

Locality.—Station 233, Bay of Kobé, Japan, May 17, 1875; depth, 8 fathoms; bottom, mud. Three specimens.

Remark.—The specific name is derived from the locality. The great similarity which prevails among the more or less definitely ascertained species of this genus, and the scantiness of the details which in many instances have been thought sufficient for their identification, necessarily leave new species on a very insecure footing. To review all the species of *Amphithoë* will be a task by itself for any one who is willing to undertake it.

For the original definition of the genus *Podocerus* and of the genus *Jassa*, see Note on Leach, 1814 (p. 86); for the definition of *Ischyrocerus*, see Note on Krøyer, 1838 (p. 179); for that of *Cratophium*, see Note on Dana, 1852 (p. 257); for that of *Janassa*, see Note on Boeck, 1870 (p. 402). Boeck in 1876 thus defines the genus *Podocerus* :—

" *Mandibles* with the palp elongate, not broad; the last joint of the palp apically rounded and furnished with very many plumose setæ.

" Front side-plates small.

" *Upper Antennæ* with the third joint of the peduncle tolerably long; the flagellum short but multiarticulate; the accessory flagellum small.

" *Second Gnathopods* very large, stronger in the male than in the female; the fifth joint constituting a subcheliform hand.

" *First and Second Peræopods* with the first joint only a little dilated.

" *Third Uropods* biramous; the rami short but thick.

" *The Telson* thick."

To these should be added, from his account of the subfamily Podoerinae, the following characters :—

- “ *Upper Lip* apically little sinuate.
- “ *Secondary plate of the Mandibles* large.
- “ *Lower Lip* broad.
- “ *First Maxillæ* having the palp armed with few, elongate spines ; the inner plate little, ovate, without setæ.
- “ *Second Maxillæ* broad ; the outer plate very broad and longer than the inner.
- “ *Maxillipeds* with the plates of moderate size ; the inner plate armed with three teeth, the outer with very many strong teeth [on the inner margin], longer teeth on the apical margin, the series ending with curved setæ on the outer margin ; the palp very large ; the second joint elongate.
- “ The body subdepressed ; the back rounded ; the side-plates small.
- “ The *Eyes* situated on the lateral lobes of the head.
- “ *Upper Antennæ* with the peduncle long ; the third joint almost equalling the second in length.
- “ *Lower Antennæ* with the flagellum of few or many, never very many, joints.
- “ *First Gnathopods* subchelate, smaller than the *Second*.
- “ *Telson* thick, furnished with spines or teeth.”

The other characters mentioned by Boeck have either been included in his character of the family, or do not refer to the genus *Podocerus*. It has been pointed out by S. I. Smith¹ that for *Cerapus [Ericthonius] longimanus*, which Boeck assigns to this group, he himself figures the inner plate of the first maxillæ with setæ, so that the absence of setæ from that plate is not a valid character of the group. It may be added that in the description of *Podocerus latipes*, Kröyer, Boeck expressly states that the inner plate of the first maxillæ has setæ on the apex.

Podocerus falcatus (Montagu) (Pl. CXIX.).

To give what is now supposed to be the full synonymy of *Podocerus falcatus*, would be to repeat the great majority of the references already given for the genus. Leach is inclined to adopt the name *Jassa falcata* for Montagu's species, but he does not definitely adopt it. Meinert, Chevreux, Koehler, and perhaps some other writers, have used the actual name *Podocerus falcatus*, but as a rule I do not think it necessary to enlarge the synonymy of a species by references to simple catalogue names. It will be of interest here to notice how the grouping of various forms and various names under one species has gradually arisen. In 1857 Spence Bate in his Synopsis, giving the species "*P. falcatus* (Montagu)," but omitting *Jassa pelagica*, Leach, remarks in a footnote, "It is usual to divide this genus into two, *Podocerus* and *Jassa*, but there is great reason to believe that the difference is merely sexual. It is evidently synonymous with Dana's genus *Cratophium*; the species *C. validum* being almost identical with *P. pulehellus*." Norman in 1869, mentioning five species of *Podocerus*, makes "*Podocerus falcatus* (Montagu)" the fourth, and "*Podocerus pelagicus* (Leach)" the fifth, but in reference to the place of capture, says of the latter, "With the last, of which I believe it to be the female. I have never met with a male *pelagicus*, nor a female *falcatus*. The two forms occur in company, and the structural differences seem confined to the exact form of the hand of the gnathopods, organs which seem generally to differ among the Amphipoda according to the sex." Boeck in 1870 and 1876 places in the synonymy of *Podocerus falcatus*, Montagu, the species *Jassa pulchella*, Leach, *Jassa pelagica*, Leach, *Cerapus pelagicus*, Milne-Edwards, *Podocrus calcaratus*, Rathke, and *Podocerus monodon*, Heller. In regard to the union of the three forms named respectively *falcatus*, *pulchellus*, and *pelagicus*, Metzger and Meinert imply their agreement with Boeck, and Hoek definitely expresses and gives reasons for his. Nebeski in 1880 adds the form known as *Podocerus variegatus*, Leach, which Boeck had named *Janassa variegata*, at the same time making *Podocerus capillatus*, Rathke, a synonym of it. Bonnier in 1887 accepts the whole group thus united, but presumably on the authority of the various authors mentioned.

Lower Antennæ.—In the male specimen the flagellum has six joints, the first much longer than any of the following; in the female specimen the flagellum has only two joints, the first long and stout. Boeck in describing *Podocerus falcatus* says that the flagellum of the lower antennæ has five joints, of which the first is the longest; for *Janassa variegata* he says that this flagellum is composed of a long first joint, which is narrower than the last joint of the peduncle, but nearly as long, and of two short joints.

Mandibles.—The cutting edge is divided into five teeth; the secondary plate on the left mandible has four teeth, on the right mandible two moderately conspicuous teeth and three very inconspicuous denticles; the spine-row has five spines on the left, and four on the right mandible; the molar tubercle on each mandible has a very irregular edge to the crown, and in a cavity of this edge is planted a small lamina, narrow at the base, distally crenulate, with a breadth about equal to the length.

It is probably to this which Boeck alludes when he says,¹ “Tyggeknuden er meget hoi, og den nedre Tandrad afbrydes i den indre Kant af en Børste,” but to speak of this laminar process as a seta seems inappropriate and misleading.

Lower Lip.—Principal lobes rather widely dentate, inner margins strongly ciliated, the outer margins with a small interruption as if an incipient jointing near the apex; the oval inner lobes filling up a portion of the gap between the other two, the inner and distal margins well ciliated; the mandibular processes rather long, narrow, and divergent.

First Maxillæ.—The inner plate narrow; the outer plate carrying on the broad distal margin nine spines, each of which appears to have a small lateral tooth on the outer or on the inner margin; in some of the spines there may be more than one such tooth on the inner margin; the first joint of the palp very short, the second very long, carrying on the dentate apex four serrate spine-teeth, with two that are narrower on the inner margin just below the apex; there are also several slender spines crossing the surface from the outer apex to the inner margin. Boeck in describing the outer plate of these maxillæ says there are six strong spines, each of which is armed on the concave edge, near the apex, with a little accessory tooth. In *Podocerus latipes* he also mentions only six spines, but that is probably in both species rather the number he observed than the full normal number.

Second Maxillæ.—The inner plate rather shorter and narrower than the inner, with plumose setæ or setiform spines descending to the middle of the inner margin.

Maxillipeds.—The inner plates have on the widened distal margin some curved plumose spines and three small spine-teeth which are not set close together; a row of seven plumose setæ, beginning rather far up the inner margin, passes across towards the distal margin; the outer plates do not reach to the apex of the second joint of the palp; the crenulate inner margin has seven graduated serrate spine-teeth; on the apical margin the series is continued by three that are similar but longer and by two long setæ.

Second Gnathopods.—The inner margin of the finger is not dentate, but carries a series of small not very prominent spine-teeth.

Locality.—A specimen that appears to be a female of this species was taken from the screw of the ship on the 18th of December 1873. This date corresponds with Station 142, in the neighbourhood of the Cape of Good Hope, lat. $35^{\circ} 4'$ S., long. $18^{\circ} 37'$ E.

¹ De Skand. og Arkt. Amph., p. 607.

Station 149E, Greenland Harbour, Kerguelen Island, January 21, 1874; depth, 30 fathoms; bottom, volcanic mud. One specimen. Dredged.

Remarks.—There is the possibility, as I have elsewhere suggested, that these creatures may have travelled out from our own waters along with the vessel to the southern latitudes at which they were captured.

Podocerus validus (Dana) (Pl. CXXXVIII. B).

1852. *Cratophium validum*, Dana, U.S. Explor. Exped., p. 841, pl. lvi. fig. 2.
 1862. *Podocerus validus*, Sp. Bate, Brit. Mus. Catal. Amph. Crust., p. 253, pl. xlvi. fig. 9.
 1886. " " Thomson and Chilton, Trans. New Zealand Inst., vol. xviii. p. 143.

Upper Antennæ.—The third joint of the peduncle longer than the first, shorter than the second; the flagellum much more slender than the peduncle, of six joints, together scarcely longer than the second of the peduncle, the first much longer than any of the others, the second not completely separated from the first; the secondary flagellum slender, scarcely half the length of the first joint of the primary, two-jointed, but the second joint minute, tipped with setules as long as the secondary flagellum itself.

Lower Antennæ.—Peduncle stout; the flagellum also stout except the small fourth joint at the apex, the four joints together as long as the fourth joint of the peduncle, the first joint being much longer than the other three together, bordered with many spines, both slender and short stout curved ones, the remaining joints having similar armature apically.

Mandibles.—The cutting edge with four or five teeth on the left mandible, with five on the right, of which the lowest but one is conspicuously the largest; the secondary plate with four teeth on the left mandible, on the right mandible with one tooth and a dentieulate border above it not cut into actual teeth; the spine-row with three broad spines (serrate on the outer edge) on the left mandible, and two such on the right mandible. The molar tubercle powerful, very similar to that described for *Podocerus falcatus*; the first joint of the palp short, widening distally; the second joint broad, at first widening, but narrowing at the distal part, carrying many spines on and near the irregular front margin; the third joint shorter than the second, from a very narrow neck widening rapidly, along the distal half of the inner margin and round the broad apex carrying many unequal, long and broad, slightly feathered, more or less curved spines.

Maxillipeds.—The inner and outer plates not very different from those of *Podocerus falcatus*; the palp broad, the first joint almost triangular, reaching beyond the inner plates, the second joint not twice as long as the first, with many slender spines about the inner and apical margins, and the inner apex having two that are very long; the

outer margin, besides some small spines at the apex, has a group at some distance below it; the third joint little longer than the first, its distal half beset with very numerous spines; the finger short, having at its blunt apex an unguial spine much longer than the base, accompanied by several shorter spines on the inner part of the apex of the finger.

Pleopods.—Coupling spines small, slightly bent, with two retroverted hooks on one margin and three on the other, the apical in each case included, the cleft spines five in the series on one of the pairs, four on another; the joints of the rami eleven in the inner ramus, twelve in the outer.

Third Uropods.—The peduncles broad and long with a small stout spine at the inner apex, three along the middle of the distal border and several slender spines at the outer apex; the rami short, the inner a narrow oval, with a small spine at the apex, the outer broad near the base, narrowing distally, with an upturned spine at the apex, and two retroverted spines close above it, the nearest having a very broad base.

Telson almost an equilateral triangle, with two feathered setæ at the apex, and one near each margin higher up.

Locality.—The specimen from which the figures were drawn had been mounted in glycerine during the voyage, and was labelled as having been taken at the surface in the Pacific, December 28, 1875. This date corresponds with Station 302, lat. $42^{\circ} 43'$ S., long. $82^{\circ} 11'$ W.

A second specimen, which also appears to belong to this species, was also mounted during the voyage, this one in Canada balsam, and labelled as having been procured also at the surface, "Philippines, off Tablas."

Remark.—Mr. Chilton¹ says of his *Podocerus frequens*—"This species appears closely to resemble *P. validus*, Dana, from Rio Janeiro, but that species has the inferior antennæ 'very stout.'" He adds that "the process on the propodos of second gnathopoda of male varies in size in different specimens, and is often longer and more distinct than shown" in his figure. A specimen of the large second gnathopod of *Podocerus validus* from New Zealand was kindly sent me for comparison by Mr. G. M. Thomson.

Podocerus hocki, n. sp. (Pl. CXX.).

Rostrum small, lateral lobes of the head not large or very prominent, rather acute above; the postero-lateral angles of the first three pleon-segments rounded, especially those of the first segment, those of the third the least so. The animal everywhere covered with little dots that are bright when seen with transmitted light.

Eyes not perceived.

¹ Trans. New Zealand Inst., vol. xv. p. 85, 1883.

Upper Antennæ.—The first joint thick, shorter than the head, with slender spines at three points of the under margin; the second joint longer, much thinner, with spines at six points of the under margin, and spinules at three or four of the upper; the third joint thinner than the second, a little longer than the first, with spines at five points of the lower margin; the flagellum curved, of six rather stiff joints, together longer than the second joint of the peduncle, each joint tipped with a couple of spines and several setules; the secondary flagellum not half as long or half as broad as the first joint of the primary, consisting of a single narrow joint tipped with a seta and setule.

Lower Antennæ.—The first two joints short, the gland-cone narrow, acute, decurrent; the third joint as long as the two preceding united, with spines at two points of the under margin, and several about the apical; the fourth joint longer and stouter than the second of the upper antennæ, with spines at six points below, and some spinules above; the fifth joint similar, but thinner and slightly longer, both a little curved; the flagellum of five joints tipped with groups of short spines and setae, the five together equal in length to the second joint of the upper antennæ, the first longer than the two following united, and having several marginal spines and spinules. Both pairs of antennæ have what appear to be little hairy parasites, some of which are figured; in every case they are situated in a group of setæ or setules.

Mandibles.—The cutting edge divided into five teeth; the secondary plate with four teeth, stronger on the left than on the right mandible, the latter having only one that is at all prominent; the spine-row of three spines on the left, seemingly followed by one or two plumose setæ; on the right mandible there are only two spines; the molar tubercle prominent, with long teeth round the crown; in this species the laminar process is much longer than in *Podocerus falcatus*, fully twice as long as broad, bent close to its base, then straight, widening but little distally, much striated or ciliated, with the apical margin faintly dentate; the first joint of the palp short, distally widened, the second a good deal longer than the third, with many spines along both margins, a small space being vacant at the distal end of the inner and the basal end of the outer margin; the third joint from a narrow neck is expanded distally, the basal part free from spines, but the rest set with many feathered spines round both the outer and inner margin and the broad distal margin, where the spines are long. One mandible is figured in position beside the lower antenna to show the comparative sizes.

Lower Lip.—The principal lobes with the distal margins flattened, the inner lobes oval, neither pair strongly ciliated; the mandibular processes short, conical.

First Maxillæ.—The inner plate small, with a seta on the narrow apex; the outer plate narrow, with nine spines on the truncale distal margin, of which two have a single lateral tooth near the apex on the outer side, one may be considered as falcate, and the remainder have one denticle, two, or none, on the inner side; the first joint of the palp

is very short, the second rather long, widening distally, with a very convex outer margin, reaching a little beyond the outer plate, having seven spine-teeth set very closely round the angled distal margin, and having seven slender spines arranged near the top of the inner margin and under the distal margin.

Second Maxilla.—The inner plate shorter and much narrower than the outer, the row of plumose setæ beginning above the middle of the inner margin, the row of spines rather higher and continuing round the apex, but not descending the outer margin; the longer spines of the outer plate begin at the top of the inner margin, and pass round the broad apex, five or six of them being on its outer slope.

Maxillipeds.—The inner plates reaching beyond the first joint of the palp, having several plumose setæ on the inner margin, with a spine-tooth near and a denticle close to the apex, and on the somewhat angled distal margin three strong spine-teeth and several feathered spines; the outer plates not reaching the end of the second joint of the palp, their base very short, the serrate inner margin set with eight or nine spine-teeth, closely followed by eight spines on the serrate distal margin, the first four elongate spine-teeth, the last four tending to setiform; the first joint of the palp very short, the second two or three times as long, with setiform spines along the inner margin and round the apical; the third joint longer than the first, narrow, a little widened distally, with spines on the upper part of the inner margin, round the apical, and across the surface below the apical margin; the finger is nearly as long as the third joint if the ungual spine be included, this substitute for a nail being as long as the broad blunted basal part of the finger, which on the inner margin close to the root of the ungual spine carries half a dozen other spines more slender, but some of them nearly as long.

First Gnathopods.—Side-plates directed a little forward, of nearly even width throughout, the lower and hinder margins convex, the front tending to eoneave. The first joint reaching much beyond the side-plate, curving forwards, almost unarmed; the second joint short, with a group of several slender spines at the apex behind; the third joint with the convex front and hind margins on the inner surface converging to a pointed apex, with numerous spines along the lower half of the hind margin, some also on the front; on the outer surface this joint is much narrower, its front margin nearly straight; the wrist triangular, distally eup-like, much shorter than the hand, with a minute spine above the centre of the front margin and one or two slender spines at its apex, the hind margin having a large group of spines on the rounded apex and the adjacent distal margin, and a row of six or seven across the surface nearer the hind than the front margin; the hand is long and broad, with seven or eight groups of spines adjacent to the long convex front margin, three or four on or close to the short serrate hind margin, and four or five along the surface nearer the hind than the front margin; at the apex of the hind margin there is a stout palmar spine, and one above and one below it; the palm itself is oblique in a straight course, finely dentate or tuberculate,

fringed with submarginal spines of various lengths. The finger is broad, with the inner margin toothed, closing tightly along the palm till the nail which bends rather sharply on to the surface within the apex of the hind margin; the dorsal cilium is small, close to the base.

Second Gnathopods.—Side-plates considerably larger than the preceding pair. Branchial vesicles narrow, shorter and narrower than the first joint. Marsupial plates longer than the first joint and much broader, especially at the centre, surrounded by setæ which are not extremely long. The limb in the female differing very little from that of the first gnathopods, but with the hand rather larger. In the male the third joint is, as in the female, more oblong than in the preceding pair, with several spines about the distal margin which is pointed in front, rounded behind; the wrist is very small in comparison with the hand, triangular, distally cup-like, with some short stiff spines at the apex of the front margin, and long spines on the short free portion of the hind margin; the hand large, oval, broadest near the base, with many slender feathered spines, distributed much as in the first gnathopods, the serrate hind margin ending in a small apical tooth, within which is a palmar spine, near to which the obliquely sinuous palm is smooth for a short space, then has one or two low tubercles followed by two that are large and irregular in outline, concluding with a nearly straight tract of seven or eight little tubercles which reach the hinge; the broad curved finger bends on to the surface within the palmar spine; the dorsal cilium is short, near the base; the inner edge of the finger is cut into little spine-like rather distant teeth, and has some setules near the base of the nail.

First Peræopods.—Side-plates larger than the preceding pair. Marsupial plates longer than the first joint. The first joint reaching beyond the side-plate, packed with gland-cells in three rows; the margins with a few small spines and spinules; the second joint short, with one or two slender spines at the hinder apex; the third joint longer than the fourth, as long as the fifth, widening downwards, a little decurrent, with slender apieal spines; the fourth joint slightly armed at the apex in front, and at two or three points of the hind margin; the fifth joint narrowing distally, the hind margin almost straight, bordered with a few spinules or setules; the finger narrow, curved, about three-quarters as long as the fifth joint, with an opening in the tip.

Second Peræopods.—The side-plates larger than the preceding pair, the margins convex. The limb like that of the first peræopods.

Third Peræopods.—The first joint broad throughout its length, with five or six minute spines on the front margin and two or three slender ones at its apex, the convex hind margin almost smooth; the second joint short with some spinules at the apex in front; the third joint much longer than the fourth, about as long as the fifth, with spines at three points of the hind margin, and at two of the front; the fourth joint with spines at two points in front, and a group at the apex behind; the fifth joint with spines

at four points in front and a small group at the apex behind; the finger more than half the length of the fifth joint, curved, acute, with a very small dorsal cilium.

Fourth Peræopods longer than the third, similar, except that the front margin of the first joint is straighter, and the hind margin rather sinuous, the joint being a good deal narrower below than above.

Fifth Peræopods like the fourth, but longer, and with the fifth joint longer than the third.

Pleopods.—Coupling spines very thin, bent, with two or three small lateral hooks; the cleft spines not well made out, apparently three or four in a series; joints of the rami about ten in number.

Uropods.—Peduncles of the first pair longer than the rami, with five spines on one of the upper margins and six on the other, and the usual large spine on the lower apex; the outer ramus shorter than the inner, with five spines on one margin, one on the other, and a small apical group; the inner ramus with one margin free, otherwise armed like the outer; the peduncles of the second pair a little longer than the inner ramus, the apical spine short; the shorter outer ramus has four spines on each margin and an apical group; the inner ramus has seven on one margin, two on the other, and an apical group; the peduncles of the third pair longer than the rami, reaching beyond the other peduncles and the telson, with five or six groups of spines along the inner margin, and six small spines about the distal margin in two groups; the rami are short and narrow, subequal, with the acute apices a little bent, especially that of the slightly shorter outer ramus, this apex being a little pectinate; the inner ramus has a marginal spine.

The Telson in outline forms a pointed arch reversed, about as long as the greatest breadth; below it appears to have a carina, narrow near the apex, but towards the base spreading out into a triangular surface.

Length.—The male specimen from which fig. *gn.2. ♂.* was drawn, measured just over a fifth of an inch, in a straight line from the front of the head to the extremity of the uropods.

Locality.—Station 168, off New Zealand, July 8, 1874; lat. $40^{\circ} 28' S.$; long. $177^{\circ} 43' E.$; depth, 1100 fathoms; bottom, blue mud; bottom temperature $37^{\circ} 2$. Two specimens, male and female.

Remarks.—All the figures except *gn.2.* were drawn from the female specimen.

The specific name is given in compliment to Dr. P. P. C. Hoek, who in 1882 gave a brief description and some figures of a new species, *Podocerus tuberculatus*, among the Crustacea of the "Willem Barents" Expedition. This species was obtained in lat. $71^{\circ} 23' N.$, long. $49^{\circ} 38' E.$, and judging only from the preliminary description and the figures of the two gnathopods, third uropods, and telson, presents an extraordinary resemblance

to the Challenger species. The finger, however, in each gnathopod, is figured without the least trace of dentation on the inner margin, and the tuberculation of the palm in the second gnathopod, though similar, is not exactly like that of our species. Considering the enormous distance between the places of capture, I have not thought it right to identify the two forms. Had they belonged to a single species of so wide a distribution, it is highly improbable that it would have escaped discovery for so long, and then suddenly have been discovered almost simultaneously at two enormously distant points.

Podocerus tristanensis, n. sp. (Pl. CXXI.).

Rostrum minute, lateral lobes of the head not large or very prominent, acute above.

Eyes rounded, oval, occupying the lateral lobes of the head, dark in the specimens preserved in spirits.

Upper Antennæ.—The first joint thick, not quite so long as the head; with setiform spines at four or five points of the lower margin; the second joint longer, much thinner, with spines at five points of the lower margin; the third joint about as long as the second, with spines at six points, several of them feathered and of great length, on each joint the distal spines the longest; the flagellum of four joints, together longer than the third joint of the peduncle, with similar spines at each lower apex, the first joint the longest of the four and having spines at two points of the lower margin besides those at the apex.

Lower Antennæ.—The first two joints short, gland-cone small, decurrent; the third longer than the preceding two united; the fourth as long as the second of the upper antennæ and stouter, with spines at five points of the lower margin; the fifth joint rather longer, with six groups of spines; the flagellum of four joints, together as long as the third and fourth of the peduncle united, all carrying long apical spines and setæ, but not so long as those on the upper antennæ; the spine at the apex of the fourth joint shorter than the others.

Mandibles.—The cutting edge of both the principal and secondary plates appeared to be cut into several little teeth, of which two only on the right mandible are conspicuous in the secondary plate; the spine-row consisting of three denticulate spines on the left, and two on the right, mandible; the molar tubercle prominent, with strongly denticulate crown and a long seta; the laminar process on the front margin of the tubercle seems to be similar to that described for *Podocerus falcatus*; the first joint of the palp short, widening a little distally, the second joint longer than the third, with about seven pairs of spines along the front; the third joint with about a dozen long pectinate spines round the broad apex, three or four on the convex front margin, a row of four long ones across the middle of the outer surface, and two, one above the other, close to the convex outer margin.

Lower Lip.—The inner margins of the principal lobes not strongly sinuous; the mandibular processes rather long and divergent.

First Maxillæ.—The inner plate very small; the outer plate apparently carrying nine spines, of which the denticleation could not be clearly made out; the first joint of the palp very short, the second long, with four serrate spines on the apical margin, and three slender submarginal spines.

Second Maxillæ.—The inner plate shorter and narrower than the outer; the spines tolerably numerous on the apical border in each, not descending the outer margin in either.

Maxillipeds.—The inner plates not reaching quite to the distal end of the first joint of the palp, with a few setæ on the inner margin and several feathered spines on the broad distal margin, which probably also carries the usual three spine-teeth; in the figure the inner margin of this plate faces outward; when the maxillipeds are divided into two halves, the inner plate as a rule becomes reversed; the outer plates not nearly reaching the end of the second joint of the palp, with five spine-teeth on the serrate inner margin, and three or four more spines, partly spine-teeth, partly setiform, on the serrate apical margin; the first joint of the palp short, with a spine at the outer apex; the second more than twice as long as the first, with a spine at the outer apex, and many spines along the inner margin; the third joint narrower than the first, scarcely longer, with spines at the upper part of the inner margin and all round the apical margin; the trunk of the finger very little longer than broad, the slender apical spines longer than the trunk, the two together longer than the third joint.

First Gnathopods.—The side-plates broader than deep, the hind margin deeper than the front. The first joint reaching beyond the side-plates, narrow, widening distally, not longer than the wrist, almost entirely unarmed; the second joint short, with slender spines at the apex behind; the third joint with front and hind margins convex, each with a group of spines, the distal scarcely distinct from the hind margin, with seven feathered spines at the junction; the wrist much longer than broad, the front margin smooth, with an apical spine, the hind margin more convex than the front, fringed with numerous feathered geniculate spines; the surface carries five spines in three groups at a little distance from the hind margin; the hand tending to oblong, subequal in length to the wrist, with five groups of spines near the almost straight front margin, four single spines along the centre of the surface, and near the almost straight hind margin three or four groups; on this margin there are two stout spines, one at the centre, one nearer the apex, which may be considered as palmar spines, though remote from the palm, which is short, nearly straight, finely pectinate, joining the finely pectinate distal part of the hind margin by a rounded angle; the finger is broad, with a finely pectinate nearly straight inner margin ending in a tooth at the base of the strongly curved nail, and having three or four submarginal setules along its course, and a little spine-tooth near the centre; the finger

for half its length projects beyond the palm; the dorsal cilium is rather long, close to the base. In the female the shape of the gnathopods is the same, the spines are fewer; the side-plates are directed a little forwards, narrow, the lower margin very convex, separated from the hinder by a little notch.

Second Gnathopods.—Side-plates rather larger than the preceding pair, the breadth and depth about equal, the margins convex. The branchial vesicles very small, oval, the two following pairs larger, the fourth and fifth pairs again smaller. The first joint much shorter than the hand, bent forwards, narrow at the base, distally, beyond the side-plate, expanded in front into a rounded lobe carrying a couple of spinules; the second joint is very short, broader than long; the third not much longer than broad, with spines on the distal margin; the wrist very short, broader than long, distally cup-like, with a few spines on the apex behind; the hand broad and long, not twice as long as broad, with some spinules at the apex of the slightly convex front margin, and a couple of setules higher up; the much shorter hind margin has three groups of slender spines upon it and other spines on the adjacent surfaces, and apically forms a tooth-process, nearly an equilateral triangle, from which the long concave palm runs almost parallel to the front margin towards the finger, bordered with many submarginal slender spines, and before reaching the hinge bends abruptly, then conforming to the inner margin of the finger; the finger is stout, much curved, the inner margin smooth, the short nail reaching the triangular process already mentioned, of which the inner margin is crenulate; the part of the palm-margin near the finger appears to be finely serrate; the dorsal cilium of the finger is very short. In the female the first joint is less expanded distally, the hind margin of the hand is relatively longer, the palm rather shorter, the triangular process at the junction less conspicuous and accompanied by two submarginal palmar spines which were not observed in the other form; the finger is broad, curved, with the inner margin finely pectinate, carrying two little spine-teeth, and ending in a larger tooth, accompanied by three setules, at the base of the long curved smooth-edged nail, which reaches beyond the triangular process, of which the outer margin is pectinate. The dorsal cilium is long.

First Peraopods.—Side-plates rather deeper than broad. The first joint packed with three rows of gland-cells, reaching a little beyond the side-plate, not twice as long as broad, the front margin more convex than the hinder, with a spinule below the centre, the hind margin carrying three or four spinules, the distal margin projecting beyond the next joint; the second joint a little longer than broad, with an apical spinule; the third joint much longer than the fourth, and a little longer than the fifth, with a group of spines on the decurrent front apex, and a small spine higher up, the much shorter hind margin similarly armed; the fourth joint very little longer than broad, with two single spines on the hind margin, and an apical group; the fifth joint with two spinules on the convex front margin, and a group of slender spines at its apex, the hind margin almost straight, with two single stiff spines, followed by three small groups of slender spines;

the finger curved, almost as long as the fifth joint, with a small dorsal eilium near the base, and an opening in the apex.

Second Peræopods scarcely differing from the first, except that the first joint is more dilated, oval, with two spinules on the very convex front margin, and some long spines on the surface near the hind margin and at its apex.

Third Peræopods.—Side-plates with the front lobe as deep as the preceding side-plates, the hind lobe small. The limb missing. The side-plate and branchial vesicle are figured in position together with *prp.2.♂*.

Fourth Peræopods missing.

Fifth Peræopods.—The first joint little but evenly dilated, shorter than the fifth joint, with four or five spinules on each margin; the second joint longer than broad, with a spinule on the apex in front; the third joint longer than the fourth, shorter than the first or fifth, with slender spines at each apex, and a spine or spinule on each margin higher up; the fourth joint similarly armed; the fifth with a group of slender spines at the apex of the hind margin and a spinule at its centre, slender spines at three points of the straight front margin, and two little stiff spines close to the finger; the finger is short, curved, with two or three very small setules along the otherwise smooth inner margin.

Pleopods.—Coupling spines minute, narrow, bent, with two pairs of hooks; there appeared to be only one cleft spine on the inner ramus; the joints of the rami five in number; the outer ramus rather the shorter, with its first joint more dilated than the first of the inner ramus.

Uropods.—Peduncles of the first pair longer than the rami, with four spines on each of the upper margins, the inner of which has an acute apex; the apical spine below is broad but not very long; the rami are nearly equal, each with three marginal spines and an apical group; the peduncles of the second pair longer than the rami, with three spines on one margin; the outer ramus the shorter, with two spines on the outer margin, one at the blunt apex, and a little one above it, the inner ramus with a spine on the inner margin, and three at or near the apex; the peduncles of the third pair very broad, longer than the rami, reaching beyond the other peduncles, with two setæ on the outer margin, the apical border having two stout spines with two thinner ones on one side and one on the other; of the short rami the outer is a good deal shorter than the inner, with two minute spines at its slightly bent tip, the inner ramus with one such spine a little larger than those of the outer ramus.

The Telson as broad as long, forming a pointed aræ, not reaching the end of the peduncles of the third uropods, with a raised point near the margin on each side, some way above the apex, and a eilium adjacent to this tubercle.

Length.—The female specimen, in the position figured, with the pleon folded and the antennæ outstretched, was a tenth of an inch; the male was rather larger.

Locality.—Station 135c, off Nightingale Island, Tristan da Cunha, October 17, 1873; depth, 110 fathoms. Two specimens.

Remarks.—The specific name refers to the place of capture.

Genus *Dryopoides*, n. gen.

Mandibles with dentate cutting edge and secondary plate, spine-row of several spines, the third joint of the palp longer than the second.

Lower Lip with the mandibular processes long and pointed.

First Maxillæ with the inner plate small, carrying a single seta.

Second Maxillæ having a fringe of setæ near the inner margin of the inner plate.

Upper Antennæ.—The first two joints of the peduncle long, the third short; a very small secondary flagellum.

Lower Antennæ not longer than the upper; the fourth and fifth joints of the peduncle elongate.

Gnathopods subchelate, the *First* larger than the *Second*.

The *First* and *Second* pairs of *Peræopods* having the first and third joints a little widened for gland-cells, and having an opening in the apex of the finger.

The *Third*, *Fourth*, and *Fifth* pairs of *Peræopods* with the first joint little dilated; the third pair very short, the fourth pair longer than the third, and the fifth than the fourth.

Uropods with the rami equal in each pair; the third pair with minute rami and short broad peduncles that reach beyond the telson.

Telson simple, almost circular.

Side-plates not deep.

Sixth segment of the *Pleon* dorsally evanescent.

This genus is nearly related to *Dryope*, Spence Bate; in that genus as in this the upper antennæ have a small secondary appendage; the first gnathopod is larger than the second; the first joint in the last three pairs of peræopods is not broadly expanded; the rami of the third uropods are minute; the telson is undivided, approaching a circular form; on the other hand in *Dryope* the first and third joints of the first and second peræopods do not appear to be expanded for gland-cells as in *Dryopoides*, in all three pairs the rami of the uropods are unequal, and the dorsal arch of the sixth pleon-segment though very short is present. The genus *Dryope* was founded by Spence Bate in 1862 (Brit. Mus. Catal. Amph. Crust., p. 276) to receive a species which Gosse had described and figured in 1855 (Marine Zoology, p. 141, fig. 256) as *Uneiola irrorata*, Say; to this Spence Bate added a supposed new species, *Dryope crenatipalma*. For the original definition of *Dryope*, see Note on Spence Bate, 1862 (p. 336). The genus is also defined in the British Sessile-eyed Crustacea, vol. i. p. 487, and by Gerstaecker, in Bronn's

Klassen und Ordnungen, Bd. v. Abth. ii. p. 496, 1886. In all three definitions the upper antennæ are said to be without a secondary appendage, although Gosse, in describing the antennæ of the type species, had rightly observed "superior pair furnished with a minute appendage at the base of the lash." Spence Bate describes the three posterior pairs of peræopods (in his specific accounts) as subequal, but in fact the third pair is considerably shorter than those which follow. Gerstaecker in the generic definition says of these three pairs, "die drei letzten Paare verlängert, mit erweitertem Schenkclglied," whereas in fact attention should rather be called to the comparative narrowness of the first joint. The name *Dryope* will require alteration, being, according to Scudder's Nomenclator Zoologicus, preoccupied among Diptera in 1830.

The generic name is derived from *Dryope*, the genus above mentioned, and εἰδος, likeness.

Dryopooides westwoodi, n. sp. (Pl. CXXII.).

Rostrum very small, acute; lateral lobes more advanced, distally rounded, not broad, the head squared below the lobes; the back of the animal flatly rounded; the postero-lateral angles of the first three pleon-segments rounded; the fourth segment of the pleon as long as any of the three preceding segments, having a feathered cilium on the hind margin at either side, not showing any transverse dorsal depression; the fifth segment short; the sixth segment without any dorsal arch, so that from above the telson appears as if attached to the fifth segment.

The Eyes round, with about seventy ocelli in each, situated close to, rather than on, the lateral lobes of the head.

Upper Antennæ longer than the lower, but with much shorter peduncle. The first joint rather longer than the head, slightly curved, with two groups of spines on the under margin; the second joint longer than the first, also slightly curved, with slender spines on the lower margin and some spinules on the upper; the third joint little more than a quarter the length of the second; the flagellum of about thirty joints, the distal longer than those nearer the base, all together much longer than the peduncle; the secondary flagellum not visible on the outer side of the antennæ, consisting of a slender joint, with a minute terminal joint, the two together not so long as the first of the primary.

Lower Antennæ.—The first two joints short, the gland-cone decurrent, but very short; the third joint a little longer than the united first and second, with two groups of spines on the under margin, and two of shorter less slender spines near the upper; the fourth joint long, a little curved, longer than the second of the upper antennæ, slightly widening distally, carrying several groups of spines on both margins; the fifth joint longer than the fourth, with numerous spines; the flagellum not so long as the

fifth joint of the peduncle, of seven principal joints, all carrying strong curved spines at the apices, besides slender spines and setæ both there and elsewhere; there is a group of three strong curved spines on the apex of the seventh joint, but also an appearance of two little terminal joints tipped with long setæ or setiform spines. In both specimens of this species the lower antennæ were unsymmetrical, that is, one of the pair was longer than the other; this, however, is obviously only a curious coincidence, not indicating a specific character.

Upper Lip.—The distal margin broadly rounded, with a shallow central emargination, the tract on either side ciliated.

Mandibles.—The cutting edge with five teeth; the secondary plate with four strong teeth on the left mandible, alternately larger and smaller; the secondary plate on the right mandible consisting of one long tooth with three or four denticles on its upper edge; the spine-row of seven denticulate spines on the left, and six on the right mandible; the molar tubercle prominent, ciliated, with strongly dentate, more or less oval crown; the first joint of the palp longer than broad, slightly curved, and distally widened; the second joint more than twice as long, straight, with several spines grouped on and near the front margin; the third joint longer than the second, the outer margin strongly convex, carrying four long spines near the centre, the inner margin at first smooth and diverging from the outer, but at about a third of its length from the base becoming thickly fringed with pectinate spines, and forming a large conavity, so that the joint ends in a long narrow piece with a small apex, from which projects one strong spine. The left mandible is figured on the right, and the right mandible on the left, of the Plate.

Lower Lip.—The principal lobes not broad, dehiscent, lightly ciliated, but carrying a prominent row of five or six close-set spines at the point where the distal and inner margins meet; the inner lobes are comparatively broad; the mandibular processes are divergent, strongly produced to an acute apex.

First Maxillæ.—Inner plate small, oval, with a single long, slender, apical seta; the outer plate not very broad, the distal spines not in very good condition in our specimen, ten, I believe, in number, in some instances with a single lateral denticle on the inner or outer margin; the others with two or three not very conspicuous denticles on the inner margin; the first joint of the palp short, with a long spine or seta and a short one on the outer apex, the trunk below it having two or three spinules on the outer margin; the second joint widening from the base, subequal in breadth to the outer plate, and reaching beyond it, the dentate distal margin carrying eight spine-teeth, of which the outermost is the longest, and submarginal to these are six slender spines.

Second Maxillæ.—The inner plate a little shorter and a little wider than the outer; a series of six and twenty plumose setæ passes from near the base of the inner margin in a gentle curve towards the outer apex; a little higher up the margin begins a row of plumose spines, which keep pretty close to the margin; the spines round the inner part

of the apex are numerous, but do not descend its outer slope ; the outer plate has the inner margin smooth, slightly concave at the centre ; numerous long spines fringe the apical border, which on the outer side becomes very oblique.

Maxillipeds.—The inner plates reaching fully as far as the apex of the first joint of the palp, having the usual plumose setæ on the inner margin, the distal margins sloping inwards, carrying three strong but short spine-teeth and several feathered spines ; the outer plates not reaching the apex of the second joint of the palp, having nine spine-teeth not very closely set on the slightly crenate inner margin, and five spines round the serrate distal margin, the two outermost too long and slender to be called spine-teeth ; the first joint of the palp short, its particularly short inner margin carrying a slender spine ; the second joint more than twice as long as the first, with both margins convex, the inner having in or near it many very long slender spines ; the third joint a little longer than the first, the convex outer margin interrupted at some distance from the apex by a large row of feathered spines, the distal half of the inner margin and the concave apical margin also carrying spines ; the finger slightly curved and tapering to a blunt end, even with its terminal spine scarcely so long as the third joint, the dorsal cilium very near the hinge ; the ungual spine scarcely half the length of the trunk of the finger, attended by three or four setules planted near the inner apex of the finger ; on one of the fingers the ungual spine seemed to be in duplicate.

The oval *triturating organs* of the stomach show round one side a row of about sixteen spines with stout bases, and on the opposite side numerous slender spines, and some like them on the surface between the two rows.

First Gnathopods.—The side-plates less deep than broad, directed forwards, the lower margin crenate and fringed with setæ. The first joint almost entirely free from the side-plate, the front margin almost straight and smooth, the hind margin convex, with some long feathered setæ above the centre and some apical spines ; the second joint short, with spines in two or three groups near the apex of the convex hind margin ; the margins of the third joint converging to a pointed apex which lies upon the wrist ; one group of spines is near the middle of the hind margin, and two larger groups are between this and the apex ; the wrist is not quite so long as the hand, distally nearly as broad, with four groups of spines at the long convex front margin ; the free front of the hind margin convex, serrate, closely fringed with spines, some groups also being inserted on the adjoining surfaces ; the hand oval, nearly as long as the first joint, with four transverse rows of long spines at the front margin, which is continuous with that of the wrist ; there are several spines, singly and in groups, on the surface near the hind margin ; the hind margin serrate, carrying five groups of spines before reaching the palm, and between the apical group and that preceding it having a long and strong palmar spine ; the palm itself convex, bordered with spines and spinules ; the finger fitting the palm, with a dorsal cilium near the hinge, the inner border cut into many decurrent teeth.

Second Gnathopods rather smaller than the first. The side-plates not very unlike the preceding pair, but deeper than broad, not so strongly directed forward; the lower margin similar. The branchial vesicles oval, broader below than above, as long as the first joint and wider. The marsupial plates rather wide and long. The first joint almost free from the side-plate, narrower than in the first gnathopods, with long setiform spines spaced along the two margins, which are nearly parallel; the second and third joints as in the preceding pair; the wrist as long as the hand and distally wider, with five or six groups of slender spines along the long front margin, and the free part of the hind margin very thickly set with the same; the hand narrower than in the first gnathopods, fully twice as long as broad, of nearly even width throughout, but with the front margin slightly convex, the hinder straight; numerous groups of spines are on and near each margin; the finger appears to be similar to that of the first pair, but is much shorter, and nevertheless its curved tip reaches just beyond the short convex palm.

First Peræopods.—The side-plates as broad as deep, directed forwards, the front margin very convex, the lower straight, a little notched for the setæ. The branchial vesicles as in the preceding segment. The marsupial plates longer and much broader than the first joint, narrowed only at the distal end, the fringing setæ not long in proportion to the breadth of the plate. The first joint almost free from the side-plate, packed with gland-cells, with slender spines along the somewhat convex margins; the second joint with a small spine on the lobe in front, and a group of spines at the apex behind; the third joint broad, longer than the fourth or fifth, with a slender spine at each of two points on the front margin, and a group at its rounded apex, the hind margin with two groups; the fourth joint much narrower than the third, but broad in proportion to its length, with spines at the apex of the front margin, and in several groups along the hind margin, which is also furred with long cilia; the fifth joint longer than the fourth, the front margin convex, with a group of spines or setæ below the middle and another at the apex; the hind margin almost straight, furred, and carrying about eight groups of spines or setæ, which like the rest on this limb are feathered, but more prominently so; the finger curved, more than half the length of the fifth joint, having a feathered cilium near the hinge, and an opening in the apex.

Second Peræopods scarcely differing from the first; the side-plates, branchial vesicles, and marsupial plates a little wider.

Third Peræopods.—The side-plates much broader than deep, the front lobe narrowed below and fringed with setæ, having also many on the inner surfaces, the hind lobe broad and shallow, with the lower margin nearly straight, the hinder rounded and carrying one or two spines. The branchial vesicles shorter than the preceding pair, very broad at the centre. The marsupial plates narrower than the preceding pair. The first joint of the limb scarcely expanded, but wider than the following joints, twice as long as broad, with spines along both margins, some in the front elongate; the second joint a little longer

than broad, with spines near the apex in front; the third joint longer than the fourth, not quite so long as the fifth, the margins almost parallel, with slender spines at the apices and a spinule or two higher up; the fourth joint similar, a little narrower, and with stout spines as well as the slender at the apex behind; the fifth joint also with the margins nearly parallel, but the hinder a little convex, having slender spines at the apex, the front margin almost straight, with four groups of short strong spines, besides some that are setiform; the lower part furry; the finger strong and curved, more than half the length of the fifth joint, with a feathered dorsal cilium near the hinge, and another near the base of the nail; the concave inner margin strongly furred, and produced into a short thick tooth at the base of the short nail, the tooth having at its base a feathered spiniform seta which is prolonged over the inner margin of the nail.

Fourth Peræopods.—The side-plates smaller than the preceding pair, the front margin fringed with feathered setæ, the convex lower margin of the front lobe smooth, the straight lower margin of the hind lobe having some strong spines. The branchial vesicles not so long as the first joint, broadest a little below the neck. The limb similar to that of the third peræopods, but all the joints longer, the third rather longer instead, of rather shorter than the fifth, the spines more numerous.

Fifth Peræopods like the fourth, but all the joints longer.

Pleopods.—The coupling spines have a stout base, a slender shaft, somewhat bent, the apex forming a strongly bent hook between a pair of lateral hooks, which are also strong; the cleft spines appear to be a series of five in each pair; the joints of the rami number from ten to twelve, the outer ramus being considerably the shorter.

Uropods.—The peduncles of the first pair considerably longer than the rami, with marginal spines, and a spine-process with a broad base on the lower apex; the rami equal in length, reaching beyond the other two pairs, the outer with four short spines on the outer margin, three not so stout on the inner, and a group at the rounded apex, consisting of two subapical and a large apical between two much smaller spines; the other ramus has four on the outer, five on the inner, margin, and the apical group; the peduncles of the second pair are longer than the rami, and have a few spines; the outer ramus nearly equal to the inner, with three stout spines on the outer margin, one more slender on the inner, and the apex as in the first pair; the inner ramus has six spines on the inner, four on the outer, margin, and the apical group; the peduncles of the third pair are short and broad, just reaching beyond the telson, but not so far as the peduncles of the second pair, with a couple of feathered setæ or setules near the outer apex; the rami are diminutive, equal, narrowly oval, not reaching beyond the peduncles of the second pair, the inner carrying a slender feathered spine at the apex, another just above it on the outer side, and a third higher up on the inner side; the outer has a much longer apical spine, which is distally setiform, and a shorter one just above it on the outer side.

Telson broader than long, distally arched in outline, with a blunt central point;

a group of feathered setæ and elia is planted a little way from the distal margin, not far from each lateral margin.

Length.—The specimen, in the position figured, measured, in a straight line from the front of the head to the extremity of the third uropods, three-tenths of an inch.

Locality.—Station 161, off Melbourne, April 1, 1874; depth, 33 fathoms; bottom, sand. Two specimens. The specimen figured is a female; the other specimen, two-tenths of an inch in length, antennæ not included, is probably a male, differing from the female in having the palm of the first gnathopod partially excavate, near the palmar spine.

Remark.—The specific name is given in honour of the celebrated entomologist, J. O. Westwood.

Genus *Paradryope*, n. gen.

Mandibles with dentate cutting edge and secondary plate, the spine-row with few spines, the molar tubercle prominent, the palp very long, its third joint very little shorter than the second.

Antennæ with the peduncles elongate; *Upper Antennæ* with the third joint longer than the second, and a small accessory flagellum; *Lower Antennæ* with the fifth joint of the peduncle longer than the fourth.

First Gnathopods larger than the *Second*.

Third, Fourth, and Fifth Peraopods with the first joint little expanded; fourth pair longer than the third, fifth than the fourth.

First and Second Uropods with the outer ramus considerably shorter than the inner; *Third Uropods* with the peduncles broad, reaching beyond the telson, the rami minute, the outer a little longer than the inner.

Telson simple.

Side-plates shallow.

Sixth segment of the *Pleon* dorsally well developed.

The generic name refers to the resemblances shown by this genus to *Dryope*, Spence Bate, and the new genus *Dryopoides*; the long-jointed peduncles of the antennæ also recall the genera *Gammaropsis* and *Podoceropsis*.

Paradryope orguion, n. sp. (Pl. CXXIII.).

The Rostrum short, acute, the lateral lobes of the head acute, produced a little beyond the rostrum; the back of the animal rather broadly rounded, with the side-plates shallow; the postero-lateral angles of the first three segments of the pleon slightly rounded, each carrying a spinule; the fourth segment having two dorsal spinules.

The Eyes very small, round, situated near the lateral lobes of the head.

The specimen was mounted in Canada balsam during the voyage, and the full figure was drawn from the animal thus mounted, but in subsequently dealing with it for purposes of dissection I had the misfortune to lose almost all the parts, except fragments of the antennæ and some of the pereopods. Luckily some important details had been drawn before the accident, but it must be understood that these were subsequently described from the drawings, not, as in other instances, from the mounted dissections. It may perhaps be worth while to remark that in the full figure it is the larger gnathopod which is the first, though its terminal joints are to the rear of the smaller second gnathopod.

Upper Antennæ.—The first joint rather longer than the head; the second thinner and considerably longer, with slender spines on the lower margin; the third joint rather longer than the second, the margins serrate, the under fringed with long spines; the flagellum of eight joints, the first longer than any of the others, all together not so long as the first two joints of the peduncle, all carrying long slender spines on the under margin; the secondary flagellum of one slender joint, together with its apical setæ not so long as the first joint of the primary.

Lower Antennæ.—The first two joints very short, the third much longer than the two preceding, but shorter than the first of the upper antennæ; the fourth and fifth joints about equal respectively to the second and the third of the upper antennæ, and similarly armed; the flagellum of nine joints rather longer than the flagellum of the upper antennæ, the terminal joint less minute.

Mandibles.—The cutting edge on the left mandible with five teeth; the secondary plate with four teeth; the spine-row, I believe, with only three denticulate spines; the molar tubercle prominent, with rounded dentate crown; the palp of great length, the first joint short, the second very long, with only a few spines observed on the front margin, some perhaps on the lower part broken off or not noticed; the third joint a little shorter than the second, with the front and hind margins gently convex, the apex almost pointed, the front margin having a series of long spines beginning near the base, first with two spaced singly, these being followed by seven pairs.

First Gnathopods.—The first joint shorter and very much narrower than the hand, the hind margin more convex than the front; the second joint short, with a group of spines near the apex behind; the third joint with convex front margin produced to a pointed apex upon the wrist, the hind margin convex, with a group of spines where it joins the oblique lower margin; the wrist longer than broad, much shorter and narrower than the hand, but distally much broader than the preceding joints, with a group of spines near the apex of the convex front margin, and three groups along the hind margin; the hand very large, oval, not quite twice as long as broad, with spines at seven points of the front margin, not including any large groups, and about as many groups on the hind margin, more closely set and containing more spines; the palm curiously

sculptured, at first continuing the hind margin of the hand by the sinuous outer margin of a long tooth, within which three strong spaced palmar spines are set on the surface, the margin itself being pectinate with little spines for some distance; beyond the tooth is a cavity bordered with submarginal spinules, and followed by a smaller tooth leaning rather towards the hinge, and to this succeeds a small cavity and a convex space pectinately fringed and reaching to the hinge of the finger; the finger is strong, curved, with the central part of the inner margin cut into six decurrent teeth; the tip of the nail closes over on the side of the hand among the palmar spines.

Second Gnathopods smaller than the first. The third joint with spines along the distal border, and a group near the front margin; the wrist longer than in the first gnathopods, about as long as the hand, broad, except at the base, with numerous spines at various points of both margins and on the surface; the hand distally wider than the wrist, the front and hind margins convex; a few slender spines at various points of the margins and surfaces, and three or four strong palmar spines where the hind margin curves round to form the finely pectinate convex palm, over which the finger extends, closely fitting it, with slightly denticulate inner margin.

First Peraopods.—The first joint nearly free from the side-plate, with three little spinules on the slightly sinuous front margin, and one at the apex of the slightly convex hind margin; the second joint with a spinule at the apex of the hind margin; the third joint widening distally, with a spinule above the middle of the straight hind margin, a spinule near the top of the front margin, and a spine a little way below it, the apex rounded; the fourth joint narrower and a little shorter than the third; the fifth joint longer.

Second Peraopods similar to the first.

Third Peraopods.—The first joint very little widened; the third longer than the fourth, scarcely as long as the fifth.

Fourth Peraopods with the joints longer than those of the third; the first with five spinules along the nearly straight front margin, and one or two on the very slightly convex hind margin; the second joint with a spinule at the apex in front; the third joint much longer than the fourth, as long as the fifth, with three spinules standing out from the front margin, a spine at its apex, two spines on the hind margin on the upper half, and a group on the rounded scarcely decurrent apex; the fourth joint with a small spine above the middle of the nearly straight hind margin, and a group at the apex of each margin; the fifth joint with spines at three points behind and four in front; the finger curved, acute, scarcely more than half the length of the fifth joint, the edges smooth.

Fifth Peraopods longer than the fourth, very similar.

Uropods.—Peduncles of the first pair longer than the rami, carrying some marginal spines, and having a spine-process on the lower apex, the outer ramus shorter than the inner, both with marginal and apical spines; the peduncles of the second pair about equal to the inner ramus in length; the outer ramus much shorter and narrower, and

with fewer spines than the inner ramus, which is broad; the peduncles of the third pair broad, longer than the rami, reaching beyond the telson, having some small marginal and apical spines; the rami minute, subequal in length, narrow, and almost acute.

The Telson rather longer than broad, the sides converging below to a not very acute apex; there is a small spine near each lateral margin rather above the centre.

Length.—The specimen, in the position figured, measured, in a straight line from the rostrum to the extremity of the uropods, scarcely a fifth of an inch.

Locality.—Station 241, North Pacific, June 23, 1875; lat. $35^{\circ} 41'$ N.; long. $157^{\circ} 42'$ E.; depth, 2300 fathoms; bottom, red clay; bottom temperature, $35^{\circ}\cdot 1$. One specimen.

Remarks.—Beyond the fact of its requiring a new genus for its reception, there is nothing in the character or appearance of the specimen to enhance the probability of its having actually come from so great a depth. That it was thought worthy of exceptional care, or considered to be a specimen of exceptional interest, is implied by its having been mounted during the voyage.

The specific name, derived from the Greek *δρυνιῶν*, of the fathoms, refers to the great depth of the ocean at the place where the specimen was obtained.

Family COROPHIIDÆ.

In 1813 Leach instituted the family Corophini for the single genus *Corophium*, but the following year he merged the Corophini in the larger family Podoceridæ. In 1849 Dana established the family Corophidæ for the genera *Cerapodina*, *Cerapus*, *Corophium*, *Podocerus*, *Unciola*, *Atylus*, and *Clydonia*; in 1852 he upheld this family, with the three subfamilies, Clydoninæ, Corophinæ, Iciliinæ, assigning to the Clydoninæ only *Clydonia*, to the Iciliinæ *Icilius* and *Pterygocera*, to the Corophinæ the genera *Corophium*, *Siphonacetes*, *Platophium*, *Cyrtophium*, *Unciola*, *Podocerus*, *Cratophium*, *Cerapus*, *Cerapodina*, and *Erichthonius*. Costa in 1857 divided the family Podoceridei into three subfamilies, the Podocerini with the genera *Erichthonius*, *Cerapodina*, *Cerapus*, *Podocerus*; the Unciolini with the genera *Microdeutopus* and *Unciola*; and the Corofiini with the single genus *Corophium*. Spence Bate in the same year adopted the family Corophiidæ with three subfamilies, the Podocerides containing the genera *Pleonexes*, *Amphitoë*, *Sunamphitoë*, *Podocerus*, *Cyrtophium*; the Cerapides with the genera *Erichthonius* and *Siphonocetus*; the Corophiides with the genus *Corophium*. In 1859 Bruzelius assigned to the "Corophidæ, Dana," the genera *Corophium*, *Erichtonius*, *Jassa*, *Podocerus*, *Autonoe*, *Amphithoe*. In 1862 Spence Bate accepted the limits of the Corophiidæ, which Dana had assigned them in 1852, but he omitted *Pterygocera* and included the genera *Amphithoë*, *Sunamphithoë*, *Derothoe*, *Nænia*, *Cratippus*, *Dryope*,

besides uniting *Platophium* and *Cyrtophium*, *Cratophium* and *Podoecerus*, *Eriethonius*, *Cerapodina* and *Cerapus*; to the subfamily Corophiides he gave the genera *Cyrtophium*, *Cratippus*, *Dryope*, *Unciola*, *Corophium*, *Clydonia*, *Ielius*. The definition of the subfamily Corophiides by Bate and Westwood is given in the British Sessile-eyed Crustacea, vol. i. p. 478 (1862), although the name Podocerides is given by an accidental error at the head of several of the following pages. In 1870 Boeck made the Corophinæ the twenty-third¹ subfamily of the Gammaridæ, placing in it the genera *Corophium*, *Siphonacetus*, *Glauconome*, *Hela*. In 1872–1876 Boeck made the Corophidæ the eighth family of the Gammarina, with two subfamilies, the Corophinæ for the genera *Corophium*, *Siphonæetes*, *Glauconome*, and the Helainæ for the single genus *Hela*.

In 1880 Nebeski gives to the "Corophiiden" two subfamilies, 1. the Podoerinae, containing *Amphithoe*, *Podoecerus*, *Microdctopus*, *Micropotopus*, *Cerapus*, and by implication *Eriethonius*; 2. The Corophinæ, with the single genus *Corophium*. Of the family he gives the following account:—

"The Crustacea that belong to this family form a group sharply defined, as well morphologically as biologically. They are in general characterised by having the body little compressed laterally, by the powerful lower antennæ, in which the peduncle has joints of considerable strength and generally far surpasses the flagellum in length; a further very important character lies in the possession of the glandular apparatus in the third and fourth thoracal-limbs [first and second peræopods], of which the finger is always perforated, affording an exit for the secretion." On the ground of the absence of this last character he excludes the genus *Cyrtophium*, as represented by *Cyrtophium darwini*, Spence Bate, from the Corophiidae, and suggests its transference to the Dulichiidae.

In the same year S. I. Smith instituted the subfamily Cerapinæ, of which the definition has been already quoted, see Note on S. I. Smith, 1880 (p. 522). In this he placed the single genus *Cerapus*, giving notes at the same time upon *Eriethonius* and *Unciola*, but without stating what subfamily he thinks they ought to stand in.

Carus in 1885 adopts the family "Corophiidae, Dana" for two subfamilies, the "Corophinæ (Dana) Cls., " with the genera *Cratippus*, *Corophium*, *Iridium*, and the "Podocerinae, Cls., " with the genera *Cerapus*, *Microdctopus*, *Micropotopus*, *Podoecerus*, *Grubia*, *Amphithoe*. The arrangement by Gerstaecker in 1886 has been already explained; see Note on Gerstaecker 1886 (p. 580).

In 1882 G. O. Sars, dropping all subfamilies, places in the family Corophiidae the genera *Corophium*, *Siphonæetes*, *Cerapus*, *Unciola*, *Helella* [*Neohela*].

¹ In Boeck's work it is numbered "XXII," the error arising from the circumstance that he gives the same number "XVI." both to the Ampeliscinæ and to the Leptocheirinæ, and numbers the subfamilies consecutively from the Leptocheirinæ onwards.

The definition which Boeck gave of the Corophidæ in 1876 is as follows :—

“ *Mandibles* with the palp generally three-jointed.

“ *First Maxillæ* with the inner plate small or obsolete ; the palp two-jointed, apically armed with teeth, rarely with slender spines (setis).

“ *Second Maxillæ* more or less broad.

“ *Maxillipeds* with the outer plate armed on the inner margin with teeth or short spines ; the last joint of the palp apically furnished with spines or unguiform.

“ The body depressed ; the side plates very small.

“ *Third Uropods* uniramous.”

The subfamily Corophinae he defines as follows :—

“ *Upper Lip* broad, apically rounded, and setose.

“ *Mandibles* strong, apically dentate ; the secondary plate also dentate ; [the molar tubercle strong and prominent]¹ and the lower series of teeth ending in a long plumose seta ; the spine-row composed of few, but broad, apically dentate, spines ; the palp three- or two-jointed.

“ *Lower Lip* broad, the inner plates strong.

“ *First Maxillæ* having the palp apically armed with strong teeth ; the inner plate small or obsolete.

“ *Second Maxillæ* more or less broad.

“ *Maxillipeds* broad, strong ; the outer plate armed on the inner margin with teeth or spines ; the fourth joint of the palp apically furnished with two strong spines or unguiform.

“ *The Body* depressed, broad, robust ; the side-plates small, rigid.

“ *The Head* dilated.

“ *Lower Antennæ* generally stronger than the *Upper*, pediform, apically furnished with curved spines (unguibus), in the male very robust.

“ *Second Gnathopods* generally stronger than the *First*.

“ *Pleopods* short, strong ; the peduncle sometimes on the inner side strongly dilated.

“ *First and Second Uropods* biramous ; the rami little elongate.

“ *Third Uropods* small, short, broad, uniramous.

“ *Telson* laminar.”

To include *Cerapus*, this definition will require to be modified by saying that the *Maxillipeds* are generally broad, and that the *Second Uropods* are sometimes uniramous.

¹ There is no equivalent for the bracketed words in either of Boeck's works, but as the definitions have evidently been copied into the larger work from the smaller and earlier one, the repetition of mistakes after the author's death is not to be wondered at ; the accounts of various species will, I think, justify the mode above adopted of filling up an obvious hiatus.

For original definition of the genus, see Note on Say, 1817 (p. 100). Boeck's definition is inapplicable, being based in fact on species of the neighbouring genus *Erithonius*, Milne-Edwards. In connection with those already given for the family (and subfamily), the following characters may suffice for the genus:—

Mandibles with the third joint of the palp nearly or quite equal in length to the second.

First Maxillæ with the inner plate small.

Maxillipeds with the palp elongate, having its fourth joint armed with an unguial spine.

Antennæ subequal in length, both pairs stout, with short flagella.

Second Gnathopods in the male much stronger than the *First*, having the wrist much larger than the hand.

First and Second Peraopods with the first joint much dilated.

Third and Fourth Peraopods with the terminal joints reversed.

Pleopods without cleft spines on the first joint of the inner ramus.

Second Uropods uniramous.

Telson bilobed.

¹ The genus *Lusyta*, Nardo, 1847 (see Note on Nardo, 1869, p. 390), is probably a synonym of *Erithonius* rather than of *Cerapus*.

Cerapus sissmithi, n. sp. (Pl. CXXIV.).

The Rostrum is acute, curving slightly downwards, prolonged beyond the small lateral lobes of the head, which viewed from above appear to be acute, but are in fact a little rounded; the sides of the head emarginate behind the lateral lobes for the lower antennæ; the back round, widening a little from the head to the third peræon-segment, the pleon-segments narrowing successively to the telson.

The Eyes small, round, situated on the lateral lobes of the head.

Upper Antennæ a little shorter than the lower. The first joint larger, longer, and much broader than the second or third, distally produced both above and below, below into a pointed apex, above in a larger rounded process carrying some setules; there are also some small spines and setules on and near the lower process; the joint is broadest where the processes begin; the second joint is broader than the third and a little longer, with a small apical pointed process, the lower margin convex, carrying four groups of spines, some of them long; the upper margin has four or five setules; the third joint with setules on the upper margin and five groups of spines on the lower, the apical especially very long; the flagellum of five joints, together not equal to the second and third of the peduncle, all armed with groups of spines and cylinders, the first joint having three groups on its under margin.

Lower Antennæ.—The first and second joints very short, the gland-cone inconspicuous; the third joint a little longer than broad, with straight upper and convex lower margin, carrying some small spines and spinules; the fourth joint nearly as long as the first of the upper antennæ; the fifth joint as long as the fourth but not so broad, the two armed nearly as the second and third in the upper antennæ; the flagellum of four joints tipped with strong spines, and also carrying groups of setæ or very slender spines; the four together longer than the fifth joint of the peduncle.

Upper Lip.—The distal margin evenly rounded.

Mandibles.—The cutting edge divided into four or five unequal teeth; the secondary plate on the left mandible with four teeth, that on the right narrower, with an apical tooth, above which the margin is only slightly dentieulate; the spine-row, as seen on the left mandible, of three spines, distally much dentieulate and bent backwards; on the right mandible there appear to be only two spines; the molar tubercle a little prominent, with the dentate crown pentagonal or almost circular, but decidedly flattened on one edge which is the most strongly dentieulate; on the opposite border there is a little laminar process, narrow at the base and widened distally; there is a small round-headed process near the base of the palp; the first joint of the palp a little longer than broad; the second joint between two and three times as long as the first, with eight or nine spines in five groups in or near the front margin; the third joint very little shorter than the second, distally a little broader, with a long feathered spine at the middle of

the front margin, followed by two pairs of similar spines at intervals, and an apical group of eight; just above the centre of the hind margin is a single spine, and on the outer surface not far from the base, distant from either margin, two very long spines are planted (shown in the figure, as seen through the transparent joint).

Lower Lip.—Both the principal and inner lobes appear to be very slightly ciliated and distally deliscent, the principal lobes also with the inner margins wide apart for a considerable distance, and having a notched appearance, as if of incipient jointing, on the outer margin; the mandibular processes rather divergent, the apices rounded.

First Maxillæ.—The inner plate very small, apically narrow, without any trace of setæ that I can perceive (in *Cerapus tubularis*, Say, they are, according to S. I. Smith, tipped with one or two setæ); the outer plate broader at the base than distally, with nine spines on the slightly convex distal margin, four of which have a little denticle below the furcate top, the other five are longer and have several minute lateral denticles; the first joint of the palp short; the second reaching beyond the outer plate, widening a little from the base, with five spine-teeth on the dentate apical margin, and three slender submarginal spines.

Second Maxillæ.—The inner plate shorter and narrower than the outer, with some spaced plumose setæ on the inner margin, beginning beyond the middle of it, near the apex, which has many long spines closely set; the spines are longer and more numerous round the broader apex of the outer plate.

Maxillipeds.—The inner plates not nearly reaching the apex of the palp's first joint, with some setæ on the inner margin, and the subapical spine-tooth, the broad distal margin having three spine-teeth and some slender spines; the outer plates reaching to about the middle of the palp's second joint, the inner margin for some distance smooth, except for the long slender spines which project beyond it from the outer surface, but near the apex having four spine-teeth, followed by four longer spines round the distal margin; the first joint of the palp of average length, with two long slender spines on the short inner margin; the second joint not twice as long as the first, with numerous long spines on its inner margin; the third joint subequal in length to the first, the margins almost parallel, the apical border carrying many long spines; the finger very short, the distal end pointed above, carrying a group of spines, one of which is long and strong, and if reckoned as the nail would make the finger equal in length to the third joint.

First Gnathopods.—Side-plates very small, rather broader above than below, not contiguous with the following pair. The first joint almost entirely free from the side-plate, widening at once from the narrow neck, very little longer than the hand, the hind margin convex, smooth, the front straighter or a little concave, with setules; the second joint short, with an apical seta; the third a little longer than the second, the front and hind margins smooth, slightly convex, the distal margin having an irregular row of long spines planted just above it; the wrist rather shorter than the hand, distally rather wider,

with spines at the apex of the front margin, the hind margin serrate, fringed with about a dozen feathered spines in double row, the surface at a little distance having another series of half-a-dozen spines; the hand narrow at the base and distally, with four groups of spines along the front margin; the hind margin (as distinct from the palm) short and smooth; the greatest breadth of the hand at the beginning of the slightly convex, serrate, finely pectinate palm, which is fringed with feathered spines in three groups of three, followed by half-a-dozen spaced singly; there are a few others on the surface apart from the margin; the finger occupies the apex of the hand, and in length matches the palm, the dorsal cilium close to the base, the inner margin finely pectinate, with three setules at intervals, a decurrent tooth before reaching the nail, and two or three long setules planted at the base of this tooth.

Second Gnathopods.—The side-plates shallow, broader than deep, with a cilium on the front margin. The first joint free from the side-plate except at the narrow neck, then at once attaining its greatest width, the distal width more than half the length; the second joint narrower than the first, but broader than long, with an apical seta; the third joint narrowly oval, longer and narrower than the second, with a few spines on the rounded apex; the wrist of great size, very much broader and longer than the first joint, wide at the base but much wider distally, the front margin sinuous, the hind margin rather longer than the front, and where free from the third joint slightly crenate, with about five small groups of spines, ending in a strong dental process, between which and the apex of the front margin its distal margin is as long as the front margin; of this distal edge rather over a third in front is occupied by the articulation of the hand, the remainder forming a palmar margin, consisting of a large, convex, finely denticulated prominence between two small cavities, within which some slender spines project; there are a few more such spines at points on the surface; the hand is subequal in length to the wrist, but very much narrower, so as to be strap-shaped, but strongly curved, with a little denticulate process on the inner margin close to the hinge, the convex outer margin having a few spinules at intervals, the concave inner margin seemingly sharp-edged and smooth till near the apex, where it carries a row of close-set adpressed teeth or spines, being also fringed throughout with submarginal spinules; the finger is rather less than half the length of the hand, with a tolerably large dorsal cilium near the base, the inner margin smooth except for a decurrent tooth near the base of the nail accompanied by setules, and a group of four setules close together at some little distance from the base.

First Peræopods.—The side-plates rather larger than the preceding pair, forming a separate little lobe in front, armed with a feathered cilium. The branchial vesicles narrowly oval, much shorter and very much narrower than the first joint. The first joint free from the side-plate, nearly as long as the next four united, broad, and occupied with gland-cells; immediately below the narrow neck the front margin is strongly convex, fringed with a few setules and feathered setæ; below it is nearly

straight; the hind margin somewhat more evenly convex, converges to the narrowed distal margin, which is nearly straight, projecting in front beyond the second joint, parallel with a continuation of the hind margin, which crosses the surface just below the neck; near the convex part of the front margin, a curved slit crosses the outer surface of the joint nearly halfway; the second joint longer than broad, with one or two setules on the hind margin; the third joint longer than the fourth, widening distally, with feathered spines at the apex of the convex front, and at three points of the straight hind margin, one at its apex elongate; the fourth joint not longer than the second, with spines at the apex in front, and at two points of the hind margin; the fifth joint subequal in length to the third, narrowing distally, with feathered setæ at the apex of the very convex front margin and a spinule above, and setæ at four points of the straight hind margin; the finger three-quarters the length of the fifth joint, rapidly tapering, curved, with an opening in the apex.

Second Peræopods.—The side-plates with a front lobe as in the preceding pair. The branchial vesicles larger than in the preceding pair. The first joint with the front margin evenly convex, making the plate more regularly oval than in the first peræopods, less broad above but equally long; in this pair the third joint is nearly as long as the fourth and fifth united, and the fourth is quite as long as the fifth; the limb otherwise nearly as in the preceding pair.

Third Peræopods.—The side-plates much broader than deep, having the convex lower margin of the front lobe bordered with feathered setules, the small and shallow hind lobe having a cilium in a notch of the lower margin. The branchial vesicles much smaller than the preceding pair. The first joint irregularly squared, as broad as long, but rather broader above than below; the second joint broader than long; the third distally as broad as the length, the front margin convex, with small spines at the apex, the hind margin nearly straight, with three strongly plumose spines at the slightly decurrent apex; the short fourth joint almost embedded in the third, than which it is abruptly much narrower, distally broader than long, the hind margin very convex, its rounded apex furred and carrying a feathered seta, the apex in front rounded, carrying two or three setules; the fifth joint almost as long as the third, tending to oval, but with the hind margin almost straight, carrying a small seta above the apex, the front margin convex, smooth, with two setæ at the apex; the finger very short, stout at the base, with a broad sharp nail abruptly upturned behind, there being a small dorsal cilium near the base of this nail, and still nearer two little dorsal teeth.

Fourth Peræopods.—The side-plates not very unlike the preceding pair in outline, but smaller and with smooth edges. The branchial vesicles very small. The first joint narrower and longer than in the preceding pair, more oval than square; the second joint scarcely longer than broad; the third much longer than the fourth, a little widened distally, with a setule at the apex of the almost straight hind margin, one at the middle

of the slightly convex front margin, and some setæ at its apex ; the fourth joint a very little longer than broad, with long feathered spines or setæ at the apices ; the fifth joint as long as the third, resembling the fifth joint in the preceding pair, but longer, and its finger having a longer nail.

Fifth Peraopods.—The side-plates apparently smaller than in the preceding pair. Branchial vesicles perhaps not present. The first joint a little longer and more pyriform than in the fourth peræopods, the front margin nearly straight ; the second joint longer than broad ; the third, fourth, and fifth all longer than in the preceding pair, the fifth having the hind margin convex and the front straight, instead of reversed as in the two preceding pairs, the two margins, however, being nearly parallel ; the finger with the upturned point in front.

Pleopods.—The coupling spines small and slender, the apical and a second pair of retroverted hooks being close together and sharp ; there do not appear to be any cleft spines ; in the first pair the joints of the inner ramus are seven or eight in number, of the outer nine, the first of the outer being much more expanded than that of the companion ramus and fringed on the outer margin with many long feathered setæ ; the other two pairs were not observed with precision, but were successively smaller, as in the next species.

Uropods.—The peduncles of the first pair longer than the rami, with a few slender spines along the distal half of the upper outer margin, the distal margin pectinate ; the outer ramus longer than the inner, with eight or nine setiform spines within the slightly curved outer margin, which is also bordered with rows of little tooth-like spines ; there is a strong spine at the rounded pectinate apex ; the shorter inner ramus appears to have both lateral margins smooth, the apex as in the outer ramus ; the peduncles of the second pair do not reach so far as those of the first, but are longer than the single ramus, of which the inner margin is smooth, nearly straight, the outer convex, fringed to some extent like the outer ramus of the first pair, the apex blunt, not pectinate, carrying a setiform spine ; the short broad peduncles of the third pair begin about on a level with the apices of those of the other pairs and extend beyond the telson ; they have the inner margin convex, carrying a setule, the outer tending to concave, armed with two setules ; the ramus is minute, only just projecting beyond the peduncle, with two upturned sharp spine-teeth and a little tooth behind each.

The Telson is very short, broader than long, bilobed, with a girdle round the middle of about fifty little spine-teeth.

Length.—The specimen, in the position figured, measured, from the rostrum to the back of the seventh peræon-segment, a little over one-tenth of an inch.

Locality.—The specimen, evidently a male, was obtained at Kerguelen Island, Station 149 H, off Cumberland Bay, Jan. 29, 1874 ; depth, 120 fathoms ; bottom, volcanic mud. There are two other specimens in little cylindrical tubes of sand, one with the head and

antennæ protruding. This is represented in the Plate, fig. A, natural size. The case has two or three little warty exerecesses of sand upon it, and an empty Globigerina shell.

Remarks.—The specific name is given in compliment to S. I. Smith, Esq., who has redescribed *Cerapus tubularis*, Say, in a very important paper. See Note on S. I. Smith, 1880 (p. 522). I ought to mention that the separate figures of the gnathopods in the Plate were drawn with the A eye-piece of my microscope, and those of the peræopods with the B eye-piece, so that in these figures the peræopods are on a larger scale than the gnathopods.

Cerapus flindersi, n. sp. (Pl. CXXV.).

The Head with a small, sharp, carinate, slightly depressed rostrum; the lateral lobes of the head well advanced, apically a little rounded, the head emarginate below and a little behind the lobes; the first two segments of the peræon very short, together not as long as the head, the next three segments very long, especially the third of them; the pleon tapering distally, the postero-lateral angles of the third segment acute.

The Eyes round oval, situate on the lateral lobes, retaining a dark colour in the specimen preserved in spirits.

Upper Antennæ grooved on the under side for the reception of the dilated fourth joint of the lower antennæ. The first joint winged near the base, much longer than the second joint, the upper margin convex, the opposite margin below the wing straight, with four groups of long spines; the second joint with the margins slightly convex, some spinules on the upper, six groups of long spines on the lower; the third joint with straight margins, narrower than the second, as long as the first, with spinules above, and on the lower margin two groups of short and seven of long spines; the flagellum of four joints, the first the longest, the four together equal in length to the third joint of the peduncle, all carrying cylinders and strong denticulate spines.

Lower Antennæ subequal in length to the upper. The first two joints very short, gland-cone very small; the third joint a little longer than broad, the upper margin convex, some spinules and spines distributed at various points, chiefly on the distal margin; the fourth joint dilated at the base, abruptly broader than the preceding joint, subequal in length to the third joint of the upper antennæ and thicker, with several groups of long spines planted near the upper margin and some groups of spines and some spinules near the lower margin; the fifth joint longer and more slender, narrowing a little distally, fringed below with several groups of long feathered spines; the flagellum of four joints, the first the longest, the four together a little longer than the last of the peduncle, all carrying denticulate spines, and the last a very strong one, shorter than the rest, with an almost hooked tip.

Upper Lip.—The distal margin evenly convex, with a small piece at the centre smooth, between two tracts that are finely furred.

Mandibles.—The cutting edge divided into five teeth; the secondary plate on the left mandible having four strong teeth, on the right mandible having an oblique irregularly dentieulate margin, with a small tooth at the upper, and a more prominent one at the lower, end; the spine-row of two broad spines distally tapering and strongly denticulate and feathered; the molar tubercle prominent; on one edge of the dentate crown on the right mandible were seen eleven teeth very distinct, not crowded, at one corner a long plumose seta, and on the opposite side a small oval dentieulate excrescence, corresponding to the laminar process already noticed in some other species; the first joint of the palp a little longer than wide, widening distally; the second joint two and a half times as long as the first, with four spines, three of which are on the lower half and very long; the third joint very little shorter than the second, with five long feathered spines on the distal half of the front margin, followed by three on the narrow apex.

Lower Lip.—The principal lobes a little dehiscent, and like the inner lobes not very strongly ciliated; the mandibular processes divergent, rather long and narrow.

First Maxillæ.—The inner plate small, with a long apical seta; the outer plate with ten spines easy to count on the distal margin, whereas in *Cerapus sismithi* there are, I think, certainly only nine; of the ten in the present species five that are longer than the rest have several minute lateral denticles, of the others three have a denticle on the outer side; the second joint of the palp has seven spine-teeth on the distal margin and four submarginal slender spines.

Second Maxillæ.—The setæ of the inner plate do not appear to descend the inner margin so far as in *Cerapus sismithi*.

Maxillipeds.—The inner plates not reaching so far as the distal end of the palp's first joint, with setæ passing from the inner margin across the distal angle, the distal margin broad, with three spine-teeth and several feathered spines, a subapical spine-tooth on the inner margin; the outer plates reaching beyond the middle of the second joint of the palp, having ten spine-teeth on the inner and oblique apical margins, successively longer, the six on the inner margin also successively thicker, the apical four becoming successively thinner; the first joint of the palp more than half the length of the second, its inner margin only half as long as the outer, carrying two spines; the second joint fringed on the inner margin with many long spines; the third joint shorter than the first, the margins nearly parallel, the apical part crowded with long spines; the finger very short, narrowing distally, the ungual spine on the apex rather longer than the basal part, the two together rather longer than the third joint.

First Gnathopods.—Side-plates small, a little broader than long, with two or three spinules at the lower margin. The first joint all but free from the side-plate, much longer than the hand or wrist, widening distally, the front margin eveneave, fringed with

spinules, the hind margin convex, with a slender spine at the apex; the second joint as broad as long, with a similar spine near the apex; the third very little longer than the second, with some spines on the rounded hind corner, and long ones projecting from the surface on the distal margin; the wrist a little longer and distally a little broader than the hand, the convex front margin smooth, with a group of spines on the apex; the hind margin jutting out when free from the third joint, then straight, serrate, carrying six groups of spines, some strongly denticulate except at the distal part; on the surface at some distance from this margin is a group of two followed by a row of five spines; the convex front margin of the hand has seven groups of long curved spines on or near it; the hind margin juts out a little from the base, but not far enough to bring the slightly convex palm-margin on a level with the hind margin of the wrist; the palm-margin has two little projecting teeth, the distal end serrate, and six or seven groups of spines like those on the wrist; planted on the surface a little remote from the margin, but projecting beyond it, there are three strong spines apart from one another; the finger matches the palm; there is a rather long dorsal cilium near the base, the inner margin almost straight, and at first almost smooth, then becoming more and more strongly pectinate, and forming a strong decurrent tooth near the base of the slightly inflected nail, there being two short and two long setules in the neighbourhood of the tooth.

Second Gnathopods.—The side-plates broader than deep, with some setules in front, much shallower behind than in front. Marsupial plates narrow, shorter than the first joint, having seven long setæ. The first joint expanded on the outer side, with a convex front margin fringed with slender spines and spinules, but the front margin of the unexpanded inner surface resembling that in the first gnathopods; the second joint as in the preceding pair; the third joint rather longer, with some spines of various lengths along the distal part of the convex hind margin, and some short spines on and projecting from the surface beyond the truncate distal margin; the wrist triangular, longer than in the preceding pair, very similar in armature; the hand as long as the wrist, narrowly oval, narrower distally than at the base; the armature very similar to that in the first gnathopods, but the groups more widely spaced; the finger a little longer, its inner margin more curved, denticulate.

First Peræopods.—Side-plates broad and shallow. Branchial vesicles a very elongate oval. Marsupial plates like the preceding pair. First joint of the limb free from the side-plate, very large, packed with gland-cells, longer than the next four joints united, broader above than below, articulated almost at the top of the hind margin, the front squarely and very prominently angled, the sides carrying several marginal spinules, and the angle two or three feathered setæ; the lower margin projects beyond the second joint; a long transverse slit crosses the surface of the joint from the front almost to the rear near the centre; the second joint broader above than below, rather longer than broad, with some spinules at either apex; the third joint shorter than the second,

broader than long, both margins strongly convex, with long apical spines ; there is a long spine also on the inner surface near the hind margin, and a longitudinal groove in front of the middle of the outer surface ; the fourth joint shorter and narrower than the third, with long feathered spines at each apex ; the fifth joint shorter than the second, longer than the third or fourth, with a row of four setiform spines on the slightly concave hind margin, three or four on the rounded apex of the front, with a spinule higher up ; the finger more than half as long as the fifth joint, tapering at first abruptly, then gently, with an opening on the tip.

Second Peraopods.—Side-plates very broad and very shallow, with a little front lobe carrying a couple of feathered spines at the lower front corner. The branchial vesicles long oval, broader than the preceding pair, and not much apically narrowed. Marsupial plates like the preceding pairs. The first joint of the same character and size as in the first peraeopods, but of different outline, broader below than above, the front margin evenly convex, unangled ; the second joint twice as long as broad ; the third joint longer than the second, longer than the fourth and fifth united, with some marginal spinules besides the apical spines ; the remaining joints much as in the first peraeopods.

Third Peraopods.—The side-plates attached to the lower border of the long segment for almost its whole length, forming a small lobe in the rear, but for the most part of considerable and nearly uniform depth, the slightly crenulate margins armed with setæ of moderate length, twenty-four in number, the series beginning about the middle of the front margin and continued nearly to the hinder lobe. From the appearance of this pair of side-plates it may be supposed that they fulfil the function of marsupial plates, dispensing with the necessity for a separate pair of those appendages, and, if this be so, it will help to explain the peculiarity which Professor S. I. Smith has already noticed in regard to the kindred species, *Cerapus tubularis*, in which he says the ovigerous lamellæ are "only three pairs, and these are borne upon the eoxæ of the second pair of gnathopods and of the first and second peraeopods." In the figure *ppp.3* it is not the proper side-plate of this limb, but the torn and dislocated side-plate of the next segment that appears. The branchial vesicles similar to those of the preceding pair, or a little shorter. The first joint of the limb squared, a little wider above than below, with one or two spines near the apex of the slightly convex front margin and some spinules on the lower curve of the hind margin, which projects beyond the short broad second joint ; the third joint is longer than any of the others except the first, and distally nearly as broad as long, the front margin convex, with two little setules near the produced rounded apex, the hind margin sinuous, forming with its rounded apex a narrow lobe produced more than the front, tipped with four very long plumose setæ, and a spinule ; the fourth joint is almost embedded in the third, none of the short front margin free, the hind margin convex, thickly furred with adpressed cilia and tiny spines, the rounded decurrent apex carrying a single feathered spine ; the fifth joint

almost oval, a little longer than the fourth, the convex front margin having a very slender spine and spinule at the apex, the less convex hind margin having two slender spines; the finger very short at the base, as broad as long, but abruptly narrowing before reaching the sharp upturned nail, with a hair in the cavity; there is a sharp dorsal tooth preceding the base of the nail.

Fourth Peræopods.—The side-plates broad and comparatively deep, except at the extremities, the lower margin strongly ciliated. The branchial vesicles, if rightly observed, very small and narrow, bent at the base. The first joint attached near the end of the side-plate, oval, but with the front margin flattened; this has nine setules in a series, the hind margin has six more scattered; the second joint short; the third longer than the fourth, with three setules on the slightly convex front margin and one at the apex of the straight hind margin; the fourth joint not much longer than distally broad, with a spinule or two at the apex of the convex front, and a long thin spine at that of the straight hind margin; the fifth joint subequal in length to the third, with a group of slender spines on the apex of the convex front, and two on the lower part of the straight hind margin, which has also a little short apical spine; the finger as in the preceding pair.

Fifth Peræopods.—The side-plates much smaller than in the preceding pair, with the lower margin smooth and nearly straight. The first joint a little longer and more pyriform than in the fourth peræopods; the third a good deal longer, widening a little distally, the margins nearly straight, both with long apical spines, the front also with spinules at three points; the fourth joint also widening distally, much longer than broad, with the front margin a little convex, and a group of long spines at each apex; the fifth joint shorter than the third, very little longer than the fourth, with a group of several long slender spines at the apex of the convex front margin, which has two groups higher up, the almost straight hind margin and the finger much as in the preceding pair.

Pleopods.—On the peduncles of the first pair there appear to be four very small coupling spines, each with an apical pair of hooks, but on the second pair only two spines were perceived; no cleft spines were discovered; in the first pair each ramus has nine joints, the first of the outer ramus much expanded and fringed on the outer side with more than twenty plumose setæ; in the second and much shorter pair, the outer ramus has four joints, the first expanded, with a dozen setæ on the outer margin; the inner ramus has but one joint, shorter and much narrower than the first of the outer ramus; the third pair is much shorter than the second, the outer ramus two-jointed, the first joint expanded, with eleven setæ on the outer margin; the inner ramus rudimentary or (?) absent.

Uropods.—The peduncles of the first pair a little longer than the outer ramus, which has the outer margin fringed with little denticles and also with about a dozen setules, the apex finely pectinate, carrying a large spine; the inner ramus shorter and narrower, with a similar apex, the margins smooth; the second pair with the peduncles much longer

than the ramus, which is minute, little longer than broad, with a cleft apex carrying a feathered setule; the third pair similar to the second, the peduncles rather shorter, with some marginal setules, the ramus not longer than broad, scarcely appearing beyond the peduncle, ending in upturned sharp teeth.

The Telson very short, not longer than broad, in a lateral view appearing to have the apical border set round with two rows of sharp upturned teeth.

Length.—The specimen, in the position figured, measured, from the rostrum to the end of the first or second segment of the pleon, less than one-fifth of an inch.

Locality.—The single specimen, a female, was obtained in Flinders Passage.

Remark.—The specific name is taken from the place of capture.

For the original definition of the genus, see Note on Say, 1818 (p. 104). For the definition of *Glauconome*, see Note on Krøyer, 1845 (p. 212). *Unciata*, Milne-Edwards, 1838, is a mere misprint, and *Cyrthophium*, Danielssen, 1859, is only a name, the identification of which with *Glauconome* rests upon Boeck's authority. Boeck gives the following definition of the genus:—

"Mandibles with three-jointed palp; the third joint elongate, narrow, but shorter than the second."

"First Maxillæ with the inner plate small.

"Maxillipeds with the outer plate small, furnished on the inner margin with few but strong teeth; the inner plate broad; the last joint of the palp almost unguiform.

"Upper Antennæ only a little longer than the Lower; the flagellum multiarticulate; the accessory flagellum small.

"Lower Antennæ in the male much stronger than in the female, almost pediform; flagellum of several joints, its last joint armed with two curved spines.

"First Gnathopods strong; the hand subeheliform.

"Second Gnathopods much slighter and narrower than the first; the hand not to any great extent subeheliform.

"First and Second Peræopods slightly built.

"Fourth Peræopods longer than the Third, Fifth than the Fourth; the first joint in these three pairs little dilated.

"Third Uropods uniramous; the peduncle dilated on the inner side.

"Telson laminar."

Unciola irrorata, Say (Pl. CXXXVIII. C).

Maxillipeds.—Besides the three spine-teeth on the distal margin of the inner plates, there is near the apex of the inner margin a more than usually prominent bent spine-tooth; on the broad outer plates the inner margin at the distal part has six spine-teeth, while the apical margin has nine spines, of which the outer six are very slender and much curved; the nail or ungual spine of the palp is very nearly as long as the narrow finger, from which it projects, and at the apex of which there are two or three setules or

slender spines, which lie alongside of the much stronger ungual spine, not in agreement with the latter part of Boeck's account, that "the fourth joint is very narrow towards the end and furnished with *two* strong spines."

First Gnathopods.—Second joint very short, broader than long; with slender spines at the hinder apex; third joint narrowing distally, longer than broad, having an acute front apex resting on the wrist, slender spines at four points of the hind margin and some small groups on the inner surface; wrist not much longer than the third joint, broader than long, distally cup-like, with spines on and near the short projecting hind margin; the hand large, longer than broad, the front margin convex, with some groups of slender spines near it, the hind margin scarcely half the length of the front, strongly serrate, with three powerful spine-teeth in the notches; the palm long, oblique, sinuous, commencing with a rounded tooth, within which is planted a small palmar spine; the finger long and broad, the narrowed apex reaching beyond the palm to the second spine-tooth of the hind margin, much of its inner margin strongly dentieulate, its outer margin carrying six transverse rows of very long pectinate spines. Of these conspicuous ornaments of the finger, Say makes no mention, but it is more curious that Boeck also leaves them unnoticed, although for his own two species, *Glaucome krøyeri* and *Glaucome steenstrupii* he mentions spines on the hind margin of this finger. Krøyer in his description emphatically remarks that "*the finger shows the altogether unusual circumstance of being furnished on the front side with a number of long coarse close-set bristles.*"¹

Pleopods.—The peduncles (in the pair examined) much shorter than the rami, ciliated, and carrying a few slender plumose setæ; the coupling spines rather large, broad at the base, bent, with four retroverted teeth in a series below the minute one at the apex; the inner ramus longer than the outer,² the first joint not very long, much dilated on the outer side, on which distally it carries three setæ, on the inner margin armed with five graduated cleft spines, the lowest the longest, the longer arm strongly serrate on the inner margin, the shorter widened just before the apex and then sharply pointed; the joints of the inner ramus eighteen in number, the outer ramus with an interlocking process at the base of the first joint, its outer margin dilated, carrying seven or eight flattened setæ, the joints seventeen in number, the feathered setæ on both rami long and strong.

Uropods.—The angle of the fourth pleon-segment is produced with a strongly serrate margin far along the side of the peduncles of the first pair of uropods; these peduncles are much longer than the rami; the inner ramus is a little shorter than the outer; the second uropods are much smaller than the first with less difference in length between the peduncles and the rami, but the peduncles are longer than the rami, the inner ramus a little shorter than the outer; the third uropods very small, the peduncle

¹ Naturh. Tidsskr., R. 2, Bd. i. p. 497.

² Krøyer says, "the outer little longer than the inner."

produced on the inner side almost to the apex of the outer ramus, the inner ramus being absent, unless we may suppose that it is in fact coalescent with the peduncle and represented by the produced portion of the peduncle.

Telson nearly circular, apically a little angled.

Locality.—Station 49, south of Halifax, Nova Scotia, May 20, 1873; lat. $43^{\circ} 3' N.$, long. $63^{\circ} 39' W.$; depth, 85 fathoms; bottom, gravel, stones; bottom temperature, 35° . One specimen, female.

INCERTÆ SEDIS.

Genus *Haplocheira*, Haswell, 1880.

- 1884. *Corophium*, Chilton, Trans. New Zealand Inst., vol. xvi. p. 262.
- 1885. *Haplocheira*, Haswell, Proc. Linn. Soc. N.S.W., vol. x. pt. iv. p. 273 (extr. p. 12).
- 1886. *Corophium (pars)*, Thomson and Chilton, Trans. New Zealand Inst., vol. xviii. p. 143.

For the original definition of the genus, see Note on Haswell, 1880 (p. 512), and for a supplementary account see Note on Haswell, 1885 (p. 565). The type-species had been described by Mr. G. M. Thomson in 1879 as *Gammarus barbimanus*. It was again described by Mr. Chilton in 1884 as *Corophium lendenfeldi*. The following definition is offered for comparison with those of neighbouring genera:—

Mandibles with cutting edge and secondary plate dentate; spine-row of numerous denticulate spines; molar tubercles large and prominent; palp three-jointed, the second joint the longest.

First Maxillæ with the inner plate rather large, carrying many plumose setæ; nine spines on the outer plate.

Second Maxillæ having a long fringe of setæ on the inner side of the inner plate.

Maxillipeds with the inner plates broad, the outer plates not larger than the inner, the palp elongate, the finger not unguiculate, tipped with a very long spine.

Antennæ subequal; the upper antennæ with a small accessory flagellum.

First Gnathopods not subchelate, the hand and finger long and slender.

Second Gnathopods not subchelate, the wrist and hand long and slender.

First and Second Peræopods with gland-cells in the first and third joints, the finger perforated.

Fourth Peræopods longer than the *Third*, *Fifth* than the *Fourth*; the first joint expanded in all three pairs.

All three pairs of *Uropods* biramous, the rami in the first two pairs not very unequal; the third pair with short and stout peduncles, the inner ramus minute, much smaller than the outer.

Telson tending to circular, not reaching the apex of the peduncles of the third uropods, having a small hook at each corner of the distal margin.

Body little compressed.

By the habit of body this and the following genus appear to belong to the Corophiidæ, but they are excluded from that family as defined by Boeck through having the third uropods biramous. From the Photidæ and Podoceridæ *Haplocheira* is removed by the gnathopods, of which neither pair is subchelate.

Haplocheira plumosa, n. sp. (Pl. CXXVI.).

Body little compressed, narrowing from the third or fourth segment of the pereon; the rostrum small, acute, the lateral lobes of the head triangular, produced considerably beyond the rostrum, acute; the segments of the pereon short, the first three of the pleon successively longer, the third segment having the lower margin straight, long, equipped with some submarginal setæ, the postero-lateral angles rounded, having a cilium in a little notch.

The Eyes small, oval, advanced into the lateral lobes of the head, with about thirty ocelli, retaining dark colour in spirits.

Upper Antennæ.—The peduncle longer than the flagellum, not so long as the peduncle of the lower antennæ; the first joint about as long as the head, as long as the second and broader, with a group of tolerably stout spines and a slender one at the lower apex, also a spine near the middle of the lower margin; the second joint with some small spines; the third half the length of the second, and thinner; the flagellum of nine or ten joints, together as long as the second and third of the peduncle, equipped with cylinders; the secondary flagellum, apparently broken, showing one narrow joint, not tapering, not so long as the first of the primary.

Lower Antennæ slightly longer than the upper. The first two joints short, but the gland-cone rather long, decurrent, acute; the third joint stout, scarcely longer than the second including the produced gland-cone, with one or two spines on the convex upper margin, a slender spine and spinules on the lower; the fourth joint a little curved, longer than the first joint of the upper antenæ, carrying a few slender spines; the fifth joint shorter and thinner than the fourth, almost as long as the first of the upper antennæ; the flagellum of five joints, together not quite so long as the fifth joint of the peduncle, the last joint minute, tipped with slender spines, the other four having each two groups of spines, including one or more strong ones.

Upper Lip.—The distal border with a very slight unsymmetrical emargination, the tract on either side of which is slightly ciliated.

Mandibles.—The trunk broad, the cutting edge not very elongate, with four very unequal teeth; the secondary plate of the left mandible with two teeth as large as the

largest two of the principal plate, other teeth, if present, not perceived; the secondary plate on the right mandible consisting of a single long tooth, denticles on the upper edge perhaps worn down, none visible; the spine-row of eight long, closely set, backward-curved, denticulate spines, widening from the base for two-thirds of the length; the molar tubercle large and prominent, the crown not strongly dentate, with one edge smooth; there is a small rounded process above the molar tubercle at some distance behind the base of the palp; the palp set very much forward; the first joint longer than broad, with two spines standing out from the distal part of the front margin; the second joint long, slightly curved, nearly three times as long as the first, with eleven long spines standing out from the inner margin, and nine smaller spines placed along the surface; the third joint rather more than half the length of the second, with several groups of long spines planted on the surface; the narrowly rounded apex, the distal part of the convex outer margin, and most of the straight inner margin, also carrying spines.

Lower Lip rather compact; the principal lobes broadly rounded, the inner margins dehiscent; the inner lobes distally flatly rounded; the mandibular processes short and broad, little prominent, and not divergent; a kind of ridge runs from the inner margin of these processes to the middle of the distal margin of the principal lobes.

First Maxilla.—The inner plate fringed along the inner margin with twelve plumose setæ; the outer plate much curved, with nine spines on the truncate distal margin, of which six have several minute denticles on the inner edge, while three have a single more prominent denticle on the outer side; in the figure *mx.1.*, only eight spines are shown, one having been accidentally broken off in the specimen; the first joint of the palp very short, the second long, widening a little distally, reaching beyond the outer plate, carrying six spine-teeth on the dentate apical border, and about ten slender spines distributed on the surface from the inner margin towards the outer apex.

Second Maxilla.—The inner plate wider below than above, with a series of eighteen long plumose setæ beginning at some little distance from the base of the inner margin, and curving away from it below the apex; at the middle of the margin begins a row of long spines, which nearer the apex are supplemented by short ones, neither row descending the outer slope of the apex; this plate and conspicuously its inner and apical margins are strongly furred; the outer plate is very little longer than the inner, widening slightly at the apical margin, which is broader than that of the inner plates and fringed with long spines.

Maxillipeds.—The inner prismatic plates reaching about to the apex of the first joint of the palp, with plumose setæ passing from the upper part of the inner margin across the inner corner, the broad distal margin sinuous, serrate at the outer part and carrying five setiform feathered spines, the inner part excavate, and having a slender spine-tooth at the apex of the inner margin, a broad spine-tooth next to this, and then another slender one; the outer plates narrow, not reaching the middle of the palp's second joint,

apically narrowed, having numerous long spines on both surfaces but especially on the outer surface, with apparently only one spine that could be properly designated a spine-tooth, and even that a slender one, just below the apex; the distally serrate outer margin carrying four very long spines; the spines on the outer surface of the bases of both the inner and outer plates form long and striking series in this species; in the figure it is as usual the inner surface that is shown; the first joint of the palp about half the length of the second, with a long spine on the apex of the short inner margin; the second joint long, not broad, the inner margin crowded with feathered spines; the third joint longer than the first, a little apically produced, with several groups of feathered spines over the surface except near the base, and a long row of pectinate spines only visible when the joint is turned at a particular angle; the finger narrow, rather more than half the length of the third joint, with a dorsal cilium some little way from the hinge, the inner margin distally serrate, with four slender spines and a fifth much longer than the other four; at the apex a still longer and stronger spine, longer than the base of the finger, the equivalent of a nail, not however in a continuous line with the base but at right angles to it.

First Gnathopods.—The side-plates broader below than above, the lower front corner rounded, produced forwards, the convex lower margin carrying a few spinules. The first joint reaching little beyond the side-plates, having four long setæ about the middle of the convex hind margin; the second joint short, with a group of very long spines on the hinder apex; the third joint a little longer than the second, the front and hind margins convex, with long spines at six points of the hind margin, and two groups crossing the inner surface above the oblique distal margin and its acute front apex; the wrist shorter but broader than the hand, twice as long as broad, more than half the length of the hand, with spines at three points of the distal part of the convex front margin, the whole of the slightly convex hind margin densely crowded with feathered spines, an oblique row, in which fourteen spines may be counted, traversing the inner surface; the hand almost as long as the first joint, gently tapering, a small tract at the base of the slightly convex front margin free, the rest, till near the apex, and the apex crowded with long feathered spines, the front margin still more densely set with spines, some here being shorter and stiffer than the prevailing setiform type; at the apex is a palmar spine with an incurved tip, but there is no palm worth speaking of; the finger is about half the length of the hand, with a long dorsal cilium not far from the hinge, the inner margin a little bulging at the base, then pectinate, slightly curved, running out into a tooth, with three unequal setules near its base, the nail beyond this being long, sharp, smooth-edged, more curved than the rest of the finger.

Second Gnathopods.—The side-plates longer than in the preceding pair, the lower part less widened, fringed with slender spines and spinules. The branchial vesicles a long smooth oval, nearly as long as the first joint. The first joint rather larger than in

the first gnathopods; the second joint with a spinule on the hinder apex; the third broad, scarcely longer than broad, with a spinule in the middle of the convex front margin, and a group of unequal spines, the hinder very long, crossing the broad distal margin; the wrist quite as long as the first joint and rather longer than the hand, narrow, of almost even width throughout, the hinder margin a little erenate, fringed with about twenty-four feathered spines that exceed the length of the joint itself, and having an inner similar row, the feathering of the spines long and close; the hand narrower than the wrist, almost as long, tapering, with a row of about fourteen long spines along the hind margin, those nearer the apex shorter than those nearer the base, the inner surfaces also having numerous groups of very long spines which might project on either margin according to circumstances; the finger about a third of the length of the hand, slender, with the inner margin convex near the base, then very concave, smooth, not running out into a tooth, with cilium and setules as in the first gnathopods. It should be stated that the flexibility of the immensely long spines in these gnathopods would perhaps make it more correct to call them setæ than spines.

First Peraopods.—Side-plates not longer but of more even width than in the preceding pair. Branchial vesicles rather broader than the preceding pair. First joint reaching below the side-plate, packed with three rows of gland-cells, having a few marginal spinules; the second joint short, with a small spine on the hinder apex; the third joint large, widening distally, nearly as long as the first joint, with some small spines at two or three points of the hind margin, spinules at three points of the front, and some slender spines on its slightly decurrent apex; the fourth joint half the length of the third, with spines at the front apex, and at four points of the hind margin; the fifth joint shorter than the third, much longer and thinner than the fourth, tapering, a little curved, with a slender spine near the top of the convex front, a spine or seta at its apex, and spines at six points of the hind margin; the finger narrow, more than half the length of the fifth joint, with a long dorsal cilium near the hinge, and an opening in the tip.

Second Peraopods.—The side-plates rather broader than the preceding pair, the hind margin a little concave. The limb scarcely differs from that of the first peraeopods.

Third Peraopods.—The side-plates with a deep front lobe, having a small spine and spinule near together on the rounded lower margin; the shallower hind lobe has on its lower margin a strong backward-curved spine, followed at a little distance by a spinule. The branchial vesicles are smaller than in the preceding segment. The first joint broad, longer than broad, the front margin convex, with small spines at intervals, and on the lower part two groups of larger spines, the hind margin tending to concave, slightly serrate, furnished with spinules; the short second joint with a group of slender feathered spines on the front apex, and a spinule higher up; the third joint longer than the fourth, with slender spines at three or four points in front, and a stout spine at the apex, the hind margin nearly straight, having at the apex two stout spines, one much larger than

the other ; the fourth joint not quite twice as long as broad, having a slender curved feathered spine at the apex in front, accompanied by stout spines, and a slender spine and spinule higher up, the hind margin having an apical group, in which the spines are broad and curved, and having also a group of three stout spines on the surface near its centre ; the fifth joint narrower, about as long as the third, with four groups of powerful spines along the front margin, and a mixed group at the apex of the hind margin ; the finger short, half the length of the fifth joint, much curved, with a long dorsal cilium near the hinge.

Fourth Peræopods.—The side-plates much smaller than the preceding pair. The limb larger and longer than in the preceding pair, but similar ; the hind margin of the large first joint slightly convex ; the third joint with spines at six points in front and two behind ; the fourth joint fully twice as long as broad, with three groups in front and two behind ; the fifth joint with five groups of spines on the true front and three on the true hind margin. The fifth and sixth joints in fig. *prp. 4.* are reversed, but this is perhaps not their normal position, though no doubt these joints have free play upon the preceding joint.

Fifth Peræopods missing in the specimen described, but present in a second specimen. The side-plates are small. The limb is similar to the preceding pair, but larger ; the first joint considerably larger in both dimensions, the front margin slightly convex, with eight small spines spaced along it and an apical group, the hind margin very convex except at the oblique upper part, fringed with small plumose setæ, serrate, the lower margin well rounded, similarly equipped ; the third joint fringed in front with feathered spines or setæ, with strong spines at the apex of this and at three points of the hind margin ; the fourth joint only a little shorter than the third, with three groups of spines in front and two behind ; the fifth joint longer than the third, with five groups of spines in front and three behind ; the finger not half the length of the fifth joint.

Pleopods.—The peduncles short and stout, shorter than the rami, the coupling spines slender, a little distally bent, with four teeth on one side and three on the other, and the sharp apex apparently also forming a minute hook ; the cleft spines from three to four in a series ; the outer ramus shorter than the inner, but the joints appear to be of the same number, eleven, in each.

Uropods.—The peduncles of the first pair much shorter than the rami, with some spines on the upper margins, a small one projecting from near the top of the lower margin, and at the apex of this margin one of great length, which added to the base would make the peduncles longer than the rami ; one ramus is rather longer than the other, and has spines at six points of one margin and a group at the blunt apex ; the shorter ramus is similar, but with three pairs of spines on the margin and the apical group ; the second pair shorter than the first, the peduncles shorter than the rami, also with a very long curved spine on the lower apex, the rami broad, and the spines

stout, the larger ramus with five spines on one border and the apical four, consisting of two large and two small; the shorter ramus has three pairs on the border, and the usual four on the apex; the third pair are very short, the peduncles broad, longer than the rami, reaching beyond the telson, having a few spines on the margins; the outer ramus might be described as a narrow oval, with two strong spines not far below the centre, two just above the apex, and at the apex a group of slender spines, two longer and thinner than the others; the inner ramus also oval, about half the breadth and scarcely half the length of the outer, therefore very small, yet carrying two stout spines, one at the apex and one higher up.

Telson about equal in breadth and length, widest near the base, narrowing only a little to the truncate distal margin, which has a small but strong hook at each corner, turned upwards and backwards, near the base of which are planted some slender spines and spinules, there being also a couple on each margin higher up; the distal margin between the hooks is not absolutely straight, but rather tends to concave in the centre, with a little pimple-like jutting-out of the margin on either side of the very shallow curve.

Length.—The specimen, in the position figured, measured, from the rostrum to the extremity of the uropods, one-quarter of an inch.

Locality.—Station 149H, off Cumberland Bay, Kerguelen, January 29, 1874; depth, 127 fathoms; bottom, volcanic mud. One specimen.

The specimen from which the fifth peræopod is described was also taken at Kerguelen, depth not mentioned.

Remarks.—The specific name refers to the ornamentation of the gnathopods. Of *Haplocheira typica*, Haswell, I have been enabled to examine a specimen through Mr. Haswell's kindness. Of *Gammarus barbimanus*, Thomson, Mr. G. M. Thomson, not at the time having any but the type-specimen available, very obligingly sent me enlarged figures. Since then in a joint paper Messrs. Thomson and Chilton have identified as one species, under the name *Corophium barbimanum*, *Gammarus barbimanus*, Thomson, *Corophium lendenfeldi*, Chilton, *Haplocheira typica*, Haswell. Mr. Haswell also in a recent paper has expressed the opinion that *Corophium lendenfeldi* is probably the same as *Haplocheira typica*. The genus is distinguished from *Corophium* by many particulars, of which it may suffice to mention the three-jointed mandibular palp, the inner plate of the first maxillæ fringed with setæ, the accessory flagellum of the upper antennæ, the short third joint of the second gnathopods, and the biramous third uropods. The name of the species referred to must therefore be *Haplocheira barbimanus*, Thomson.

Without the opportunity for comparison, one might have easily jumped to the conclusion that the Kerguelen species was specifically identical, as well as generically, with that reported from Australia and New Zealand; but though the resemblances are the

more striking, the differences are numerous. The Kerguelen species is not so *Corophium*-like, the back being less broad; the lower antennæ are less strikingly pediform; the hand of the first gnathopods is distally narrower; at least Mr. Haswell says of his species, "The anterior gnathopods might be described as very imperfectly subcheliform—the propus having a small lobe at the base of the daetylus." In the Kerguelen species the fingers in both pairs of gnathopods are more important, the first pereopods have the third, fourth, and fifth joints more developed in comparison with the first, in the third pereopods the first joint is much less narrowed below, and in the fifth less expanded below, than in the Australian species; in the latter species there is in the peduncles of the pleopods an apical prolongation on the inner side; and the telson, which is wider at the base than the length, has the centre of the distal margin convex instead of concave.

Genus *Camacho*, n. gen.

Mandibles with cutting edge and secondary plate dentate; spine-row of numerous denticleate spines; molar tubercle large and prominent; palp three-jointed, the third shorter than the long second joint.

Lower Lip with both pairs of lobes large; the mandibular processes narrow, divergent.

First Maxillæ with the inner plate small, carrying a single seta; eleven spines on the outer plate.

Second Maxillæ having a long fringe of setæ on the inner side of the inner plate.

The *Maxillipeds* with spine-teeth fringing the inner margin of the outer plates; the finger of the palp having a short ungual spine, so as to appear unguiculate.

Upper Antennæ with the first joint elongate.

The *First* and *Second* pairs of *Gnathopods* similar, elongate, with the wrists long, the hands long-oval, subchelate.

All three pairs of *Uropods* biramous, the rami in the first and second pairs subequal, in the third pair very unequal, the outer not large, but much larger than the minute inner one; the peduncle strongly dilated on the inner side.

The *Telson* tending to circular, not reaching beyond the peduncles of the third uropods.

The body elongate, little compressed; the side-plates shallow, not close set.

This genus seems to have some affinity with *Haplocheira*, Haswell, the mandibles being in close agreement, and the rami of the third uropods not dissimilar; the widened peduncles of the third uropods recall those of *Siphonacetes*, Krøyer, but in that genus the third uropods are not biramous.

The generic name is derived from a personage mentioned in *Don Quixote*.

Camacho bathyploous, n. sp. (Pl. CXXVII.).

The animal elongate, widest at the fourth and fifth segments of the pereon, lateral compression beginning with the pleon; the rostrum minute, pointed; the lateral lobes of the head very small, also acute, the sides emarginate below them for the bases of the lower antennæ; there is a groove on each side of the head near the hind margin; the last five segments of the pereon and the first three of the pleon differing but little from one another in length, the second to the fourth of the pereon with the lower part convex, directed forwards; all laterally dimpled; the side-plates all shallow, the first four pairs with the front corner directed forwards; not contiguous to one another; the postero-lateral corners of the first three pleon-segments somewhat squared.

Eyes not perceived.

Upper Antennæ.—The first joint considerably longer than the head, narrowing a little distally. The rest of the joints missing.

Lower Antennæ.—The first two joints short, the gland-cone acute, a little decurrent; the third joint much longer than the first two united, half the length of the first joint of the upper antennæ, with some marginal spines and spinules. The remaining joints missing. An incomplete antenna, which occurred with the specimen and may possibly belong to it, began with a long narrow joint which might be the fourth; this had several marginal spines, and was followed by a similar but rather thinner joint of about equal length, and a flagellum of nine joints, together equal to the last of the peduncle; these joints were tipped with groups of long slender spines, and the last three had each a conspicuous pair of short, stiff, curved spines.

Upper Lip.—The distal margin broad, unsymmetrically and rather flatly bilobed, the small emargination being almost in the centre; the inner plate with a nearly straight distal edge.

Mandibles.—The cutting plate on the left mandible is divided into four strong unequal teeth; on the right mandible it has two strong teeth and three that are minute; the secondary plate on the left mandible has three strong teeth and a denticle; on the right mandible this plate is of slighter build, with two prominent slender teeth, and three little denticles; the spine-row contains about ten long curved spines, bent, feathered, and denticulate; the molar tubercle is large and prominent, with the dentate crown furred on the sides; there is a blunt-headed process near the base of the palp; the first joint of the palp is much longer than broad; the second joint is very long, with about sixteen spines in two rows along the front, all slender, some very long, lightly feathered, the outer apex also has a long spine; the third joint is more than half the length of the second, with spines at two points of the front margin, all round the apex, and in four rows on the surface near the distal half of the outer margin; these spines are strongly peeltinate almost to the very tip, and being very

long and most of them a little curved, form in the aggregate a thick bush reaching beyond the apex.

Lower Lip.—The distal margins of the principal lobes broadly rounded, the inner margins dehiscent, retreating from one another before they re-advancee to meet near the base; the inner lobes oval, with their distal and inner margins, like those of the principal lobes, strongly ciliated; the mandibular processes narrow, divergent.

First Maxillæ.—The inner plate with straight inner margin partly strongly ciliated, and at the narrow apex carrying a seta attended by two or three very small setules; the outer margin convex; the outer plate with a bush of cilia near the base, the apical border carrying eleven strong spines, with strong but not numerous lateral denticles, five of the spines a good deal longer than the rest, one long one and one short one fureate, and one or two more of the short ones with a single denticle, one of them eertainly with two denticles; the first joint of the palp is little longer than broad, and has two setules on the outer margin; the second is curved, reaches beyond the outer plate, widens a little distally, has a setule on the outer margin not far from the base, and eight strong spine-teeth on the apical border, the outermost the longest; below these on the surface and approaching the inner margin are four slender spines.

Second Maxillæ.—The inner plate not quite so long as the outer, as broad or distally a little broader; a series of about thirty-five plumose setæ beginning near the base passes in a gentle curve along the surface towards, but not to, the outer apex, a long series of spines passes along the inner margin and becomes crowded at the inner apex, but there stops, leaving the remainder of the distal margin unoccupied; of the outer plate the whole apieal margin is crowded with long spines.

Maxillipeds.—The inner plates are broad, reaching about as far as the distal end of the palp's first joint, with plumose setæ on the inner margin, and three spine-teeth and feathered spines on the distal margin; the outer plates reach beyond the middle of the second joint of the palp, with nine spine-teeth on the inner margin, and six longer spines on the apical; the slender spines within the inner margin are long; the first joint of the palp has two spines on its inner margin, and is less than half the length of the long second joint, which is slender, and has numerous long spines on and near the inner margin; the third joint is not longer than the first, the distal half carrying many spines; the finger is narrow and little curved, with a short spine-like movable nail (or ungual spine), the two together longer than the third joint; on the inner margin of the finger, near the base of the nail, three or four setæ or setules are inserted.

First Gnathopods.—The side-plates very small. The first joint seareely at all covered by the side-plate, of very even breadth throughout, earrying some marginal setules; the seeond joint short, the distal half of the convex hind margin fringed with slender spines, those near the apex being very long and numerous; the third joint with convex margins converging to an acute apex which rests upon the wrist, the hind margin fringed with

long spines, the front margin applied to the wrist, with numerous spines on the inner surfacee near it; the wrist not much shorter than the first joint, rather longer and narrower than the hand, the long front margin with apieal spines but otherwise nearly smooth, having one or two groups of very slender long spines on the outer surfacee near it, but the inner surface and the long serrate hind margin crowded with long spines, many, perhaps all, of the spines being peetinate; the hand is oval, with numerous groups of long spines at both margins, the eonvex palm only slightly distinguished from the hind margin, but with a long palmar spine on the inner surfacee of the hand a little remote from the margin, the palm itself fringed with submarginal spinules on both sides; the finger fitting the palm, having its inner edge apparently cut into a few deurrent teeth, and when closed having the tip of the nail resting on the surfacee of the hand.

Second Gnathopods closely resembling the first pair, but the first joint longer and thinner, the spinules or setules numerous on the front margin, the wrist a little longer and narrower, the hand also a little narrower. The marsupial plates narrow.

Peræopods.—The branehial vesicles as observed for the first, seeond, and third pairs of peræopods were narrowly oval. The marsupial plates of the same three pairs were broader than the branehial vesicles, and in the first two pairs much, in the third a little, longer; in all surrounded by long setæ. Only a single peræopod remained, whieh beeame immediately detaehed on the handling of the speeimen. It belongs, I believe, to the third pair. The first joint longer than the following three united, the sides nearly parallel, almost unarmed, with a slender apical spine in front; the seeond joint short, the front margin eonvex, with an apieal very slender spine; the third joint longer than the fourth, widening distally, the front margin eonvex, the hinder more straight, both earrying a few spinules; the fourth and fifth joints with the finger are probably not in their natural position in the figure *ppp.*, but should be reversed; desribing them under this point of view one would say,—fourth joint with the front margin eonvex, carrying long slightly feathered spines at four points, the hind margin straight, with a strong curved spine at the apex; the fifth joint as long as the third but much thinner, a little curved, the front margin eonvex, with two spinules on the upper part, and spines and a feathered seta on the apex, the hinder margin eoneave, with spines at three points, and a large one at the apex; the finger slender, curved, about one-third the length of the fifth joint.

Pleopods.—The peduneles much shorter and broader than the rami, distally widened, so that they come close together, while the slender pairs of rami stand wide apart; the coupling spines have a broad base, a narrow bent shaft, a series of from five to seven strong teeth below the apex on one side, and on the other side apparently only three or four, of whieh the lowest is very large; the cleft spines are five in number on one pair, perhaps on all three, very slender and brittle, stretching out aerooss the wide interval that separates one inner ramus from the other, and borne on a long first joint whieh is

dilated at the upper part; the outer ramus is much shorter than the inner, but the number of joints seems to be the same, fourteen, in both.

Uropods.—The peduncles of the first pair a little longer than the outer ramus, with about five spines on each margin, and a large one at the lower apex; the outer ramus long and slender, with long spines, singly or in pairs, at five points of the inner margin, and a group of four or five at the apex; the broader inner ramus is probably longer, but it is broken; the fragment has five long spines on the inner margin, and three nearer the outer margin, at the top of which it has three little spines; the second pair are shorter than the first, the peduncles a little longer than the rami, which are subequal, with a few strong marginal spines, and a group on the rounded apex, of which one is curved; the peduncles of the third pair almost broader than long, nearly concealed by the telson, beneath which their inner edges meet, projecting much beyond the rami; the outer ramus longer than the peduncle, with an apical group of long and very slender spines; the inner ramus oval, less than half the length of the outer, with two spines at, and one a little above, the apex.

The Telson rather broader than long, very little narrowed distally, the distal margin being for the most part convex, with the angled apex of each lateral margin not produced quite so far as the centre of the convexity.

Length.—The specimen, in the position figured, measured, from the rostrum to the extremity of the uropods, nearly thirteen-twentieths of an inch.

Locality.—Station 168, off New Zealand, July 8, 1874; lat. $40^{\circ} 28' S.$, long. $177^{\circ} 43' E.$; depth, 1100 fathoms; bottom, blue mud; bottom temperature, 40° . One specimen, female.

Remark.—The specific name is derived from the Greek $\beta\alpha\thetaυπλόος$, going deep in the water.

Family DULICHIIDÆ.

In 1849 Dana established the Dulichidæ as sixth family of the Gammaracea, containing the single genus *Dulichia*, Krøyer; in 1852 he made it the first family of the Gammaridea (see Note on Dana, 1852, p. 260). In 1857 Spence Bate established the Dyopedidæ as “Group B. Aberrantia. Family VIII.” of the Gammarina (see Note on Spence Bate, 1857, p. 294); in the same year he altered the name Dyopedidæ into Dulichiadæ, which appears as Dulichidæ in his British Museum Catalogue, and as Dulichiidæ in the British Sessile-eyed Crustacea. In 1859 Bruzelius accepted the Dulichidæ as the first family of the Gammaridea, adding to it the new genus *Lætmatophilus*. The family was also accepted by Goës in 1865, and in the same year Lilljeborg, in one of the tables to page 18 of his paper on the *Lysianassa magellanica*, thus defines

it as the sixth family of the Amphipoda :—" Pedum eaudalium unum vel pluria absunt —*Aberrantia*, S. BATE," this character embracing also the families Caprellidae and Cyamidae, the next being peculiar to the Dulichidae, "Cauda minime obsoleta, segmentis 6 composita." The telson is included as one of the six segments mentioned. Boeck in 1870 added two new genera, *Paradulichia* and *Xenodice*, and gave the following definition of the family :—

" *Upper Lip* very broad, apically subsinuate.

" *Mandibles* strong, apically dentate, with the secondary plate large and dentate; molar tubercle robust; spines of the spine-row few but strong, serrate at the extremity of the convex margin; the palp long, very slender, its third joint shorter than the second.

" *Lower Lip* strong; with the inner plates very strong.

" *First Maxillæ* with the inner plate larger or smaller; the second joint of the palp elongate, apically spined.

" *Maxillipeds* having the outer plate armed with thick spines on the inner margin; the fourth joint of the palp thick, apically armed with one strong unguiform spine.

" The body elongate, linear, depressed; the side-plates very small; the pleon consisting of only five segments and furnished with five pairs of appendages, (the sixth segment of the peraeon generally coalesced with the seventh).

" *Upper and Lower Antennæ* subpediform, elongate, (the upper generally furnished with an accessory flagellum)."
